ASM HANDBOOK®

VOLUME 21

Composites

ASM INTERNATIONAL®

The Materials Information Company

Publication Information and Contributors

Introduction

Composites was published in 2001 as Volume 21 of *ASM Handbook.* The Volume was prepared under the direction of the ASM International Handbook Committee.

Volume Chair

Daniel B. Miracle and Steven L. Donaldson were the Volume Chairs.

Foreword

ASM International is proud to offer *Composites* as Volume 21 of the *ASM Handbook*. The nominal basis for this volume was the *Engineered Materials Handbook*, Volume 1, published in 1987. However, this new edition is, to a large degree, a brand new volume. New or greatly expanded coverage is provided, in particular, in the Sections on constituent materials, analysis and design, and processing. New sections have been added to address the important topics of maintenance, repair, and recycling. Coverage of polymer-matrix composites has been enhanced to address the latest materials advances and new application areas. Coverage of metal-matrix and ceramic-matrix composites has been revamped and greatly expanded to reflect the increasing industrial importance of these materials.

With the release of this new edition of the *Composites* volume, it seems like a natural transition for it to become part of the *ASM Handbook* series. The *Metals Handbook* series was renamed the *ASM Handbook* in the mid-1990s to reflect the increasingly interrelated nature of materials and manufacturing technologies. Since that time the *ASM Handbook* has incorporated increasing amounts of information about nonmetallic materials in each new and revised volume. ASM expects that other volumes in the *Engineered Materials Handbook* will become part of the *ASM Handbook* when they are revised.

Creating the new edition of this monumental reference work was a daunting task. We extend thanks and congratulations on behalf of ASM International to the Volume Chairs, Dan Miracle and Steve Donaldson, and the Volume's 13 Section Chairs for the outstanding job they have done in developing the outline for the revision and guiding its development. Our gratitude is also due to the over 300 international experts from industry,

academia, and research who contributed as authors and reviewers to this edition. In addition, we express our appreciation to the ASM International editorial and production staff for their dedicated efforts in preparing this volume for publication.

Aziz I. Asphahani, President, ASM International

Michael J. DeHaemer, Managing Director, ASM International

Preface

It should be apparent with just a quick glance through this Volume that a great deal of technical progress has been made since the first edition was published in 1987 (as Engineered Materials Handbook, Volume 1). Much of the earlier promise of high performance organic-matrix composites (OMCs) has been fulfilled. These materials are now the preferred design solution for an expansive scope of applications. Earlier concerns related to high cost and marginal manufacturability have been satisfactorily addressed through high volume and innovative design and manufacturing, including extensive use of unitized design and construction. A clear example of the success in these areas is illustrated by the growing use of high-performance composites in the commodity applications of civil infrastructure. Nonetheless, cost and manufacturability continue to be areas of vigorous development and hold hope for significant future advancements, along with the development of composite materials with higher specific properties, higher operating temperatures, and improved supportability. One can expect to see broad advances in innovative structural concepts and certification methods in the future.

The progress in metal-matrix composites (MMCs) has been equally remarkable. Although only marginal coverage was warranted in the first edition, MMCs now represent a significant material option in the international marketplace. The world market for MMCs was over 2.5 million kg (5.5 million pounds) in 1999, and an annual growth rate of over 17% has been projected for the next several years. Significant applications are in service in the aeronautical, aerospace, ground transportation, thermal management/electronic packaging, and recreation industries. The ability to offer significant improvements in structural efficiency and to excel in several other functional areas, including thermal management and wear, and to utilize existing metalworking infrastructure have aided this progress. Continued future extension into both new and existing markets is expected.

While ceramic-matrix composite (CMC) technology is still largely centered in the research and development phase, significant advancements have been made. Some commercial applications now exist, and strategies for growing market insertion are being pursued. The traditional motivation of structural performance and environmental resistance at the highest application temperatures continue to provide incentive for development. Recent important research accomplishments provide growing optimism that significant aeropropulsion structural applications will be fielded in the coming decade.

The primary objective of ASM Handbook, Volume 21, Composites is to provide a comprehensive, practical, and reliable source of technical knowledge, engineering data, and supporting information for composite materials. Coverage of OMCs and MMCs is provided in a balanced fashion that reflects the maturity of each material class. Given the current status of CMC materials, less coverage is provided, but it, too, is focused in areas of current industrial importance. This Handbook is intended to be a resource volume for nonspecialists who are interested in gaining a practical working knowledge of the capabilities and applications of composite materials. Thus, coverage emphasizes well-qualified information for materials that can be produced in quantities and product forms of engineering significance. This Volume is not intended to be a presentation of fundamental research activities, although it certainly provides an important reference for scientists engaged in the development of new composite materials. The full range of information of importance to the practical technologist is provided in this Volume, including topics of constituent materials; engineering mechanics, design, and analysis; manufacturing processes; post-processing and assembly; quality control; testing and certification; properties and performance; product reliability, maintainability, and repair; failure analysis; recycling and disposal; and applications.

This new edition builds on the success of the version published as Volume 1 of the Engineered Materials Handbook. Information on OMCs has been updated to reflect advancements in this technology field, including improvements in low cost manufacturing technologies and significantly expanded applications in areas such as infrastructure. Progress in MMCs has been particularly dramatic since the previous edition, and new information on these materials provides an up-to-date comprehensive guide to MMC processing, properties,

applications, and technology. CMCs also have entered service in limited applications since the previous edition, and the coverage of these materials reflects this progress. These three classes of composites are covered in each Section of the Volume as appropriate to provide a unified view of these engineered materials and to reduce redundancies in the previous edition.

We would like to offer our personal, heartfelt appreciation to the Section Chairpersons, article authors, reviewers, and ASM staff for sharing both their expertise and extensive efforts for this project.

Staff

ASM International staff who contributed to the development of the Volume included Scott D. Henry, Project Editor; Charles Moosbrugger, Technical Editor; Gayle J. Anton, Editorial Assistant; Bonnie R. Sanders, Manager of Production; Nancy Hrivnak and Carol Terman, Copy Editors; Jill Kinson, Production Editor; and Kathryn Muldoon, Production Assistant. Editorial assistance was provided by Jill Brown, Kelly Ferjutz, Edward J. Kubel, Jr., Heather Lampman, Elizabeth Marquard, Beverly Musgrove, Mary Jane Riddlebaugh and Juli Williamson. The Volume was prepared under the direction of William W. Scott, Jr., Director of Technical Publications. The Volume was prepared under the direction of William W. Scott, Jr., Director of Technical Publications.

Conversion to Electronic Files

ASM Handbook, Volume 21, Composites was converted to electronic files in 2002. The conversion was based on the first printing (2001). No substantive changes were made to the content of the Volume, but some minor corrections and clarifications were made as needed.
ASM International staff who contributed to the conversion of the Volume included Sally Fahrenholz-Mann, Sue Hess, Bonnie Sanders, and Scott Henry. The electronic version was prepared under the direction of William W. Scott, Jr., Technical Director.

Introduction to Composites

Daniel B. Miracle and Steven L. Donaldson, Air Force Research Laboratory

Introduction

A COMPOSITE MATERIAL is a macroscopic combination of two or more distinct materials, having a recognizable interface between them. Composites are used not only for their structural properties, but also for electrical, thermal, tribological, and environmental applications. Modern composite materials are usually optimized to achieve a particular balance of properties for a given range of applications. Given the vast range of materials that may be considered as composites and the broad range of uses for which composite materials may be designed, it is difficult to agree upon a single, simple, and useful definition. However, as a common practical definition, composite materials may be restricted to emphasize those materials that contain a continuous matrix constituent that binds together and provides form to an array of a stronger, stiffer reinforcement constituent. The resulting composite material has a balance of structural properties that is superior to either constituent material alone. The improved structural properties generally result from a load-sharing mechanism. Although composites optimized for other functional properties (besides high structural efficiency) could be produced from completely different constituent combinations than fit this structural definition, it has been found that composites developed for structural applications also provide attractive performance in these other functional areas as well. As a result, this simple definition for structural composites provides a useful definition for most current functional composites.

Thus, composites typically have a fiber or particle phase that is stiffer and stronger than the continuous matrix phase. Many types of reinforcements also often have good thermal and electrical conductivity, a coefficient of thermal expansion (CTE) that is less than the matrix, and/ or good wear resistance. There are, however, exceptions that may still be considered composites, such as rubber-modified polymers, where the discontinuous phase is more compliant and more ductile than the polymer, resulting in improved toughness. Similarly, steel wires have been used to reinforce gray cast iron in truck and trailer brake drums.

Composites are commonly classified at two distinct levels. The first level of classification is usually made with respect to the matrix constituent. The major composite classes include organic-matrix composites (OMCs), metal-matrix composites (MMCs), and ceramic-matrix composites (CMCs). The term "organic-matrix composite" is generally assumed to include two classes of composites: polymer-matrix composites (PMCs) and carbon-matrix composites (commonly referred to as

carbon-carbon composites). Carbon-matrix composites are typically formed from PMCs by including the extra steps of carbonizing and densifying the original polymer matrix. In the research and development community, intermetallic-matrix composites (IMCs) are sometimes listed as a classification that is distinct from MMCs. However, significant commercial applications of IMCs do not yet exist, and in a practical sense these materials do not provide a radically different set of properties relative to MMCs. In each of these systems, the matrix is typically a continuous phase throughout the component.

The second level of classification refers to the reinforcement form—particulate reinforcements, whisker reinforcements, continuous fiber laminated composites, and woven composites (braided and knitted fiber architectures are included in this category), as depicted in Fig. 1 (Ref 1). In order to provide a useful increase in properties, there generally must be a substantial volume fraction (~10% or more) of the reinforcement. A reinforcement is considered to be a "particle" if all of its dimensions are roughly equal. Thus, particulate-reinforced composites include those reinforced by spheres, rods, flakes, and many other shapes of roughly equal axes. Whisker reinforcements, with an aspect ratio typically between approximately 20 to 100, are often considered together with particulates in MMCs. Together, these are classified as "discontinuous" reinforcements, because the reinforcing phase is discontinuous for the lower volume fractions typically used in MMCs. There are also materials, usually polymers, that contain particles that extend rather than reinforce the material. These are generally referred to as "filled" systems. Because filler particles are included for the purpose of cost reduction rather than reinforcement, these composites are not generally considered to be particulate composites. Nonetheless, in some cases the filler will also reinforce the matrix material. The same may be true for particles added for nonstructural purposes, such as fire resistance, control of shrinkage, and increased thermal or electrical conductivity.

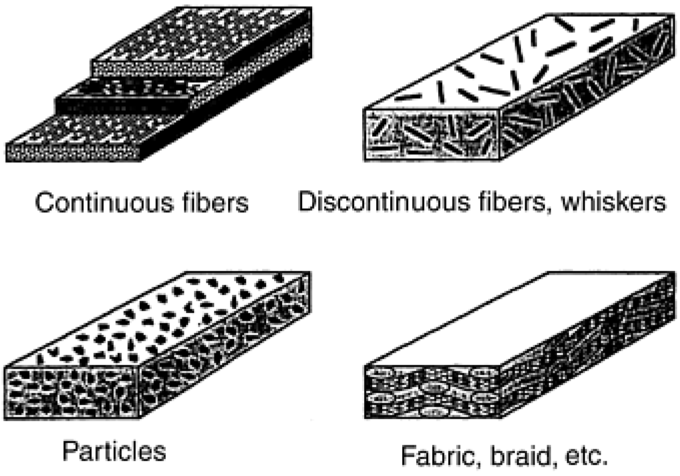

Fig. 1 Common forms of fiber reinforcement. In general, the reinforcements can be straight continuous fibers, discontinuous or chopped fibers, particles or flakes, or continuous fibers that are woven, braided, or knitted. Source: Ref 1

Continuous fiber-reinforced composites contain reinforcements having lengths much greater than their cross-sectional dimensions. Such a composite is considered to be a discontinuous fiber or short fiber composite if its properties vary with fiber length. On the other hand, when the length of the fiber is such that any further increase in length does not, for example, further increase the elastic modulus or strength of the composite, the composite is considered to be continuous fiber reinforced. Most continuous fiber (or continuous filament) composites, in fact, contain fibers that are comparable in length to the overall dimensions of the composite part. As shown in Fig. 1, each layer or "ply" of a continuous fiber composite typically has a specific fiber orientation direction. These layers can be stacked such that each layer has a specified fiber orientation, thereby giving the entire laminated stack ("laminate") highly tailorable overall properties. Complicating the definition of a composite as having both continuous and discontinuous phases is the fact that in a laminated composite, neither of these phases may be regarded as truly continuous in three dimensions. Many applications require isotropy in a plane, and this is achieved by controlling the fiber orientation within a laminated composite. Hybrid organic- metal laminates are also used, where, for example, layers of glass/epoxy are combined with aluminum alloy sheets. These laminates provide improved wear, impact and blast resistance, and fire resistance.

The final category of fiber architecture is that formed by weaving, braiding, or knitting the fiber bundles or "tows" to create interlocking fibers that often have orientations slightly or fully in an orientation orthogonal to the primary structural plane. This approach is taken for a variety of reasons, including the ability to have structural, thermal, or electrical properties in the third or "out-of-plane" dimension. Another often- cited reason for using these architectures is that the "unwetted" or dry fiber preforms (fibers before any matrix is added) are easier to handle, lower in cost, and conform to highly curved shapes more readily than the highly aligned, continuous fiber form.

In addition to these general categories, it is possible to create fiber architectures that are combinations of two or more of these categories. For example, it is possible to create laminated structures of both knitted fabric and continuous fiber layers. The design flexibility offered by composites is truly infinite!

Introduction to Composites

Daniel B. Miracle and Steven L. Donaldson, Air Force Research Laboratory

---

A Brief History of Composite Materials

Organic-matrix composites, or OMCs, originated through efforts in the aerospace community during World War II to produce materials with specific strength and stiffness values that were significantly higher than existing structural materials. In addition, existing aerospace structural alloys, such as those based on aluminum, were subject to corrosion and fatigue damage, and OMCs provided an approach to overcome these issues. By the end of the war, glass-fiber-reinforced plastics had been used successfully in filament-wound rocket motors and demonstrated in various other prototype structural aircraft applications. These materials were put into broader use in the 1950s and provided important improvements in structural response and corrosion resistance. Commercial applications in consumer sporting equipment in the 1960s provided a larger market, which improved design and production capabilities, established consumer familiarity and confidence, and lowered costs.

Defense spending during the Cold War ensured sufficient resources for research and development of new, high-technology materials, and a market for their application. The significant number of new military aircraft, and the large numbers of systems ordered, provided an ideal environment for the development and insertion of high-performance OMCs. The energy crisis during the 1970s provided a significant incentive for the introduction of OMCs into commercial aircraft, and the successful experience in military aircraft was an important factor in their acceptance in the commercial industry. Dramatic improvements in structural efficiency became possible during this period, through the introduction of high-performance carbon fibers. Improved manufacturing capabilities and design methodologies provided the background for significant increases in OMC use for military and commercial aircraft and spacecraft structures.

Over the past 30 years, OMCs have won an increasing mass fraction of aircraft and spacecraft structures. This is demonstrated by the fact that the vintage 1970s application of OMCs to fighter aircraft was typically confined to tailskins and other secondary or “noncritical” flight structures. For example, only 2% of the F-15 E/F was comprised of OMCs. During the subsequent years, significant government and private investments were made toward research, development, fabrication, testing, and flight service demonstration of composite materials and structures. Parallel programs were also ongoing for the use of composites in military and civilian land and naval vehicles. For example, the development of fiberglass structures for boats and other marine applications was extremely successful and now accounts for a significant portion of composite production volume. During these years, confidence in using composite materials increased dramatically. This was also a period of great innovation in manufacturing, assembly, and repair method development.

The advantages demonstrated by composites, in addition to high stiffness, high strength, and low density, include corrosion resistance, long fatigue lives, tailorable properties (including thermal expansion, critical to satellite structures), and the ability to form complex shapes. (This advantage was demonstrated in the ability to create “low observable,” or stealth, structures for military systems.) An example of recent OMC application is the next-generation U.S. tactical fighter aircraft, the F-22. Over 24% of the F-22 structure is OMCs. The B-2 bomber, shown in Fig. 2, is constructed using an even higher percentage of composites, as are current helicopter and vertical lift designs. For example, the tilt- rotor V-22 Osprey is over 41% composite materials. The upper-use temperature of PMCs has also increased dramatically: early epoxies were considered useable (for extended periods) up to 121 °C (250 °F). Current generation polymers, such as bismaleimides, have increased that limit to around 204 °C (400 °F), and the use of polyimide-matrix composites has extended the range to 288 °C (550 °F).

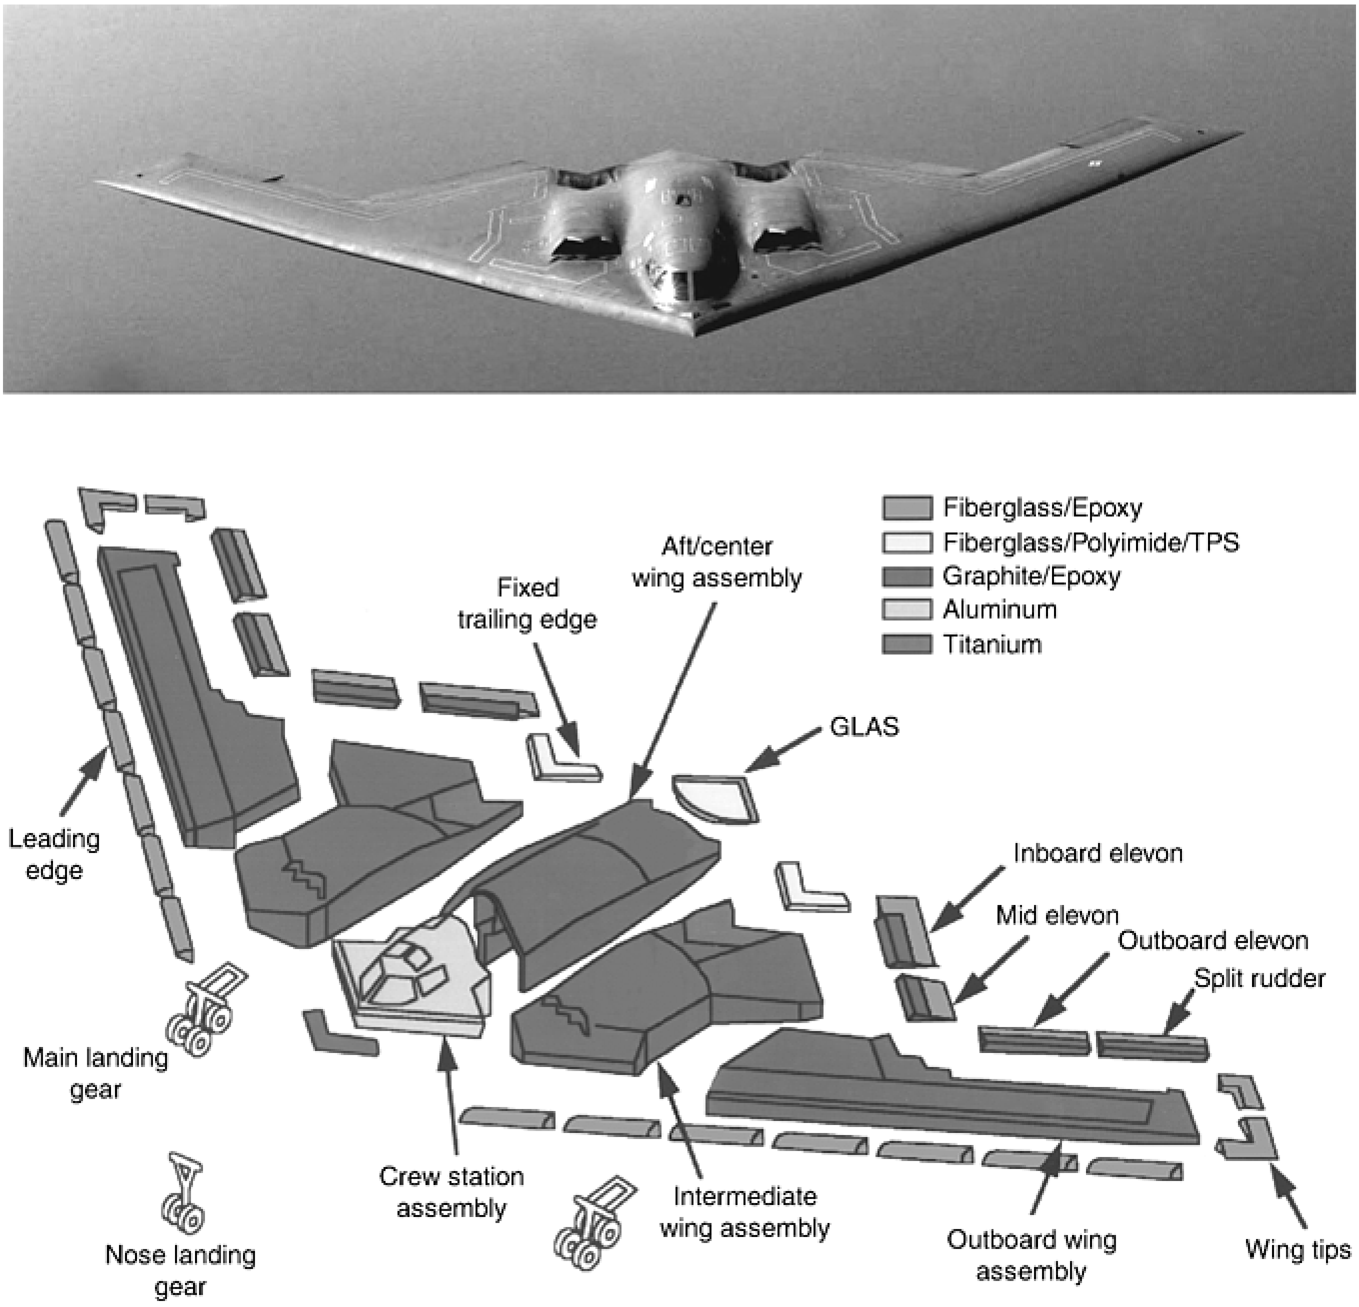

Fig. 2 The U. S. Air Force B-2 advanced “stealth” bomber, which is constructed to a large extent of advanced composite materials

Once considered premium materials only to be used if their high costs could be justified by increased performance, OMCs can now often “buy their way onto” new applications. This is due not only to a dramatic drop in materials costs, but also in advances in the ability to fabricate large, complex parts requiring far less hand labor to manually assemble. A recent example of this is the addition of large composite structures in the tail and landing gear pods on the C-17 cargo aircraft. Clearly, the applications, technology, confidence, and other considerations of high-performance OMCs have expanded dramatically since the 1980s. Perhaps the most dramatic example of this is the growing use of high-performance OMCs in the commodity market of infrastructure.

Metal-Matrix Composites. The first focused efforts to develop MMCs originated in the 1950s and early 1960s. The principal motivation was to dramatically extend the structural efficiency of metallic materials while retaining their advantages, including high chemical inertness, high shear strength, and good property retention at high temperatures. Early work on sintered aluminum powder was a precursor to discontinuously reinforced MMCs. The development of high-strength monofilaments—first boron and then silicon carbide (SiC)—enabled significant efforts on fiber-reinforced MMCs throughout the 1960s and early 1970s. Issues associated with processing, fiber damage, and fiber-matrix interactions were established and overcome to produce useful materials. Although these were very expensive and had marginal reproducibility, important applications were established, including 243 structural components on the space shuttle orbiters. Recession in the early 1970s produced significant research and development funding cuts, leading to an end of this phase of MMC discovery and development.

In the late 1970s, efforts were renewed on discontinuously reinforced MMCs using SiC whisker reinforcements. The high cost of the whiskers (Ref 2) and difficulty in avoiding whisker damage during consolidation led to the concept of particulate reinforcements (Ref 3). The resulting materials provided nearly equivalent strength and stiffness, but with much lower cost and easier processing. A renaissance in both discontinuous and fiber-reinforced MMCs continued through the 1980s. Major efforts included particle-reinforced, whisker-reinforced, and tow-based MMCs of aluminum, magnesium, iron, and copper for applications in the automotive, thermal management, tribology, and aerospace industries. In addition, monofilament-reinforced titanium MMCs were developed for high-temperature aeronautical systems, including structures for high-mach airframes and critical rotating components for advanced gas turbine engines. Significant improvements in performance and materials quality were matched by an increasing number of mostly small businesses that specialized in the production of MMC components for target markets. One by one, MMC applications entered service during this timeframe. However, these successful insertions were not often widely advertised, and so the full impact of MMC technology was not widely appreciated.

In the early 1990s, a U.S. Air Force Title III program provided a significant investment to establish an MMC technology base for the aerospace industry in the United States. This program produced several landmark military and commercial aerospace applications of discontinuously reinforced aluminum (DRA), which are described in some detail in the article “Aeronautical Applications of Metal-Matrix Composites” in this Volume. In addition to these dramatic successes, new MMC insertions in the ground transportation, industrial, and thermal management/ electronic packaging industries far exceeded the growth in the aerospace industry. Thus, the insertion of new materials in military and commercial aircraft has actually lagged behind the industrial sector, reversing the trend of earlier years for the insertion of new materials. The MMC market for thermal management and electronic packaging alone was five times larger than the aerospace market in 1999, and this gap is expected to increase in the coming five years, due to aggressive growth in the ground transportation and thermal management markets (Ref 4).

Ceramic-Matrix Composites. Ceramic-matrix composite development has continued to focus on achieving useful structural and environmental properties at the highest operating temperatures. The high risk associated with this task foreshadows the relatively small number of commercial products. However, development of CMCs for other uses has also been pursued, and significant commercial products now exist. These are described in the article “Applications of Ceramic-Matrix Composites” in this Volume.

General Use Considerations

General Characteristics. First and foremost, composites are engineered materials that have been designed to provide significantly higher specific stiffness and specific strength (stiffness or strength divided by material density)—that is, higher structural efficiency—relative to previously available structural materials. In composite materials, strength and stiffness are provided by the high-strength, high-modulus reinforcements. The actual magnitude in composite strength and stiffness can be controlled over a significant range by controlling the volume fraction of reinforcements and by selecting reinforcements with the desired levels of strength and stiffness. In fiber-reinforced composites, the strength and stiffness may be further controlled by specifying the fiber orientation. The highest levels of properties are achieved when all fibers are aligned along the primary loading direction within the composite. However, this simultaneously produces a material with the lowest specific properties for loads perpendicular to the fiber direction. These highly anisotropic properties must be considered in the use of the material. Of course, various laminate architectures can be produced to provide isotropy within a plane, and this is often done with OMCs.

Figure 3 shows the specific strength and specific stiffness of a wide range of engineering structural materials. The highest structural efficiency is obtained with graphite-fiber uniaxially reinforced epoxy matrix (graphite 0° in Fig. 3), and this provides part of the motivation for the widespread use of these materials. However, this material also provides the lowest structural efficiency for loads that are normal to the fiber axis (graphite 90°). There are two common approaches for dealing with the low properties in the off-axis condition. The first is to use the axially reinforced material in components with largely axial loading, so that the off-axis stresses on the composite are minimal, and the material is used most efficiently. The second approach is to cross-ply the reinforcement so that some fraction of the fibers are aligned along the

off-axis loads. Both approaches are fully successful and have been used extensively, thereby overcoming the poor transverse properties of OMCs. A great deal of flexibility exists in the lay-up of a composite, so that the fraction of fibers in any given direction can be tailored in proportion to the load that must be supported. In-plane isotropy is required in some applications, so a quasi-isotropic (Q/I) graphite/epoxy laminate is produced. This is most often accomplished by orienting the laminating plies at equal numbers of 0°, 90°, +45°, and–45° plies, although there are other stacking sequences that will result in in-plane isotropy. The specific stiffness of quasi-isotropic laminated OMCs is significantly higher than structural metals. The highest specific strength of these materials is superior to all common structural metals, with the exception of a few specialty β–titanium alloys and ultrahigh-strength steels.

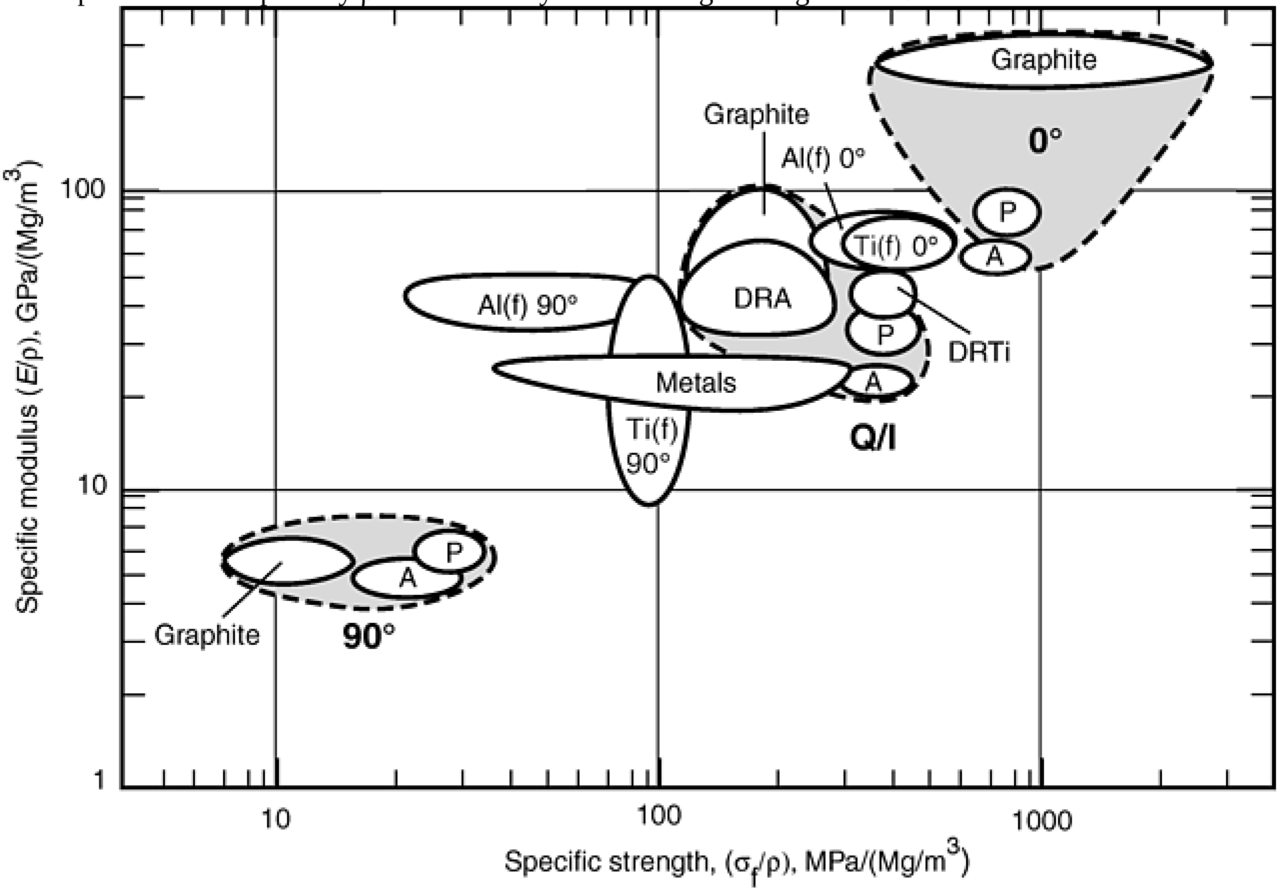

Fig. 3 Materials selection chart depicting normalized strength and stiffness characteristics for various materials systems. Note the high amount of anisotropy (or directional dependence) in composite materials, which can be exploited to create extremely lightweight structures. DRA, discontinuously reinforced aluminum; DRTi; discontinously reinforced titanium; Q/I, quasi-isotropic; P, polyacrylonitrile PAN fibers; A, aramid fibers

Fiber-reinforced metals provide axial and transverse properties that fall between the extremes of the axial and transverse graphite/epoxy OMCs. However, the technology base for fiber- reinforced MMCs is less mature. Processing difficulties currently limit the ability to form complex shapes for SiC monofilament-reinforced titanium alloys. Further, cross-plied architectures have not been successfully demonstrated in any commercial fiber-reinforced MMC. While the high cost of constituent materials dramatically limits the appeal of MMCs reinforced with monofilaments, aluminum alloys reinforced with a tow-based alumina reinforcement are commercially available and can be significantly cheaper than graphite/epoxy OMCs. As a result, these are finding applications in industries that are typically very cost-sensitive. Fiber-reinforced MMCs are now entering applications in limited areas where the metallike behavior is important, including high bearing strength, good wear resistance, high electrical conductivity, and elevated temperature operation. Some of these applications are discussed in the Section “Applications and Experience” in this Volume; for example, see the articles“Automotive Applications of Metal-Matrix Composites” and “Aeronautical Applications of Metal-Matrix Composites.”

Particle-reinforced metals provide essentially isotropic properties that are in the same general range as graphite/epoxy quasi-isotropic material (Fig. 3). Discontinuously reinforced aluminum is currently by far the most widely used MMC. For reinforcement volume fractions of ≤25%, DRA has structural efficiency that overlaps that of quasi-isotropic OMCs and has good fracture toughness and ductility, so that a number of important structural applications have been established.

(See the articles "Aeronautical Applications of Metal-Matrix Composites" and "Automotive Applications of Metal-Matrix Composites" in this Volume.) The fracture properties for higher volume fractions are lower, but these materials are used widely for wear-resistant applications and for thermal management and electronic packaging. The relatively low cost and ease of manufacturing makes DRA an affordable material where high structural efficiency is required. Discontinuously reinforced titanium (DRTi) is less mature than DRA, but already has several important applications established, including intake and exhaust valves in production automobile engines. (See the article "Automotive Applications of Metal-Matrix Composites" in this Volume.) Current DRTi materials have reinforcement volume fractions of ≤20%, and significant improvements are expected for higher reinforcement volume fractions. Current DRTi materials provide a balance of specific strength and specific stiffness that is superior to that of any isotropic engineering material, including quasi-isotropic OMCs.

Almost all high-strength/high-stiffness materials fail because of the propagation of flaws. A fiber of such a material is inherently stronger than the bulk form, because the size of a flaw is limited by the small diameter of the fiber. In addition, if equal volumes of fibrous and bulk material are compared, it is found that even if a flaw does produce failure in a fiber, it will not propagate to fail the entire assemblage of fibers, as would happen in the bulk material. When this material is also lightweight, there is a tremendous potential advantage in specific strength and/or specific stiffness over conventional materials. These desirable fiber properties can be converted to practical application when the fibers are embedded in a matrix that binds them together, transfers load to and between the fibers, and protects them from environments and handling. In addition, fiber-reinforced composites are ideally suited to anisotropic loading situations where weight is critical. The high strengths and moduli of these composites can be tailored to the high load direction(s), with little material wasted on needless reinforcement.

To be useful for structures, materials must offer more than just strength and stiffness. Damage tolerance, fatigue resistance, environmental resistance, and other secondary properties are also required so that the composite can perform its primary structural function. Additional functional properties for which a composite may be developed include high thermal or electrical conductivity (or conversely, electrical and/or thermal insulation), good wear resistance, controlled CTE, and/or environmental resistance. Although composites with significantly different constituents can be conceived to optimize any of these functional properties, the typical organic and metallic composite systems described previously provide a useful range of these functional properties. Specifically, in addition to high strength and stiffness, the reinforcements commonly used in OMCs and MMCs generally have low CTE, high hardness, good electrical and thermal conductivity, and good chemical inertness. As a result, the structural composites in common use can also be tailored to provide other useful functional properties with only minor alterations. The balance of properties obtained in these composites typically cannot be obtained in any other monolithic material. Examples of these functional applications are provided in the Section "Applications and Experience" in this Volume.

Materials Selection and Use. The selection of an optimal material for an intended application is a difficult and multidisciplinary task that requires careful understanding and analysis of a great many variables. The simple introductory comments given previously regarding the two primary figures of merit for structural applications provide a useful starting point for bounding this multivariable problem, but do not address the difficulty associated when trade-offs between competing characteristics must be made. The information and approaches required to help with these decisions are covered in some detail throughout this Volume, so the purpose of this brief introduction is to outline broad considerations and approaches that may help to quickly bound the problem to a tractable and well-defined set of issues.

As a starting point, the application requirements and constraints must be clearly understood. This allows definition of the primary design criteria. An approach for comparing the response across the full range of candidate materials for carefully selected relevant pairs of figures of merit to achieve these primary design criteria has recently been provided (Ref 5). To support this approach, graphical representation of a vast amount of materials properties has been undertaken and completed—these are often commonly referred to as "Ashby plots." Figure 3 provides a simple example of such a representation, because specific stiffness and specific strength are the figures of merit to resist an axial deflection or to support a given load, respectively, at minimum mass. Pairwise comparisons of figures of merit for many other design objectives provide a flexible and complete methodology for quickly bounding a difficult materials selection problem. Additional information on the use of Ashby plots is provided in the article "Material Property Charts" in *Materials Selection and Design,* Volume 20 of *ASM Handbook.*

As explicitly engineered materials, composites in actual use integrate materials specification and component design. For example, the number and orientation of plies is typically explicitly considered during the design of components produced from OMCs. By tailoring the local architecture to the component geometry and anticipated stresses, the designer is able to take best advantage of the materials properties and to produce the component at a minimum mass. In fact, the relatively high raw material cost and high lay-up cost of OMCs has led to a highly unitized approach to design and manufacturing. This has dramatically reduced the cost of manufacture by reducing material waste and by eliminating high labor costs associated with extra manufacturing and joining steps. Fewer parts also lead to reduced inventory and overhead costs. The high structural efficiency and tailorability of OMCs has enabled this important integration in design and materials specification, and this unitized design and manufacturing approach has largely offset the high perceived costs of high-

performance OMCs. While similar approaches cannot currently be achieved with fiber-reinforced MMCs, the concept of selective reinforcement in regions of high stress has been considered and is likely to find application in the near future.

Technology Overview

With some few exceptions, only "high-performance" composites are considered in this Volume. These are composites that have superior performance compared to conventional structural metals. Thus, the focus for OMCs is on continuous fiber-reinforced composites, although the principles are often applicable to other types of composites as well. Continuous fiber-reinforced composites are generally referred to as simply fiber-reinforced composites, and in some cases, as merely fiber composites or composites. Composites with organic (resin) matrices are emphasized throughout this Volume, because these OMCs are by far the most commonly used structural composites. Nonetheless, MMCs are now an established technology with strong impact and growing applications, and so MMCs are discussed explicitly throughout this Volume. Only very limited discussion of CMCs is provided in this Volume.

The following is an introduction to composite materials constituents, product forms, and fabrications processes. The purpose is to provide a simple overview that may serve as a point of departure for the nonspecialist. More detailed information is provided on each of these topics elsewhere in this Volume.

Reinforcements

The principal purpose of the reinforcement is to provide superior levels of strength and stiffness to the composite. In a continuous fiber-reinforced composite, the fibers provide virtually all of the strength and stiffness. Even in particle- reinforced composites, significant improvements are obtained. For example, the addition of 20% SiC to 6061 aluminum provides an increase in strength of over 50% and an increase in stiffness of over 40%. As mentioned earlier, typical reinforcing materials (graphite, glass, SiC, alumina) may also provide thermal and electrical conductivity, controlled thermal expansion, and wear resistance in addition to structural properties.

By far the most widely used reinforcement form in high-performance OMCs are fiber tows. These typically consist of thousands of fine filaments arranged in a single bundle. A fiber tow can be handled as a single unit and so can be wrapped or woven using commercial equipment. Fiber tows also have important applications in MMCs and CMCs. Fiber monofilaments are used in OMCs, MMCs, and CMCs; they consist of a single fiber with a diameter generally ≥100 μm (4 mils). In MMCs, particulates and chopped fibers are the most commonly used reinforcement morphology, and these are also applied in OMCs. Whiskers and platelets are used to a lesser degree in OMCs and MMCs.

Glass Fibers. Initial scientific and engineering understanding of fiber-reinforced organic-matrix composites was based on studies of glass-fiber- reinforced composites. Both continuous and discontinuous glass-fiber-reinforced composites have found extensive application, ranging from nonstructural, low-performance uses, such as panels in aircraft and appliances, to such high- performance applications as rocket motor cases and pressure vessels. The reasons for the widespread use of glass fibers in composites, both in the past and in the present, include competitive price, availability, good handleability, ease of processing, high strength, and other acceptable properties. Furthermore, the advent of highly efficient silane coupling agents, which are very compatible with either polyester or epoxy matrices, provided a strong and much-needed boost in property translation and in environmental durability.

The glass fiber most commonly used is known as E-glass, a glass fiber having a useful balance of mechanical, chemical, and electrical properties at very moderate cost. Typical strength and stiffness levels for the individual filaments are about 3450 MPa (500 ksi) tensile strength and 75.8 GPa (11×10^6 psi) Young's modulus. Higher-performance, higher-cost S-2 glass fibers have properties of 4830 MPa (700 ksi) tensile strength and a modulus of 96.5 GPa (14×10^6 psi). For specialized applications, such as ablatives, thermal barriers, antenna windows, and radomes, high-silica and quartz fibers are also used.

Boron fibers were the first high-performance monofilament reinforcement available for use in advanced composites. Developed and first marketed in the early 1960s, these high-strength, high-modulus fibers found application in composite structural components on the U.S. Air Force F-15 and the U.S. Navy F-14 aircraft. Because these aircraft are still in service and the high costs of changeover are unacceptable, boron fibers are still being used today, even though carbon fibers are now available with equivalent or better properties at a significantly lower price. Boron-epoxy composites have been used in the sporting goods industry, and boron fibers have been used in MMCs because of their excellent mechanical properties, thermal stability, and reduced reactivity with the matrix (compared to carbon fibers). Boron fibers are produced as a rather large monofilament fiber or "wire" (100 to 200 μm, or 4 to 8 mils, diameter) by chemical vapor deposition (CVD) of boron onto a tungsten or pyrolyzed carbon substrate. The resulting fibers have excellent strength (3450 MPa, or 500 ksi) and stiffness (400 GPa, or 58×10^6 psi). Because of their large fiber diameters, they form composites having extremely high compressive strengths. However, because both the precursor gases and the manufacturing process are inherently expensive, boron fibers cannot be expected to compete with carbon fibers on the basis of cost alone. The use of boron fibers has seen somewhat of a resurgence lately in the use of composite patch repairs of crack damage in aluminum aircraft structure.

Carbon Fibers. Although the search for high- performance reinforcing fibers was highly successful, the early limited demand outside the military aerospace industry did not permit the cost reductions that would have resulted from more extensive use. As a result, widespread industrial applications for the variety of new materials progressed very slowly in all but specialty applications where higher costs could be justified. Factors that changed this situation were the extensive use of carbon-fiber-reinforced composites in recreational equipment and the increased cost of energy in the early 1970s. The promise of commercial quantities of carbon-fiber materials from a number of sources at attractive prices created a resurgence of interest in advanced composites in the general aerospace industry. Currently, carbon fibers are the best known and most widely used reinforcing fibers in advanced composites. Although there are many reasons for this situation, two factors predominate. First, the manufacturing technology for carbon fibers, although complex, is more amenable to large-scale production than are those of many of the other advanced fibers. Second, carbon fibers have very useful engineering properties that, for the most part, can be readily translated into usable composite physical and mechanical properties.

Carbon fibers are available from a number of domestic and foreign manufacturers in a wide range of forms having an even wider range of mechanical properties. The earliest commercially available carbon fibers were produced by thermal decomposition of rayon precursor materials. The process involved highly controlled steps of heat treatment and tension to form the appropriately ordered carbon structure. Rayon has been largely supplanted as a precursor by polyacrylonitrile (PAN). Polyacrylonitrile precursors produce much more economical fibers because the carbon yield is higher and because PAN-based fibers do not intrinsically require a final high-temperature "graphitization" step.

Polyacrylonitrile-based fibers having intermediate-modulus values of about 240 to 310 GPa (35 to 45×10^6 psi), combined with strengths ranging from 3515 to 6380 MPa (510 to 925 ksi), are now commercially available. Because carbon fibers display linear stress-strain behavior to failure, the increase in strength also means an increase in the elongation-to-failure. The commercial fibers thus display elongations of up to 2.2%, which means that they exceed the strain capabilities of conventional organic matrices. The diameter of carbon fibers typically ranges from 8 to 10 μm (0.3 to 0.4 mils). Polyacrylonitrile-based fibers are available in various "tow sizes," meaning the number of carbon fibers per bundle. Currently, tow sizes range from low (1000 fibers per tow) at high cost ($40 to $70 per pound) to very high tow counts (hundreds of thousands of fibers per tow) for less than $10 per pound.

Carbon fibers are also manufactured from pitch precursor for specialty applications. Pitch- fiber properties typically include high modulus and thermal conductivity, as might be required on satellite structures. Modulus values in commercially available fibers range up to 825 GPa (120×10^6 psi).

Aramid Fibers. Aramid is a generic term for a class of aromatic polyamide fibers introduced commercially during the early 1960s. These high-performance fibers are all variations of poly para-phenyleneterephthalamide. A broad range of properties are available. Kevlar 149 (DuPont), for example, has a tensile modulus of 180 GPa (26×10^6 psi) and tensile strength of 3450 MPa (500 ksi). The more commonly used Kevlar 49 (DuPont) has a tensile modulus of 131 GPa ($19 \times 10_6$ psi) and a tensile strength of 3620 MPa (525) ksi).

Aramid fiber is unusual in that it is technically a thermoplastic polymer (like nylon), but rather than melting when heated, it decomposes before reaching its projected melting temperature. With polymerization, it forms rigid, rodlike molecules that cannot be drawn from a melt, as textile fiber molecules can, but must instead be spun from a liquid crystalline solution in sulfuric acid. The polymerization and manufacturing processes for aramid fibers are complex and exacting and involve many aggressive chemical species.

The high strength of aramid fiber, combined with a fiber modulus considerably higher than S- glass, gave it early application in filament- wound rocket motor cases, gas pressure vessels, and lightly loaded secondary structures on fixed- wing commercial aircraft and helicopters. The fiber shows linear tensile stress-strain behavior to failure, but unlike inorganic fibers, is surprisingly damage tolerant. However, it also displays far lower strength in compression than carbon and other inorganic fibers and relatively poor adhesion to matrix resins. Moisture uptake may also need to be considered. Nevertheless, because of properties such as its high specific strength, low density, and toughness, significant markets exist.

Other Organic Fibers. Another common category of fibers are ultrahigh-molecular- weight polyethylene fibers, such as Spectra from AlliedSignal Inc. The modulus of Spectra can range up to 113 GPa (16×10^6 psi), with tensile strengths up to 3250 MPa (470 ksi). These fibers have high chemical, impact, and moisture resistance, as well as low density, good vibration damping, and low dielectric constant. Major applications include ballistic armor, radomes, boats, and other recreational products.

Silicon Carbide Monofilaments. Silicon carbide monofilaments have been developed for reinforcements in MMCs based on aluminum and titanium alloy matrices and for CMCs. Fibers that are now commercially available are all produced by CVD of fine-grained β-SiC, which is deposited on either a tungsten or a carbon filament core. Each of the fibers also uses a carbon- based coating to improve fiber strength by healing surface defects, to improve handleability, and to protect the fiber from interaction with the metal matrix during consolidation and use. The monofilaments range in diameter from 100 to 142 μm (4 to 5.6 mils). The CTE for all of the SiC monofilaments is 4.5×10^{-6}/°C, (2.5×10^{-6}/°F) and the density is 3.0 g/cm^3 (0.11 lb/ in.^{3}) for fibers with a carbon core and 3.4 g/cm^3 (0.12 lb/in.^{3}) for fibers deposited on tungsten. There are currently three manufacturers of SiC monofilament.

Textron Systems markets the venerable SCS- 6 monofilament, which has been used longer than any other SiC monofilament. It is deposited on a carbon core by a two-pass process, which produces a distinct change in grain size at the fiber midradius. A multilayer carbon-based coating consists of an intentional gradation in silicon content to enhance the coating effectiveness. The overall fiber diameter is 142 μm (5.6 mils). The minimum specified average properties are 3450 MPa (500 ksi) strength and 345 GPa (50×10^6 psi) stiffness. The typical average properties are 4300 MPa (625 ksi) strength and 390 GPa (56×10^6 psi) stiffness. There is a great deal of data and experience behind this fiber, which has been produced by the same process since 1983. Process improvements have led to the Textron Systems Ultra SCS fiber. While the carbon core, fiber coating, and fiber diameter are identical to the SCS-6, the SiC possesses a finer grain size that is uniform across the fiber diameter. The minimum average specified properties are 5860 MPa (850 ksi) strength and 360 GPa (52×10^6 psi) stiffness. The typical average values obtained are 6550 MPa (950 ksi) strength and 415 GPa (60×10^6 psi) stiffness.

Two SiC monofilaments are available from the Atlantic Research Corporation (Gainesville, VA). Trimarc-1 is 127 μm (5 mils) in diameter on a tungsten core, with a multilayer carbon coating 4 to 5 μm (0.16 to 0.20 mils) thick. The typical mean fiber strength is 3550 MPa (515 ksi), and the modulus is 420 GPa (61×10^6 psi). Trimarc-2 is deposited on a carbon core and is 142 μm (5.6 mils) in diameter. The typical strength is 3790 MPa (550 ksi), and the typical modulus is 400 to 414 GPa (58 to 60×10^6 psi). The Sigma SiC monofilament is produced by QinetiQ, formerly the Defence Evaluation and Research Agency (DERA), in the United Kingdom. The DERA Sigma 1140+ fiber is 100 μm (4 mils) in diameter, is produced on a tungsten core, and has a carbon coating about 5 μm (0.2 mils) thick. The typical strength is between 3400 to 3500 MPa (490 to 510 ksi), and the modulus is 380 GPa (55×10^6 psi).

Alumina-Fiber Reinforcements. A number of alumina (Al_2O_3) fibers have been developed and used for MMCs and CMCs, including ceramic tows and monofilaments. At present, production MMCs only use alumina tows. The most commonly used material is the Nextel 610 fiber produced by 3M (St. Paul, MN). This is ≥99% α–alumina and has a density of 3.96 g/cm^3. Tows are available that contain from 400 to 2550 filaments per tow. The mean filament diameter is 10 to 12 μm (0.4 to 0.5 mils). The typical fiber properties are 2930 MPa (425 ksi) strength and 373 GPa (54×10^6 psi) modulus. The CTE is 7.9×10^{-6}/°C.

Particulate reinforcements in MMCs typically use abrasive-grade ceramic grit. This provides a ready commercial source, and the high volumes associated with the abrasives industry help maintain a low cost. Silicon carbide, alumina, and boron carbide (B_4C) are most often used. Titanium carbide (TiC) is also used for iron and titanium alloy matrices. While TiB is used as a reinforcement in discontinuously reinforced titanium alloys, this reinforcement is typically obtained by in situ reaction with TiB_2. Silicon carbide offers the best strength and stiffness for aluminum matrices, but is slightly more expensive than alumina. “Green” SiC offers better strength and thermal conductivity relative to “black” SiC, and so is used where these properties are important. Typical grit sizes used are between F-600 (mean grit size between 8.3 to10.3 μm, or 0.33 to 0.41 mils) and F-1200 (mean grit size between 2.5 to 3.5 μm, or 0.11 to 0.14 mils). Alumina is slightly cheaper than SiC, and so is attractive where cost is critical, such as in the automotive sector. Alumina is slightly more dense than SiC and has a higher CTE. Alumina is chemically more stable than SiC in molten aluminum, and so is frequently used in cast DRA. Silicon carbide particulates are still used for cast MMCs, and silicon is added as an alloying addition to reduce the reactivity with the molten metal.

Matrices

The purpose of the matrix is to bind the reinforcements together by virtue of its cohesive and adhesive characteristics, to transfer load to and between reinforcements, and to protect the reinforcements from environments and handling. The matrix also provides a solid form to the composite, which aids handling during manufacture and is typically required in a finished part. This is particularly necessary in discontinuously reinforced composites, because the reinforcements are not of sufficient length to provide a handleable form. Because the reinforcements are typically stronger and stiffer, the matrix is often the “weak link” in the composite, from a structural perspective. As a continuous phase, the matrix therefore controls the transverse properties, interlaminar strength, and elevated-temperature strength of the composite. However, the matrix allows the strength of the reinforcements to be used to their full potential by providing effective load transfer from external forces to the reinforcement. The matrix holds reinforcing fibers in the proper orientation and position so that they can carry the intended loads and distributes the loads more or less evenly among the reinforcements. Further, the matrix provides a vital inelastic response so that stress concentrations are reduced dramatically and internal stresses are redistributed from broken reinforcements. In organic matrices, this inelastic response is often obtained by microcracking; in metals, plastic deformation yields the needed compliance. Debonding, often properly considered as an interfacial phenomenon, is an important mechanism that adds to load redistribution and blunting of stress concentrations. A broad overview of important matrices is provided subsequently.

Organic matrices for commercial applications include polyester and vinyl ester resins; epoxy resins are used for some “high-end” applications.

Polyester and vinyl ester resins are the most widely used of all matrix materials. They are used mainly in commercial, industrial, and transportation applications, including chemically resistant piping and reactors, truck cabs and bodies, appliances, bathtubs and showers, and automobile hoods, decks, and doors. The very large number of resin formulations, curing agents, fillers, and other components provides a tremendous range of possible properties.

The development of highly effective silane coupling agents for glass fibers allowed the fabrication of glass-fiber-reinforced polyester and vinyl ester composites that have excellent mechanical properties and acceptable environmental durability. These enhanced characteristics have been the major factors in the widespread use of these composites today.

The problems of attaining adequate adhesion to carbon and aramid fibers have discouraged the development of applications for polyester or vinyl ester composites that use these fibers. Although there are applications of high-performance fiberglass composites in military and aerospace structures, the relatively poor properties of advanced composites of polyester and vinyl ester resins when used with other fibers, combined with the comparatively large cure shrinkage of these resins, have generally restricted such composites to lower-performance applications.

Other Resins. When property requirements justify the additional costs, epoxies and other resins, as discussed subsequently, are used in commercial applications, including high-performance sporting goods (such as tennis rackets and fishing rods), piping for chemical processing plants, and printed circuit boards.

Organic matrices for aerospace applications include epoxy, bismaleimide, and polyimide resins. Various other thermoset and thermoplastic resins are in development or use for specific applications.

Epoxy resins are presently used far more than all other matrices in advanced composite materials for structural aerospace applications. Although epoxies are sensitive to moisture in both their cured and uncured states, they are generally superior to polyesters in resisting moisture and other environmental influences and offer lower cure shrinkage and better mechanical properties. Even though the elongation-to-failure of most cured epoxies is relatively low, for many applications epoxies provide an almost unbeatable combination of handling characteristics, processing flexibility, composite mechanical properties, and acceptable cost. Modified "toughened" epoxy resin formulations (typically via the addition of thermoplastic or rubber additives) have improved elongation capabilities. In addition, a substantial database exists for epoxy resins, because both the U.S. Air Force and the U.S. Navy have been flying aircraft with epoxy-matrix structural components since 1972, and the in-service experience with these components has been very satisfactory.

Moisture absorption decreases the glass transition temperature (T_g) of an epoxy resin. Because a significant loss of epoxy properties occurs at the T_g, the T_g in most cases describes the upper-use temperature limit of the composite. To avoid subjecting the resins to temperatures equal to or higher than this so-called wet T_g (the wet T_g is the T_g measured after the polymer matrix has been exposed to a specified humid environment and allowed to absorb moisture until it reaches equilibrium), epoxy resins are presently limited to a maximum service temperature of about 120 °C (250 °F) for highly loaded, long- term applications and even lower temperatures (80 to 105 °C, or 180 to 220 °F) for toughened epoxy resins. Although this limit is conservative for some applications, its imposition has generally avoided serious thermal-performance difficulties. Considerable effort continues to be expended to develop epoxy resins that will perform satisfactorily at higher temperatures when wet. However, progress in increasing the 120 °C (250 °F) limit has been slow.

Bismaleimide resins (BMI) possess many of the same desirable features as do epoxies, such as fair handleability, relative ease of processing, and excellent composite properties. They are superior to epoxies in maximum hot/wet use temperature, extending the safe in-service temperature to 177 to 230 °C (350 to 450 °F). They are available from a number of suppliers. Unfortunately, BMIs also tend to display the same deficiencies (or worse) as do epoxies: they have an even lower elongation-to-failure and are quite brittle. Damage tolerance is generally comparable to commercial aerospace epoxy resins. Progress has been made to formulate BMIs with improved toughness properties.

Polyimide resins are available with a maximum hot/wet in-service temperature of 232 °C (450 °F) and above (up to 370 °C, or 700 °F, for single use short periods). Unlike the previously mentioned resins, these cure by a condensation reaction that releases volatiles during cure. This poses a problem, because the released volatiles produce voids in the resulting composite. Substantial effort has been made to reduce this problem, and there are currently several polyimide resins in which the final cure occurs by an addition reaction that does not release volatiles. These resins will produce good-quality, low- void-content composite parts. Unfortunately, like BMIs, polyimides are quite brittle.

Other Thermosetting Resins. The attempt to produce improved thermosetting resins is ongoing, with major efforts focusing on hot/wet performance and/or impact resistance of epoxies, BMIs, and polyimides. Other resins are constantly in development, and some are in commercial use for specialized applications. Phenolic resins, for example, have been used for years in applications requiring very high heat resistance and excellent char and ablative performance. These resins also have good dielectric properties, combined with dimensional and thermal stability. Unfortunately, they also cure by a condensation reaction, giving off water as a by-product and producing a voidy laminate. However, they also produce low smoke and less toxic by-products upon combustion and are therefore often used in such applications as aircraft interior panels where combustion requirements justify the lower properties. Cyanate esters are also used as matrix materials. Their low-moisture-absorption characteristics and superior electrical properties allow them to see applications in satellite structures, radomes, antennas, and electronic components.

Thermoplastic Resins. The dual goal of improving both hot/wet properties and impact resistance of composite matrices has led to the development, and limited use, of high-temperature thermoplastic resin matrices. These materials are very different from the commodity thermoplastics (such as polyethylene, polyvinyl chloride, and polystyrene) that are commonly used as plastic bags, plastic piping, and plastic tableware. The commodity thermoplastics exhibit very little resistance to elevated temperatures; the high-performance thermoplastics exhibit resistance that can be superior to that of epoxy.

Thermoplastic-matrix materials are tougher and offer the potential of improved hot/wet resistance and long-term room-temperature storage. Because of their high strains-to-failure, they also are the only matrices currently available that allow, at least theoretically, the new intermediate-modulus, high-strength (and strain) carbon fibers to use their full strain potential in the composite. Thermoplastics are generally considered to be *semicrystalline* (meaning the atoms in the polymer chains arrange themselves in regular arrays to some degree) or *amorphous* (meaning there is no local order to the molecular chains). These materials include such resins as polyether etherketone, polyphenylene sulfide, polyetherimide (all of which are intended to maintain thermoplastic character in the final composite), and others, such as polyamideimide, which is originally molded as a thermoplastic but is then postcured in the final composite to produce partial thermosetting characteristics (and thus improved subsequent temperature resistance). Thermoplastic matrices do not absorb any significant amount of water, but organic solvent resistance is an area of concern for the noncrystalline thermoplastics.

Metal and Ceramic Matrices. Unlike their organic counterparts, the metal alloy matrix in MMCs provides an important contribution to the strength of the composite. This results not only from the higher strength of metal alloys relative to organic resins typically used as matrices, but also from the fact that most MMCs currently have discontinuous reinforcements and a much higher matrix volume fraction. Metal-matrix composites are currently in service using matrices based on alloys of aluminum, titanium, iron, cobalt, copper, silver, and beryllium. Copper, silver, and beryllium MMCs are mostly used for thermal management and electrical contacts; iron MMCs are used for industrial wear-resistant applications, such as rollers and tool dies; and titanium MMCs are used primarily for automotive, aerospace, and recreational products. Cobalt MMCs (cemented carbides, or cermets) are included here as an MMC, although not all agree upon this classification, while oxide-dispersion- strengthened nickel is explicitly excluded, because strengthening in these alloys occurs by a dislocation mechanism rather than a load-sharing mechanism. By far the most widely produced MMCs are based on aluminum alloy matrices, and these are in current use for automotive and rail ground transportation, thermal management and electronic packaging, aerospace, and recreational applications.

A wide range of cast and wrought aluminum alloys are used as matrices in aluminum MMCs. A standard nomenclature, American National Standards Institute (ANSI) H35.5-1997, has been established for aluminum MMCs: 2009/ SiC/15p-T4. The first four digits (or three digits for cast alloys) are the Aluminum Association alloy designation, which specifies the matrix alloy composition. This is followed by the reinforcement composition and the reinforcement volume fraction (in volume percent). A single letter signifies the reinforcement morphology ("p" is particle, "w" is whisker, and "f" is fiber). The standard Aluminum Association temper designation is used at the end of the MMC designation, as appropriate.

The most widely used MMC casting alloys are based on aluminum-silicon, which are used to produce foundry ingots. The high-silicon aluminum alloys improve castability and minimize chemical interaction with the SiC reinforcements during melting. Common matrix alloy compositions are based on aluminum casting alloys such as 359, 360, and 380. The modifications generally include higher silicon and sometimes higher magnesium or manganese or lower copper (Ref 6). Infiltration casting also often uses aluminum-silicon alloys, such as A356, and this is common for materials used in thermal management. However, wrought alloy compositions, including common 2*xxx* and 6*xxx* alloys, can also be used for infiltration casting. For pressureless casting, the matrix composition is carefully controlled to provide the desired reactions and microstructures. Silicon is typically at 10% (by weight), and 1% Mg (by weight) is also critical.

Cast billets or blooms for subsequent thermomechanical processing often use wrought matrix alloys containing magnesium, such as 2024 and 6061. Billet obtained by powder metallurgy also uses conventional wrought alloy compositions, or may use modified alloys that have been optimized for use in an MMC matrix. Two examples are 6091, which is a modified 6061 alloy, and 6092, which is a modification of 6013. Often, the modification involves a small reduction in the concentration of alloy additions used for grain refinement, because the reinforcing particulates restrict grain growth. Also, a maximum level is specified for oxygen to ensure that the powder does not introduce a large fraction of oxide particles.

Metal-matrix composites of copper, beryllium, and silver are used primarily for their excellent electrical and thermal properties, and reinforcements are added for control of thermal expansion or improved wear resistance. The matrix is usually the pure element to retain the excellent thermal or electrical properties. Typical reinforcements, such as molybdenum in copper and silver, tungsten and tungsten carbide in copper, and beryllium oxide in beryllium, are insoluble in the matrix.

Titanium MMCs use conventional wrought alloy matrices when the reinforcement is continuous. For current applications, Ti-6Al-2Sn-4Zr- 2Mo (Ti-6242) is used. (See the article "Aeronautical Applications of Metal-

Matrix Composites" in this Volume.) Other commercial alloys, such as Ti-6Al-4V and Timetal 21S, have been used extensively in development and component demonstrations. A number of alloys have been used in research and development of DRTi. The largest commercial application of DRTi by far is for automotive intake and exhaust valves. The intake valve uses Ti–6Al–4V as the matrix, but the exhaust valve requires a high-temperature matrix alloy. The composition used is Ti- 6.5Al-4.6Sn-4.6Zr-1.0Mo-1Nb-0.3Si (Ref 7, 8).
Ceramic-matrix composites currently in use generally use SiC or inhibited carbon as the matrix. The role of the matrix is to provide the required wear and abrasion resistance, or to protect the fiber from oxidation and damage.

Material Forms

Composite materials are generally available in a range of raw product forms. These forms provide a standardized unit for cost-effective production and are a convenient input for manufacturing processes. Further, standardizing the raw product form allows better control over constituent composition and distribution. A brief discussion of the raw product forms used most often in composite manufacture is provided subsequently.
Organic-Matrix Composites. Continuous reinforcing fibers are available in many product forms, ranging from monofilaments (for fibers such as boron and SiC) to multifilament fiber bundles, and from unidirectional ribbons to single-layer fabrics and multilayer fabric mats. The organic matrices are generally mixed from the individual components if the matrix is a thermoset, or are available as sheet, powders, or pellets if the matrix is a thermoplastic. The reinforcing fibers and matrix resins may be combined into many different nonfinal material or product forms that are designed for subsequent use with specific fabrication processes. In the case of continuous fibers, these combinations of unidirectional fiber ribbons, tows, or woven fabrics with resin and formed into broad sheets are called prepregs. (In some cases, the fiber tows are impregnated with resin and wound back on spools, still as tows, to form "towpregs.") At this stage, prepregs/towpregs are still largely uncured.
Using prepregs rather than in-line impregnation of the fibers during the final composite fabrication process can offer significant advantages. Prepregs can have very precisely controlled fiber-resin ratios, highly controlled tack and drape (in the case of thermoset matrices), controlled resin flow during the cure process, and, in some processes, better control of fiber angle and placement. Prepreg materials can be produced and stored, normally under refrigeration for thermosetting matrices, and then used in processes ranging from hand lay-up to highly automated filament winding, tape laying, or tow placement. Processes such as pultrusion and braiding can also use prepreg forms instead of in-line resin impregnation. While the latter may be lower in initial cost, it may be prohibitive for some resin systems (such as thermoplastics), and parameters such as fiber-resin ratio may not be as easily controlled, as is the case with a prepreg.
Discontinuous fiber-reinforced product forms include sheet molding compounds, bulk molding compounds, injection molding compounds, and dry preforms fabricated for use in resin infusion processes. Many other forms of reinforcement exist, primarily in fiberglass materials. Both continuous and discontinuous mats, with and without binder materials, are available. Of course, composites reinforced primarily with discontinuous fibers have lower mechanical properties than those with continuous fibers. This is because all of the loads in discontinuous fiber composites must be carried by the matrix in shear from fiber length to fiber length (shear lag). In addition, fiber volume in discontinuous fiber composites is normally quite a bit lower than is typical in continuous fiber composites.
Composite materials are very often used as facesheets and combined with core materials to form sandwich structures. Common forms for core materials are foams (open and closed cell), honeycomb (often made from fiberglass, aramid, or aluminum) whereby the longitudinal axes of the cells are perpendicular to the primary plane of the structural sandwich, and foam-filled honeycomb. Sandwich structures have extremely high structural bending stiffness, which is exploited in bending- and buckling- critical applications.
Metal-Matrix Composites. The largest supplier of MMC primary product forms is Alcan Engineered Cast Products (formerly Duralcan USA). Billet and blooms for wrought processing and foundry ingots for remelting are produced by a patented casting process. Batches of 6.8 metric tons are melted, and the ceramic particles are suspended in the melt by a high-energy mixing process. The molten MMC is then cast into bloom, billet, or ingot. These material forms are then provided to customers who apply secondary forming operations, such as extrusion, forging, rolling, or remelting and casting.

The aerospace industry relies upon MMC billet produced by a powder metallurgy process. The primary process, performed by DWA Aluminum Composites, mixes matrix and reinforcing powder in a high-shear mixer, then outgases and consolidates the powder into billet. Billet sizes over 360 kg (800 lb) are typical, and billets up to 450 kg (1000 lb) are available.

A major portion of the MMC market relies upon components produced in near-net shape processes other than recasting of foundry ingot. The most commonly used processes are infiltration casting and squeeze casting. In both cases, carefully produced porous ceramic preforms are required. Infiltration preforms of ceramic particulates are produced by either a slurry-casting approach, by powder pressing, or by injection molding. These preforms provide a uniform distribution of the reinforcement and a controlled porosity for infiltration. In addition, the preform provides adequate "green strength" to resist the pressures that are sometimes applied during infiltration. Another important near-net shape process is a proprietary in situ casting technique used by DMC^2 Electronic Components (formerly Lanxide Electronic Components). As the MMC is formed in situ during solidification, special MMC foundry ingot or preforms are not required.

Wire and tape product forms of continuously reinforced aluminum MMCs are now commercially available. The MMC has a reinforcement volume fraction of approximately 55% alumina (Nextel 610). The wire is by far the most common form. A variety of diameters is available, but 2.6 mm (0.10 in.) is the median diameter. These are produced by a patented process by 3M.

Fabrication Processes

Organic-Matrix Composites. A host of processes exist for the fabrication of OMC components. Fiber-reinforced composites used in most high-performance applications are laminated with unidirectional (or fabric) layers at discrete angles to one another (such as in plywood), thereby allowing for highly tailored directional stiffness and strength properties. A variety of fiber-placement processes are available to achieve this desired combination of orientations. Two common processes are lay-up (by hand or machine) and filament winding/tow placement. With lay-up, material that is in prepreg or dry fiber form (dry fibers contain no resin, so this form typically consists of knitted, braided, or woven layers) is cut and laid up, layer by layer, to produce a laminate of the desired number of plies and associated ply orientations. In filament winding/tow placement, a fiber bundle or ribbon is impregnated with resin and wound upon a mandrel to produce a shape: with filament winding it is often a simple geometry, such as a tube or pressure vessel; with tow placement the shapes can often be more complex. As mentioned before, filament winding/tow placement may use wet liquid resin or prepreg.

Composite fiber-placement fabrication procedures can be labor intensive, so most major composite component fabricators are developing and/or using automatic fabrication equipment. Such equipment is often used for composite components that have a relatively large area and reasonable production rate. Two methods predominate. One involves laying up the plies with tape. Large tape-laying machines are computer controlled, include gantry robot systems, and are equipped with a specially designed tape-dispensing head. Another method involves the cutout of entire plies from unidirectional broad goods using laser, waterjet, or reciprocating- knife cutters. Cutout ply patterns are transferred to a tool and laid up by hand or automatic equipment with specially designed pick-up and lay- down heads. Laser-generated guidelines can be projected onto a part to indicate the location of the next part to be placed.

If the fiber-placement process involved the use of "dry" fibers, the next step in the process is to infuse this dry fiber preform with liquid resin. One of the most basic processes to do this is called resin transfer molding (RTM). In the RTM process, the dry fiber preform is first placed in an open matched mold. The mold is closed and resin is injected into ports in the mold. Excess air is forced out other vents in the mold. In vacuum-assisted resin transfer molding, vacuum can be applied to the vent ports to assist in drawing the resin into the fiber preform and removing any trapped air. There are many variations of the resin infusion process. For example, for cost reduction, molds can contain a single-sided hard tool side, where the opposite side of the tool can just be a simple, flexible vacuum bag. Other variations contain an air gap or high permeability layers over the planform surface of the part, to allow the liquid resin to flow quickly over and "above" the surface, before the slower process of diffusing through the preform (hence, using this method, the liquid has only to diffuse through the preform thickness, not across the part width direction as in RTM). In one variation of this process (liquid compression molding), once the resin has flowed through the air gap over the preform, the tool can be further closed creating additional pressure to force the resin into the preform. Probably the oldest of all methods

of resin infusion is “wet lay-up,” in which the fibers, typically textiles, are dipped in the resin (or the resin squeegeed into the textile layer) and the wet layer is placed on a single- sided mold.
The fiber placement (and resin infusion, if appropriate) process is followed by some type of cure process to harden (cross link) the polymer- matrix resin. For a low-cure-temperature or two- part mix thermoset matrix, this may simply involve holding the part at room temperature until cure completion. However, for applications involving elevated-temperature service or for thermoplastics, there must be an elevated-temperature cure. Filament-wound parts may be cured at elevated temperature in an open oven; in some cases, consolidation and surface finish may be improved by applying an external female mold or vacuum bag. Lay-ups are most commonly consolidated by applying both heat and pressure in an autoclave, but they may also be molded, pressed, or vacuum bag cured. (For example, in the RTM process, the molds themselves may be heated.)
There are also special fabrication processes, such as pultrusion, that combine fiber placement, consolidation, and elevated-temperature cure in one continuous operation. The pultrusion process is a low-cost, high-volume method to produce long parts with constant (or nearly constant) cross section containing fibers aligned predominantly along the longitudinal axis of the part. The pultrusion process is a continous “line” process, whereby fiber tows are mechanically gripped and pulled from their spools, through a resin bath, then through a heated die containing the desired cross section of the part. Another common industrial process is compression molding, typically whereby flat sheets of preimpregnated fibers are placed in an open heated mold. The mold halves are subsequently closed and the resin then cured to final shape.
To select the best composite fabrication process, the designer generally chooses the process that will provide an acceptable-quality component for the lowest cost. In evaluating cost and quality, however, tooling cost, production rate, materials cost, desired part finish, and many other factors must be considered. Only after all the pertinent factors have been weighed can the fabrication method (or the material) be selected.
Metal-Matrix Composites. Nearly twice the volume of MMCs are produced by casting and other liquid routes compared to solid-state fabrication, and this gap is expected to widen in coming years. This is lead by automotive applications, such as engine block cylinder liners and brake components, and in the thermal management industry. By a great margin, aluminum MMCs are the most commonly cast materials. A wide variety of techniques are now commercially established, including pour casting, infiltration casting, and in situ processing.
Casting typically begins with a foundry ingot material, as described previously. Upon remelting, the molten composite must be well stirred to keep the reinforcements well distributed. Both SiC and alumina reinforcements have a density slightly higher than aluminum alloys, and so tend to settle. Settling is avoided with boron carbide reinforcements in aluminum alloys, because the densities are nearly identical, but the higher cost of these reinforcements has restricted their use in high-volume applications. In cast aluminum MMCs using SiC reinforcements, the liquid metal temperature must be kept below about 730 °C (1346 °F) to avoid the formation of aluminum carbide, Al_3C_4. Due to the higher viscosity of the MMC, this process is typically used for reinforcement volume fractions of ≤20%. The Alcan material has been successfully cast using a number of standard techniques, including green sand, bonded sand, permanent mold, plaster mold, investment, lost foam, and centrifugal casting (Ref 6). Small but important modifications are sometimes required for MMC casting. For example, the design of gating systems must specifically take account of the higher melt viscosity, so that air entrapment is avoided. With proper design, excellent results have been obtained.
Pressure casting of MMCs has been used commercially since the early 1980s. In this process (often called “squeeze casting”), a porous ceramic preform is introduced into a permanent mold cavity. A fixed volume of molten metal alloy is introduced and is rapidly pressed into the ceramic preform by a mechanical force. After solidification, the part is ejected from the mold, and the process is repeated. Because the process is very rapid, it is well suited for high volumes, such as those represented by the automotive industry. Another feature leading to good cost-effectiveness is the reusability of the permanent mold. A notable example of squeeze-cast components are the selectively reinforced MMC pistons introduced by Toyota Motor Manufacturing in 1983 as the first commercial MMC application in the automotive industry. Production rates of over 100,000 per month have been achieved (Ref 4).
A number of approaches are used for the production of components via infiltration casting. The primary difference between these techniques is in the amount of gas pressure applied to force the molten metal into the porous ceramic preform. Typical gas pressures range from 5.5 MPa (800 psi) to 10.3 MPa (1500 psi). The hydrostatic pressure and moderate rates of pressurization eliminate the need for high-strength tooling and minimize the possibility of damaging the preform as the molten metal is infiltrated. The mold is not permanent,

but five to ten parts can typically be produced from a single mold before replacement. While excellent results can be obtained, a pressure chamber with adequate volume and heating capability is required. This process is well suited to aerospace components, where high quality and low or moderate production volumes are required, or to electronic packaging, where the small component size allows up to several hundred parts to be made in a single run.

A pressureless process is used to produce MMCs by infiltrating a porous, nonreactive ceramic preform. The aluminum alloy contains magnesium, and the infiltration is conducted in a nitrogen atmosphere. The magnesium reacts with the nitrogen gas to form Mg_3N_2, which enables spontaneous infiltration of the ceramic preform. As the molten aluminum is drawn into the preform, the Mg_3N_2 is reduced to form aluminum nitride, and the magnesium is released into solid solution (Ref 6).

The fabrication processes established for the metalworking industry, such as extrusion, forging, and rolling, are typically used for particle- reinforced MMCs with only small modifications. Extrusion of MMCs is used extensively: in the automotive industry (for example, driveshafts for trucks and the Chevrolet Corvette), for aerospace components (such as the fan exit guide vane of Pratt and Whitney 4*xxx* series gas turbine engines), and recreation products (such as bicycle frame tubing). Extrusion billet up to 51 cm (20 in.) in diameter has been commercially extruded. Some commercially produced components represent significant geometrical complexity. Excellent dimensional tolerances and surface finish can be achieved in the as-extruded product. Hard-face extrusion die coatings are often used to extend die life.

Commercial MMC components are also produced by rolling and forging. Rolled MMC product includes plate and sheet. Plate is used for applications such as clutch plates, thermal management input material, and fuel access doors in the aerospace industry. Sheet is used primarily for aerospace components, and material over 76 cm (30 in.) has been produced. Rolling preforms are produced by both casting and powder metallurgy processes. Forging of MMCs is used for fatigue-critical applications, such as helicopter rotor blade sleeves. A cylindrical extrusion preform is blocker-forged and then closed-die forged to the final shape. Excellent dimensional tolerances are maintained. Forging is being developed for automotive connecting rods. The microstructural refinement provided by the forging process improves the fatigue response, which is a critical requirement for this application.

The processes described previously are those most extensively used for existing applications. Many other fabrication processes are being used or have been established for MMCs, including spray forming, drawing, piercing, and ring rolling.

Machining and finishing operations for MMCs are similar to those used for metals. By far the greatest experience exists for aluminum MMCs. Standard mills, lathes, and computer numerical control machines can be used, as long as the cutting parameters are properly selected. Because of the strong, hard, ceramic reinforcements in MMCs, significant tool wear results when using simple high-speed steel tools and even carbide tools. However, economies of machining identical to that obtained with conventional tooling can be achieved in MMCs using polycrystalline diamond (PCD) on a unit-operation basis. Tool wear is reduced and surface quality improved for more aggressive cuts and higher speeds, improving the overall speed of machining. Experience at Alcan has shown that coarse- grained PCD (15 to 40 μm, or 0.6 to 1.6 mils) provides the best overall performance and cost- effectiveness (Ref 4). In some cases, operations in MMCs provide superior results compared to unreinforced metals.

Applications

The purpose of this brief introduction is to provide broad insights and unifying themes regarding the diverse applications of composite materials. An overview of OMC use is highlighted. The dramatic progress in the technology and application of MMCs is discussed, and the current status of CMC applications is provided. Because of their recent maturity to the point of becoming a robust commercial technology, the subsequent section on MMC applications is somewhat expanded in this introduction. Detailed information relating to the application of composite materials over a broad range of categories is provided in the Section “Applications and Experience” in this Volume.

Organic-Matrix Composite Applications

Based on their high-performance properties, reduced-cost manufacturing methods, and the higher level of confidence among users, the use of OMC materials has expanded greatly since the mid-1980s. These applications are well documented in the “Applications and Experience” Section of this Volume (see, for example, the articles “Automotive Applications,” “Space Applications,” “Sports and Recreation Equipment Applications,” and “Civil Infrastructure Applications”), as well as in other sources (Ref 7). High-performance composites were borne of the need for extremely high-performance aircraft structures during the days of the Cold War. The military aerospace markets still constitute a major user of the higher-end performance materials. For example, the B-2 bomber, F-22 fighter, Joint Strike Fighter, F-18E/ F aircraft, Eurofighter, Gripen aircraft, and Rafale aircraft in production, on the books, or in prototype form are all constructed using high percentages of OMCs. Current-production helicopters are now largely composite. On the commercial side, OMCs constitute a significant portion of the new large Boeing 777 and planned Airbus jumbo A380, which reportedly will contain the first carbon fiber wing center secton in a large commercial aircraft, in addition to extensive, OMC use in tail surfaces, bulkheads, and fuselage keel and floor beams), as well as intermediate-sized transport aircraft and business jets, and they are prevalent in many small commercial and homebuilt aircraft. Space applications for OMCs have flourished, from satellite structures (where low CTE, in addition to low weight, is a major advantage of OMCs) to the use of OMCs in booster fairings, shrouds, and tanks. The maturity of high-temperature OMC structures has afforded the use of OMCs in many engine applications for both air and space vehicles.

The sports and recreation market continues to be one of the primary consumers of composite raw materials. Golf clubs, bicycles, snowboards, water skis, tennis rackets, hockey sticks, and so on— the list of consumer products now produced using OMCs is extensive and commonplace. On the marine side, the consumer use of fiberglass OMCs in low- to high-end boats is the norm. Military ships have seen several applications of OMCs, primarily topside structures and minesweepers. Carbon-fiber composites can be seen in high-performance engine-powered, sail- powered, and human-powered racing boats.

A potentially huge market exists for composite materials in the upgrading of the infrastructure needs. For example, 31% of the highway bridges in the United States are categorized as structurally deficient. To address this, many activities are underway at national, state, and local levels to use composites to repair and, in some cases, replace deficient bridges. Figure 4 shows an example of an all-fiberglass bridge being installed in Butler County, Ohio. This bridge is fully instrumented to detect structural performance loss. At the time of this writing, the bridge has almost four years of service with, almost no maintenance required. Composites have also been used for seismic enhancement of existing highways and bridges.

Fig. 4 All-composite bridge in Butler County, Ohio. Factory-constructed primarily using glass fiber, the bridge was trucked to the site and installed in less than one day.

Land vehicles have also benefited greatly from the application of OMCs. Military armored vehicles have been demonstrated that offer ballistic protection of their occupants in addition to light weight. The demand for energy-efficient and low-maintenance vehicles has spurred composites use in advanced automobile, truck, bus, and train commercial products. Production parts include everything from small linkage assemblies to very large exterior structural panels.

Rounding out the OMC application discussion are a host of products. For example, the medical industry has applied OMCs to products ranging from implanted orthopedic devices to x-ray tables and lightweight assistance devices. (An example is shown in Fig. 5). Industrial applications include electronic housings, large rollers, tanks, robotic arms, and so on. Spoolable piping for oil wells allows deeper wells due to the increased strength and reduced “hang weight” of composite tubular products. In short, the development and use of OMCs were initially spurred by early investments based on military need, and, based on those successes, have now dramatically taken off in the private sector, based solely on their commercial merits.

Fig. 5 Carbon/epoxy composite crutch. This crutch is stronger than its aluminum counterpart yet weighs 50% less, is quieter, and is more aesthetically pleasing.

Metal-Matrix Composite Applications

In 1999, the MMC world market amounted to over 2.5×10^6 kg (2500 metric tons). While this is hardly remarkable relative to production volumes of more historical structural materials, it certainly illustrates that MMCs are no longer a marginal technology and have passed the threshold into a self-sufficient materials technology. This is also clearly demonstrated by the number of functions and the wide range of applications that are satisfied by MMCs. In this subsection, instructive selected applications are briefly presented in each of the major existing markets to illustrate the breadth and impact of current applications and to highlight application trends. This introduction is by no means exhaustive, and more detailed information is provided in the Section “Applications and Experience”; in particular, see the articles “Automotive Applications of Metal-Matrix Composites” and “Aeronautical Applications of Metal-Matrix Composites” and in other information sources cited in this Volume. Some of the subsequent information was taken from a recent market analysis of MMCs (Ref 4).

Ground Transportation/Automotive. The ground transportation industry (automotive and rail) accounted for 62% of the total MMC world market by volume in 1999. However, the high production rates and imperative emphasis on low cost resulted in a surprisingly low total market share by value—only 7%! By far the single most prevalent composite used in this sector is DRA. The most common application strategy is to displace components made of cast iron or steel, maximizing weight reductions. However, replacement of steel based simply on reduced weight is clearly an inadequate motivation for the use of DRA; otherwise most of an automobile structure would be displaced. Therefore, components are targeted where other benefits besides simple weight reduction are possible, so that the additional cost of insertion can be justified. Selected applications that illustrate the additional benefits obtained by the use of MMCs are provided subsequently.

A selectively reinforced piston head was introduced by Toyota Motor Manufacturing in 1983. Produced by squeeze casting, this was a reasonably low-cost and high-rate production process. The reinforcements provided improved wear

resistance and lower thermal conductivity, so that more of the heat generated by the combustion gases was available for producing work. Further, the MMC provided a lower CTE than unreinforced aluminum, so that tighter tolerances and hence, higher pressure and better performance were obtained. Squeeze-cast piston liners have been used in the Honda Prelude since 1990, displacing cast iron inserts (Fig. 6). In a novel manufacturing process, the engine block casting and piston liner preform infiltration are performed simultaneously, eliminating the cost of assembly associated with the cast iron inserts. More importantly, the MMC liners provided improved wear resistance, so that the overall liner thickness could be reduced. This yielded an increase in engine displacement, so that more horsepower is obtained from the same overall powerplant weight and volume. Finally, the thermal conductivity of the MMC is much higher than the cast iron liner, so that the operating temperature is decreased, resulting in extended engine life.

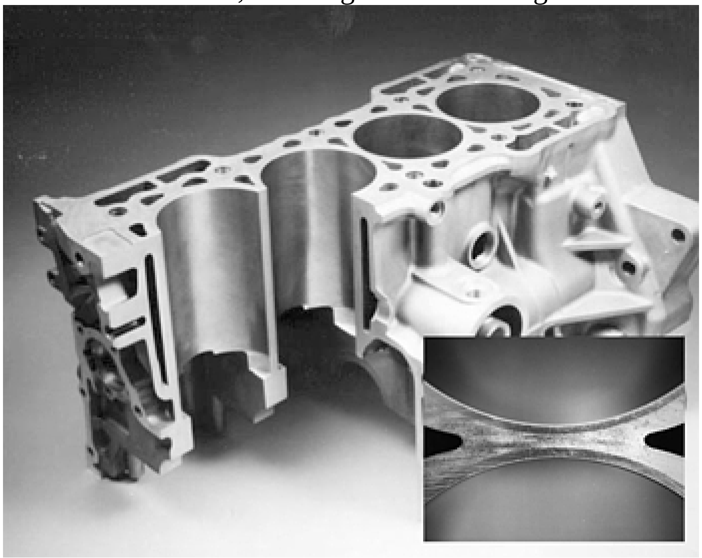

Fig. 6 Cutaway section of the Honda Prelude 2000 cc cast aluminum engine block with integral MMC piston liners. A cross section of the MMC liners is shown in the inset. These piston liners have been in production since 1990.

Automotive driveshafts represent a component application motivated primarily by structural properties. Driveshaft design is limited by rotational instability, which is controlled by the specific stiffness of the driveshaft material. The higher specific stiffness of DRA relative to steel or aluminum allows a longer driveshaft of a given diameter. This is important in trucks and large passenger cars, where two-piece metal driveshafts are often used. Replacement with DRA allows a single-piece driveshaft. Not only is significant weight saved as a result of material substitution, but elimination of the central support for the two-piece unit provides additional weight savings. Finally, MMC driveshafts require less counterweight mass compared to steel. In all, as much as 9 kg (20 lb) have been saved by this application. Metal-matrix composite driveshafts were first introduced in the Chevrolet S-10 and GMC Sonoma in 1996, and have been used in the Chevrolet Corvette beginning in 1997. In 1999, Ford Motor Company introduced MMC driveshafts in the "Police Interceptor" version of the Crown Victoria.

Other significant MMC components include automotive and rail brake components, DRA snow tire studs, and DRTi automotive intake and exhaust valves in the Toyota Altezza. Additional information is provided in the article "Automotive Applications of Metal-Matrix Composites" in this Volume.

Thermal Management and Electronic Packaging. Materials for thermal management and electronic packaging requre high thermal conductivity to dissipate large, localized heat loads, and a controlled CTE to minimize thermal stresses with semiconductor and ceramic baseplate materials. Previous preferred materials include Kovar, an Fe-Ni-Co alloy with 17% Co, and copper MMCs reinforced with molybdenum or tungsten to lower the CTE. Copper-MMCs reinforced with graphite or diamond have been developed, but are less frequently used. A beryllium/beryllium oxide MMC is sometimes used where weight is most critical, but cost and health concerns limit this application. Aluminum MMCs with 55 to 70% SiC are now widely used for thermal management applications.

Aluminum MMCs, such as DRA, provide better performance (higher thermal conductivity) relative to previous preferred materials. For example, DRA has a thermal conductivity that is nearly ten times higher than Kovar and up to 20% higher than copper-molybdenum and copper-tungsten MMCs. Discontinuously reinforced aluminum provides a dramatic weight reduction, 65 to 80% relative to copper-molybdenum and copper-tungsten, providing an important functional benefit for aerospace components and a significant commercial advantage for portable electronics, such as laptop computers and cellular telephones. Finally, processing innovations yield significant cost reductions for DRA components. Net shape processing reduces machining, which is difficult and costly for Kovar and copper MMCs reinforced with molybdenum or tungsten, and enables integration of the infiltration step with bonding to ceramic baseplate and incorporation of wire feed-throughs, resulting in fewer processing steps. Together, these provide cost savings of up to 65%.

Unlike the automotive market, MMCs for the electronic packaging sector are high value- added. Although this is the second-largest MMC market in terms of volume (26.5%), it is by far the largest in terms of value (66%) (Ref 4). Current applications of MMCs include radio frequency packaging for microwave transmitters in commercial low-earth orbit communications satellites (Fig. 7) and for power semiconductors in geosynchronous earth orbit. Metal-matrix composites are also used as power semiconductor baseplates for electric motor controllers and for power conversion in cell phone ground station transmitting towers. Finally, MMCs are being more widely used as thermal management materials for commercial flip-chip packaging of computer chips. Additional details are provided in the article “Thermal Management and Electronic Packaging Applications” in this Volume.

Aerospace. Several DRA applications emerged in the early 1990s as a result of defense investment in the United States. The ventral fin on the F-16 aircraft was experiencing a high incidence of failure as a result of unanticipated turbulence. Of the several materials and design options considered, DRA sheet was chosen as the best overall alternative. The higher specific strength and stiffness, good supportability, and affordability were considerations in the final selection of DRA. As a result of the successful experience with DRA in this application, the F- 16 project office selected DRA to solve a cracking problem of the fuselage at the corners of fuel access doors. Again, the mechanical properties of DRA and retention of the same form, fit, and function led to the selection of DRA as the final solution. Discontinuously reinforced aluminum was also qualified and entered service in a commercial gas turbine application (fan exit guide vanes) as a result of this program. Discontinuously reinforced aluminum double-hollow extrusions replaced solid graphite/epoxy to resolve an issue with poor erosion and ballistic impact response. Discontinuously reinforced aluminum also resulted in a cost savings to the manufacturer of well over $100 million.

Continuously reinforced titanium-matrix composites (TMCs) are bill of material for nozzle actuator piston rods for the Pratt and Whitney F119 engine in the F-22. Specific strength and specific stiffness, along with good fatigue response at a maximum operating temperature of 450 °C (850 °F), are the requirements. The hollow TMC rod replaced a solid rod of precipitation-hardened stainless steel and has resulted in a direct weight savings of 3.4 kg (7.5 lb) per aircraft. This is the first aerospace application of TMC materials. Following the successful specification of TMCs for this part, TMCs are now specified for nozzle actuator links in the General Electric F110 engine for the F-16 aircraft. Additional details for each of these applications are provided in the article “Aeronautical Applications of Metal-Matrix Composites” in this Volume.

Industrial, Recreational, and Infrastructure. Metal-matrix composites are used for a range of applications in these sectors, including DRA for bicycle frames and iron-based MMCs reinforced with TiC (Ferro-TiC, Alloy Technology International, Inc.) for wear-resistant tool and die coatings and industrial rollers. A continuously reinforced aluminum MMC produced by 3M is being used in high-performance automotive applications and has completed certification testing for overhead power transmission conductors (Ref 4). Steel cable is typically used as the core for “high-tension” power conductors. The steel bears the weight of the aluminum conductor, but carries little of the current, due to a low electrical conductivity (only one-eighth that of aluminum). Depending on the specifics of the transmission installation, the conductor can heat to temperatures in excess of 200 °C (400 °F) during peak use. In regions of the world such as Japan, the conductors can operate above 200 °C (400 °F) under continuous use and as high as 240 °C (460 °F) or more during peak loads. Sagging due to thermal expansion is an issue. The important properties for conductor cores are specific strength, electrical conductivity, CTE, high- temperature capabilities, and cost. Increased demand for electricity and the impact of deregulation requires utility companies to consider means for increasing the ampacity (i.e., the maximum current flow in the line). Higher ampacity produces higher conductor temperatures, resulting in line sagging that requires significant tower modifications to maintain needed line clearance. Tower construction is the major cost associated with new or increased power transmission and includes considerations such as purchasing right of way, satisfying environmental impacts, and design and construction costs. The ability to avoid the costs associated with tower

construction provides the opportunity for new conductor materials. The aluminum MMC conductor provides the strength of steel cable at less than half the density. More importantly, the MMC conductor carries four times more current than steel and has a CTE one-half that of steel. Although the aluminum MMC conductor is more expensive than conventional conductors on a unit- length basis, the ampacity gains are significant, with projected increases of 200 to 300% with no tower modifications required. Thus, at a system level, the use of MMC conductors may provide an attractive cost savings. A cross section of a conductor with an aluminum MMC core is shown in Fig. 8.

Fig. 8 Cross section of an electrical conductor for power transmission. The core consists of 19 individual wires made from a continuously reinforced aluminum MMC produced by 3M. The MMC core supports the load for the 54 aluminum wires and also carries a significant current, unlike competing steel cores. Courtesy of 3M

An aluminum MMC reinforced with boron carbide particulates is now being used for nuclear waste storage casks. The casks must meet stringent requirements for both transportation and long-term storage. The MMC is used as a liner for a carbon-steel outer container. The required neutron-absorbing capabilities are provided by the B_{10} isotope in boron carbide. Each cask uses 2.3 tonnes (2.5 tons) of aluminum-boron carbide MMC, and the first cask was delivered in 2000.

Summary. A number of insights are available regarding the application of MMCs discussed previously. The initial motivation for the application of MMCs typically comes from improved performance, such as lighter weight from better specific structural properties, improved thermal conductivity, or better wear resistance. In addition, pressures imposed by legislative, economic, or environmental concerns often play an important role. Examples include legislated financial penalties for failure to comply with corporate average fuel economy requirements for lighter, more fuel-efficient automobiles, regulatory requirements for nuclear storage, and environmental impact from the construction of towers for new overhead power conductors. Of course in every case, cost is a primary selection criterion. Although MMCs are almost always more expensive on a per-pound basis relative to the material displaced, an overall cost reduction is often a result of several considerations. Novel or simplified processing reduces costs and can eliminate steps, resulting in a cheaper component. Life cycle considerations (reduced repair frequency, higher reliability, longer life) further enhance the cost comparison. Finally, system- level benefits are sometimes obtained, such as increased engine displacement for MMC cylinder liners or reduced tolerances for MMC pistons, which further extend the payoff. The multifunctionality offered by MMCs greatly aids in obtaining these additional benefits.

The first successful entry of MMCs into a system is the most difficult. This reflects the lack of designer familiarity with MMCs. However, additional applications often follow the first use, as designer familiarity and confidence grows. These follow-on applications may be within the same system or company, but can also be from a competitor. Examples include

the fuel access doors, which followed the ventral fin for the F- 16, and specification of DRA driveshafts in Chevrolet trucks, followed by use in the Chevrolet Corvette, and then insertion in the Ford Crown Victoria.

Unlike the paradigm during the Cold War era, the first applications of MMCs have, by and large, come from the commercial sector. Both high-volume/low-cost and low-volume/high value-added technologies have been successfully pursued for MMCs. This has provided the incentive for establishing the technology base for further expansion.

Ceramic-Matrix Composite Applications

Ceramic-matrix composites have successfully entered service as exhaust nozzle flaps and seals in the F414 engine, now used in the Navy F- 18 E/F (Fig. 9). The exhaust temperature of the F414 is over 80 °C (145 °F) higher than for the F404 engine used in the previous version of the F-18. As a result, the metal flaps and seals were failing in tens of hours. The CMC parts consist of a Nicalon (Dow Corning Corp.) fiber with an inhibited carbon matrix. A thick SiC overcoat and glaze provide protection from oxidation. There are 12 flaps and 12 seals per engine, and the seals are attached to metal backing plates with metal rivets and a zirconia overcoat. The seals are subjected to the highest temperatures, and the flaps must support the largest mechanical loads. Further, the flaps must survive a high thermal gradient, and the CMC is subjected to rubbing with the back face of the seal. Insertion of the CMC flaps and seals has produced a weight savings of nearly 1 kg (2 lb) per engine relative to the metal parts. Because this mass is at the very back of the aircraft, additional weight savings can be obtained by removing ballast to shift the center of gravity of the aircraft. The CMC flaps have a useful life that is at least double the design requirement of 500 hours.

Fig. 9 Exhaust nozzle of an F414 engine on an F-18 E/F aircraft, showing the twelve sets of CMC flaps and seals. The white areas on the seals are a zirconia overcoat for mechanical fasteners. Over an order-of-magnitude increase in life has been obtained with the CMC flaps and seals.

Ceramic-matrix composites are now also commercially available as brake rotors for automobiles. Short carbon fibers and carbon powder are pressed and sintered into a porous green compact, which is then easily machined to shape. This part is then reheated and infiltrated with molten silicon, which reacts with the carbon to form SiC. The resulting disc is 50% lighter than conventional discs, yielding a 20 kg (44 lb) weight saving in the Porsche 911 Turbo. Since the rotor weight is unsprung, improved handling also results. The wear rate is half that of conventional metal rotors, and a service life of 300,000 km (185,000 miles) is reported. The new Porsche braking system uses an MMC brake pad. Ceramic-matrix composite brake rotors have also been demonstrated for the Inter-City Express high-speed trains in Germany, where a total weight savings of 5.5 metric tons is obtained per trainset.

View of the Future

A conservative view has been taken in this Volume, which emphasizes current technologies and known applications. Growth in the volume, applications, value, and impact of composites technologies is expected as a result of the natural growth of many of the existing applications. Infrastructure applications of OMCs and both automotive and thermal management components for MMCs typify this expected growth. However, there are also many composites applications in new uses and representing new technologies that are now on the verge of certification. In addition, robust research and development over the coming years is expected to provide entirely new composite materials options, opening up entirely new markets. In the closing part of this article, the prognosis for each of these possibilities is briefly discussed.

Organic-Matrix Composites. Without a doubt, military requirements fueled investments in the development of advanced composites from the 1940s through the end of the Cold War (around 1990). Since that time, however, Department of Defense requirements for advanced composites have begun to represent only a small portion of the total amount of OMCs used by all markets combined. As discussed previously, the rise in the use of OMCs in transportation, recreation, infrastructure, and industrial applications is fully expected to continue to increase. Current active research areas provide some insight into OMC technologies that will mature to practical application in both the short and long term. These future directions can be broken down into three areas: materials and processing advances, advances in structural concepts, and progress in design and certification.

Development of polymers that can withstand sustained use in realistic service environments of both moisture and high temperatures (exceeding 370 °C, or 700 °F) is expected to allow for the increased use of PMCs in hot structural areas. Current research into nanophase reinforcements, essentially third-phase reinforcements, has already shown some progress on this front. Processing of OMCs is also evolving. For example, research into the use of electron beam curing shows promise of being able to cure large structures less expensively than by using traditional autoclaves. In terms of advanced structural concepts, the highly anisotropic nature of OMCs has only begun to be exploited. Current structures often appear similar to traditional isotropic metallic ones (for example, orthogonal rib/stringer designs), in which OMCs are used primarily for their light weight and high stiffness and strength. To fully use the high-fiber properties, unconventional three-dimensional structural architectures are being explored. In addition, research into "multifunctional" materials and structures is being pursued. Examples include structures that serve thermal management, self- or external assessment, self-repair, and self-actuation functions. (An example of this would be the use of active embedded layers for vibration damping in helicopter rotor blades.)

The current aerospace structural design process relies on a "building-block" approach. This approach has served the military well, as is evidenced by the large weight savings provided by OMCs, while the number of structural failures has been negligible. However, this approach requires, for example, large statistical databases of materials properties to be established early in the structural design cycle. This leaves little flexibility for large, real-time changes in the structure to optimize design and minimize cost. As the fidelity, validation, and integration of analytical models (micromechanical through structural) increases, ultimately it is believed that structures can be designed and "tested" almost entirely analytically. This would dramatically shorten the design cycle and allow for the exploration of vast numbers of design concepts, all at very low cost. The expensive experimental testing, although probably always required to some extent, will be dramatically reduced.

Metal-Matrix Composites. For MMCs, a conservative annual market growth rate of between 15 to 20% has been projected through 2004 (Ref 4). This will be led by the ground transportation industry (automotive and rail), and in the high value-added thermal management and electronic packaging sector. Additional applications are expected to result from increased experience and confidence in MMCs, based on prior use and on natural market growth. The growth in the automotive and rail industry is expected from increasing pressure for light weight, fuel economy, and reliability. In the thermal management and electronic packaging industry, increased MMC use will result from the dramatic growth in this industry for new networking and wireless communications installations. The largest market by far, and the largest projected growth, is for DRA, which is expected to double in production volume between 1999 and 2004 (Ref 4).

This growth is anticipated from existing technologies and applications. However, significant new applications and markets are being pursued vigorously for MMC technologies that are now on the verge of widespread acceptance. A notable example is the relatively low-cost continuously reinforced aluminum MMC produced by 3M. Significant progress has been achieved in the last two years toward the acceptance of this material for overhead power transmission conductors (high tension wires), as briefly discussed previously. This application,

if successful, will represent a dramatic increase in the worldwide MMC market and may be nearly equal to the entire annual volume of the ground transportation market. The simple, flexible material form (wire and tape) is amenable to use in a wide range of other applications. The uniaxial configuration is ideal for hoop and tube or rod configurations, and it can easily be used as an insert for selective reinforcement of components. Many potential applications are currently being pursued, including flywheel containment, high- speed electric motors, and high-performance automotive components. A novel process using the tape preform is being pursued to produce large cryogen tanks for rocket propulsion, paving the way for building large structures from a simple-to-manufacture material form.

In the farther term, technology innovations leading to new and significantly improved MMC materials can be expected as a result of the robust international activity in MMC research and development. Two examples are DRA for elevated- temperature use and aerospace-grade DRTi. Titanium alloys are specified in many applications, especially aerospace, where the use temperature exceeds the current limit for aluminum alloys, about 150 °C (300 °F). The titanium is more expensive, more difficult to machine, and heavier, yet is required to support the use temperature. A modest increase in use temperature, to about 200 °C (400 °F), will provide the opportunity to replace many aerospace components currently made of titanium with an aluminum material. Discontinuously reinforced titanium shows very attractive structural properties (Fig. 3) and is currently used commercially in automotive valves for the Toyota Altezza (Ref 9). However, the approaches taken to ensure that cost goals were met are incompatible with aerospace requirements. Research and development of DRTi for aerospace applications show that this MMC has the potential of exceeding the structural efficiency of all metallic materials, and of cross-plied graphite/epoxy. While initial volumes are not expected to be large, the promise afforded by this material and other advanced MMC technologies makes the future bright for MMCs.

Constituent Material Forms

For the engineer, knowledge of the constituent material properties and understanding of the origins of those properties is important for the task of defining a composite structure for a particular application. This knowledge is needed to understand how that structure will respond to an imposed load or stimulus under a set of conditions. Often, fiber properties are the most important with respect to composite performance, as in the properties of tensile strength and stiffness of a unidirectional composite in the fiber direction. However, other aspects of composite performance depend more strongly on matrix properties, such as the maximum upper-use

temperature and interlaminar shear properties. In other cases, the fiber and matrix sometimes contribute to the composite response in direct proportion to their respective volume fractions (e.g., composite dielectric constant and moisture absorption). And finally, there are countless documented examples where performance is determined by the (complex) interaction between the fibers and the matrix, a topic discussed in the article “Interfaces and Interphases.”

Fortunately for the composites engineer, a wide variety of high-performance fibers and resins are commercially available, affording unprecedented flexibility and latitude in structural design. The most commonly used constituent materials include fibers of glass, carbon, and aramid, followed by various high-temperature ceramics. In addition, a host of polymeric resins are used, as well as metallic alloys and even ceramics. However, the constituent materials continue to evolve, as evidenced by the recent introduction of carbon nanotubes and nanofibers, as well as new varieties of carbon fiber and high- temperature ceramic fibers. On the matrix side, resins continue to improve through modified formulations and the introduction of fillers, such as silicate-based nanoclay particles (added to produce nanocomposites) and toughening agents, both of which result in enhanced performance.

Fibers. A general introduction to and comparison of the most significant fiber types is provided in the article “Introduction to Reinforcing Fibers.” At the time of publication, the most widely used, economical reinforcement in polymer-matrix composites is E-glass fiber. When higher stiffness and strength are required, carbon fibers and aramid fibers are employed. There are a wide variety of carbon fibers, differing primarily in the degree of graphitization, which affects modulus and strength, and the number of fibers per tow. Recent years have seen the price of certain types of carbon fiber plummet to the $10/kg ($5/lb) range, opening the door to a wide variety of commercial/industrial applications that were previously cost-prohibitive. Ceramic fibers based on alumina, alumina-silica, and silicon carbide are used to reinforce metallic alloys and ceramics, and in some cases, to reinforce polymers where unique physical properties are required, such as low dielectric constants or infrared transparency. Improvements to fiber performance and reductions in fiber cost will greatly change the way in which composites are used, and expand the use of composites beyond aerospace and sporting goods and into other sectors of industry.

Matrix Materials. The polymer matrix resins considered in this Section include both thermosetting and thermoplastic types, with emphasis on the former because they account for more than 80% of all matrices in reinforced plastics and essentially all matrices used in advanced composites. The most widely used thermosetting resins are the polyesters, which are most often combined with E-glass. This combination accounts for the bulk of the fiber-reinforced plastics (FRP) market. Polyesters offer a combination of low cost, versatility in many processes, and reasonably good property performance unmatched by any other resin type. The most common orthophthalic types and the premium isophthalic types, bisphenol A fumarate, chloendic, and vinyl ester, are discussed in this Section.

For more demanding structural uses, epoxy resins are the preferred candidates. Although the amount of epoxies used in reinforced plastics is small in comparison to the volume of polyester used, epoxy use dominates the more demanding aircraft/aerospace structural applications. Epoxy resins are of particular interest to structural engineers because they provide a unique balance of chemical and mechanical properties combined with extreme processing versatility. Epoxy resin performance is highly dependent on the formulation, which includes the base resin, curatives, and the modifiers. A practical introduction to these basic formulary components and epoxy- resin selection is provided in this Section.

Several high-temperature polymeric matrices are also covered, including cyanate ester, polyimide, and bismaleimide resins. These tend to be more expensive resin systems, and are employed in applications where the high-temperature performance justifies the additional cost. Cyanate esters, or polycyanurates, bridge the gap in thermal performance between engineering epoxy resins and high-temperature polyimides. Polyimide resins are used when optimum thermal stability at high temperature is required. Although polyimides may be thermosetting or thermoplastic, most composite applications use the thermosetting types, which are fully covered in this Section. The addition-type bismaleimide (BMI) resins are also covered in this Section.

The use of high-performance thermoplastics as matrices in continuous fiber reinforced composites is currently an area characterized by very low use but very high interest. This Section addresses continuous fiber reinforced thermoplastics. The focus is on materials suitable for fabrication of structural laminates such as might be used for aerospace.

The Section also includes articles that address metallic, ceramic, and carbon matrices, including the distinct advantages and limitations of these materials.

Intermediate Material Forms. Also covered in this Section are some of the intermediate material forms available for composite fabrication. These are often used as components that are joined with other components and assembled into a structure, and/or as ways of arranging and controlling the fiber architecture. Examples include sandwich core materials, fabrics and preforms, fiber mats, and braids. While the coverage is not comprehensive, the articles offer the engineer a shopping list that complements the Sections in this Volume that focus on design, manufacturing, and material properties. A key advantage of working with composite materials is the opportunity to integrate material properties, design, and manufacturing technique so that the end product—a completed structure—is optimized from both a performance and an economics standpoint.

Selection Factors

The individual articles within this Section are written to give an understanding of the composite raw materials available today and how they are processed. Because there is a great deal of flexibility in the manufacture of composite material forms, engineers and designers are encouraged to be creative when selecting a particular material form. If a particular form fits a particular design and manufacturing technique but is not listed here, engineers and designers are encouraged to ask for what they want.

Most of the forms listed are the result of such requests. For example, the tow sizes available for glass and carbon fibers resulted from particular needs. In the first case, large bundles of glass were needed to feed choppers to make sheet molding compounds. After the request was made and the potential market was found to be significant, large multiple-strand bundles in center-pull packages were developed. In the case of carbon fibers, the need for woven fabrics to form complex shapes brought a request for smaller tows. The resulting 1000, 3000, and 6000 (1, 3, and 6K) filament tows are now used to produce woven goods. More recently, the need for lower- cost carbon fiber for commercial/industrial applications led to the availability of much larger tows (48K to >200K). Similar examples can be cited for prepreg tape width, resin content, and thickness. Thus, constituent raw material forms can be adjusted to meet evolving requirements.

An all-important factor in material selection is cost, an area where composites historically have not fared well. However, recent declines in carbon fiber prices, coupled with improvements in low-cost manufacturing methods and continued demand for high structural efficiencies have begun to change the reputation of composites. As composites begin to compete with traditional low-cost materials, material cost will continue to be an important factor. Some guidelines to keep in mind are:

- *Fiber:* the greater the number of filaments per tow, the lower the cost
- *Resin:* the lower the performance temperature, the lower the cost
- *Prepreg:* the wider the product (tape or fabric), the lower the cost

The proper selection of constituent materials and material form to fit the structural application and the process design is critical to the success of the endeavor. Adding performance almost always adds cost, and cost savings generally begin with material selection.

Introduction to Constituent Materials

Steven R. Nutt, University of Southern California

Introduction

THIS SECTION describes the major matrix resins and reinforcing fibers used in composite materials, as well as some of the intermediate material forms available for composite fabrication. The Section begins with articles that provide coverage of the various fibers and matrices used in composites, including their structure, chemistry, and properties.

Steven R. Nutt, University of Southern California

Constituent Material Forms

For the engineer, knowledge of the constituent material properties and understanding of the origins of those properties is important for the task of defining a composite structure for a particular application. This knowledge is needed to understand how that structure will respond to an imposed load or stimulus under a set of conditions. Often, fiber properties are the most important with respect to composite performance, as in the properties of tensile strength and stiffness of a unidirectional composite in the fiber direction. However, other aspects of composite performance depend more strongly on matrix properties, such as the maximum upper-use temperature and interlaminar shear properties. In other cases, the fiber and matrix sometimes contribute to the composite response in direct proportion to their respective volume fractions (e.g., composite dielectric constant and moisture absorption). And finally, there are countless documented examples where performance is determined by the (complex) interaction between the fibers and the matrix, a topic discussed in the article “Interfaces and Interphases.”

Fortunately for the composites engineer, a wide variety of high-performance fibers and resins are commercially available, affording unprecedented flexibility and latitude in structural design. The most commonly used constituent materials include fibers of glass, carbon, and aramid, followed by various high-temperature ceramics. In addition, a host of polymeric resins are used, as well as metallic alloys and even ceramics. However, the constituent materials continue to evolve, as evidenced by the recent introduction of carbon nanotubes and nanofibers, as well as new varieties of carbon fiber and high- temperature ceramic fibers. On the matrix side, resins continue to improve through modified formulations and the introduction of fillers, such as silicate-based nanoclay particles (added to produce nanocomposites) and toughening agents, both of which result in enhanced performance.

Fibers. A general introduction to and comparison of the most significant fiber types is provided in the article “Introduction to Reinforcing Fibers.” At the time of publication, the most widely used, economical reinforcement in polymer-matrix composites is E-glass fiber. When higher stiffness and strength are required, carbon fibers and aramid fibers are employed. There are a wide variety of carbon fibers, differing primarily in the degree of graphitization, which affects modulus and strength, and the number of fibers per tow. Recent years have seen the price of certain types of carbon fiber plummet to the $10/kg ($5/lb) range, opening the door to a wide variety of commercial/industrial applications that were previously cost-prohibitive. Ceramic fibers based on alumina, alumina-silica, and silicon carbide are used to reinforce metallic alloys and ceramics, and in some cases, to reinforce polymers where unique physical properties are required, such as low dielectric constants or infrared transparency. Improvements to fiber performance and reductions in fiber cost will greatly change the way in which composites are used, and expand the use of composites beyond aerospace and sporting goods and into other sectors of industry.

Matrix Materials. The polymer matrix resins considered in this Section include both thermosetting and thermoplastic types, with emphasis on the former because they account for more than 80% of all matrices in reinforced plastics and essentially all matrices used in advanced composites. The most widely used thermosetting resins are the polyesters, which are most often combined with E-glass. This combination accounts for the bulk of the fiber-reinforced plastics (FRP) market. Polyesters offer a combination of low cost, versatility in many processes, and reasonably good property performance unmatched by any other resin type. The most common orthophthalic types and the premium isophthalic types, bisphenol A fumarate, chloendic, and vinyl ester, are discussed in this Section.

For more demanding structural uses, epoxy resins are the preferred candidates. Although the amount of epoxies used in reinforced plastics is small in comparison to the volume of polyester used, epoxy use dominates the more demanding aircraft/aerospace structural applications. Epoxy resins are of particular interest to structural engineers because they provide a unique balance of chemical and mechanical properties combined with extreme processing versatility. Epoxy resin performance is highly dependent on the formulation, which includes the base resin, curatives, and the modifiers. A practical introduction to these basic formulary components and epoxy- resin selection is provided in this Section.

Several high-temperature polymeric matrices are also covered, including cyanate ester, polyimide, and bismaleimide resins. These tend to be more expensive resin systems, and are employed in applications where the high-temperature performance justifies the additional cost. Cyanate esters, or polycyanurates, bridge the gap in thermal performance between engineering epoxy resins and high-temperature polyimides. Polyimide resins are used when optimum thermal stability at high temperature is required. Although polyimides may be thermosetting or thermoplastic, most composite applications use the thermosetting types, which are fully covered in this Section. The addition-type bismaleimide (BMI) resins are also covered in this Section.

The use of high-performance thermoplastics as matrices in continuous fiber reinforced composites is currently an area characterized by very low use but very high interest. This Section addresses continuous fiber reinforced thermoplastics. The focus is on materials suitable for fabrication of structural laminates such as might be used for aerospace.

The Section also includes articles that address metallic, ceramic, and carbon matrices, including the distinct advantages and limitations of these materials.

Intermediate Material Forms. Also covered in this Section are some of the intermediate material forms available for composite fabrication. Introduction to Reinforcing Fibers

Frederick T. Wallenberger, PPG Industries, Inc.

Introduction

REINFORCING FIBERS are a key component of polymer-matrix composites (PMCs), ceramic-matrix composites (CMCs), and metal- matrix composites (MMCs). They impart high strength and stiffness to the matrix material that they modify, and in addition, may offer other valuable properties such as low dielectric constant, high temperature resistance, or high creep resistance. Depending on the design requirements, it is possible to select an appropriate composite-reinforcing fiber to manufacture a commercial composite part having high value-in-use. The composite will achieve the desired property values for a specific or generic application at a reasonable cost, even though the cost of the fibers themselves may appear high (Ref 1).

Reference cited in this section

1. F.T. Wallenberger, *Advanced Inorganic Fibers—Processes, Structures, Properties, Applications*, Kluwer Academic Publishers, Dordrecht, the Netherlands, 1999

Overview

Composite-reinforcing fibers can be categorized by chemical composition, structural morphology, and commercial function. Natural fibers such as kenaf or jute are derived from plants and are used almost exclusively in PMCs. Oxide glass fibers (Ref 2) are derived from a mixture of oxides; silica, or quartz, fibers are from a single oxide. They are amorphous and primarily used to reinforce thermoplastic and thermoset PMCs. Aramid fibers (Ref 3) are crystalline polymer fibers and mostly used to reinforce PMCs. Carbon fibers (Ref 3) are based on ordered planar structures; they are primarily used to reinforce PMCs. Ceramic fibers are polycrystalline. Oxide ceramic (e.g., silica-alumina and pure alumina) fibers and nonoxide ceramic (e.g., silicon carbide) fibers (Ref 4) are used to reinforce CMCs and MMCs (Ref 5).
Value-in-Use. In a PMC, the primary function of a reinforcing fiber is to increase the strength and stiffness of a matrix material so that the resulting part can satisfy the design requirements or replace an existing part at equal strength, stiffness, and lower weight. In a CMC, the primary function of a reinforcing fiber is to facilitate the use of a given part at the highest possible ultimate-use temperature, offer superior fracture toughness, and prevent premature brittle failure. In a MMC, the primary function of a reinforcing fiber is to sustain the ultimate-use temperature of the part by preventing ductile failure. The value-in-use of a selected reinforcing fiber, whether based on a single property or on a combination of selected properties, depends on its cost as indexed to that property or combination of properties (Ref 1).
Specific Modulus and Specific Strength. Polymeric-matrix composite reinforcing fibers have adequate strength and yield adequate composite strength. Their value-in-use, therefore, depends mostly on their stiffness or elastic modulus (GPa). In transportation, aircraft, and aerospace applications, value-in-use additionally depends on their density, g/cm^3 (lb/in.^{3}), and therefore on the specific modulus. Specific properties are material properties divided by the density of the material. Specific modulus and specific strength are commonly expressed in units of length, for example, 10^6 meter (Mm). (Units of modulus or strength over density are also used. In SI units, this is Mpa · m^3/Mg. See the article "Material Property Charts" in *Materials Selection and Design,* Volume 20 of *ASM Handbook*, for example. The design engineer is cautioned to observe the units when comparing specific property data from multiple sources.) The specific modulus of PMC reinforcing fibers ranges from 25 to 437 Mm (Table 1(a), Fig. 1), thus facilitating the design of composites with vastly different part stiffness at equal weight, or with vastly lower part weight at equal stiffness.

Fiber Toughness. Toughness is the ability of a material to absorb work, which is proportional to the area under the stress-strain curve. It is the actual work per unit volume or unit mass that is required to rupture the material, so it is a measure of impact damage resistance. Some PMCs require high toughness. Amorphous reinforcing fibers, such as E-glass, S-glass, and single-crystal sapphire fibers, have high elongation at break and offer high fiber and composite toughness. Carbon fibers are typically more brittle, having lower elongation at break, and thus have lower fiber and composite toughness. Fracture toughness is the measure for damage resistance of CMCs (Ref 6).
Ultimate-Use Temperature. CMC and MMC reinforcing fibers, in contrast to PMC reinforcing fibers, have low to moderate stiffness or moduli (Fig. 1). Their function is not to stiffen an already stiff ceramic part, but to prevent brittle failure and to facilitate its use at the highest possible ultimate-use temperature of 1000 to 1400 °C (1830 to 2550 °F).
Nonmechanical Properties. Depending upon their chemical composition, PMC reinforcing fibers can offer additional value-in-use, due to their nonmechanical properties, such as electrical properties ranging from high conductivity to superior insulation. They can lower vibration transmission and thus provide quieter parts. The life cycle cost can be a greater value due to the extended life of the composite resulting from its corrosion resistance.

PMC Reinforcing Fibers

The following overview of PMC reinforcing fibers focuses on the cost-considered value-in- use of specific modulus and ultimate-use temperature of selected fibers in four fiber categories: natural fibers, oxide glass fibers, aramid fibers, and carbon and graphite fibers (Table 1(a) and Fig. 1). The individual reinforcing fibers in each category were deliberately selected to represent those commercial products that have the highest, midpoint, and lowest values, respectively, of specific modulus and of ultimate-use temperature.
Natural Plant Fibers. Kenaf, sisal, hemp, and jute are finding commercial use in automotive PMCs, where they offer adequate performance in interior composite applications (Ref 6) at a lower cost than that of comparable composites from incumbent reinforcing fibers. The density of kenaf fibers is 1.52 g/cm^3 (0.0549 lb/in.^{3}) (Table 1(a), Fig. 1) and its specific modulus of 6.0 Mm is therefore higher than that of commercial low modulus aramid fibers (5.1 Mm). Sustained use of fibers is possible at temperatures below 150 °C (300 °F).
Oxide Glass Fibers. Three types of oxide glass fiber are used as reinforcements for composites: silicate E-glass, silicate S-glass, and ultrapure silica fibers. E-glass is commercially available as a boron-containing and a boron-free variant. Owens Corning, PPG, and Vetrotex sell boron-containing E-glass. Owens Corning also sells boron-free E-glass under the trade name Advantex. S-glass is the predominant version of a group of high-strength fibers, which is sold by Owens Corning. Other high-strength fibers are R-glass, which is sold by Vetrotex, and Te-glass, which is sold by Nitto Boseki. Ultrapure silica fibers are also known as quartz fibers, despite the fact that they are amorphous and do not therefore exhibit the otherwise typical hexagonal crystal structure of quartz. An ultrapure silica fiber is sold by Vetrotex under the trade name Astroquartz.

The density of these three glass fibers increases from 2.15 g/cm^3 (0.0777 lb/in.^{3}) for silica glass fibers to 2.54 g/cm^3 (0.0918 lb/in.^{3}) for E-glass. The specific modulus, as reflected in Table 1(a) and Fig. 1, increases from 3.1 Mm for E- glass to 3.6 Mm for S-glass. This is an important property for transportation and aircraft composites. The ultimate-use temperature ranges from 500 °C (930 °F) for E-glass to 1050 °C (1920 °F) for silica/quartz glass fibers.

Aramid Fibers. Three grades of aramid fibers are known: low modulus (LM), intermediate modulus (IM), and high modulus (HM) fibers. The LM fiber is sold by Teijin under the trade name Technora T-200, the IM fiber is sold by Akzo under the trade name Twaron, and the HM fiber is sold by DuPont under the trade name Kevlar 140. The specific density increases from 1.39g/cm^3 (0.0502 lb/in.^{3}) for the LM fiber to 1.47 g/cm^3 (0.0531 lb/in.^{3}) for the HM fiber. Strength increases from 3.0 GPa (435 ksi) for the LM fiber to 3.5 GPa (510 ksi) for the HM fiber. Modulus increases from 70 GPa (10×10^6 psi) for the LM fiber to 179 GPa (26×10^6 psi) for the HM fiber. The specific modulus increases from 5.1 Mm for the LM fiber to 12.4 Mm for the HM fiber. The specific modulus of aramid fibers is an important property for aircraft composites. It is higher than that of the family of oxide glass fibers but lower than that of the family of carbon fibers. The temperature at which sustained use of aramid fibers is possible is about 160 °C (320 °F) (Ref 7).

Carbon and Graphite Fibers. Five grades of carbon fibers are known (Ref 3): standard modulus (SM), ultrahigh modulus (UHM), high modulus (HM), high tenacity-high strength (HT) or intermediate modulus (IM), and low modulus (LM) fibers. The LM fibers are fibrous carbons used as gland packing, furnace insulation, and as reinforcement to provide toughness. Three examples were selected for this overview. They represent the extreme values of strength and modulus within the wide range of fiber properties that are commercially available today. In order of increasing specific modulus, they are SM, HT, and UHM fibers. The SM fiber is sold by Zoltek under the trade name Panex, the HT fiber is sold by Toray under the trade name Torayca T1000, and the UHM fiber is sold by BP Amoco under the trade name Thornel K-100X.

The density of carbon fibers increases from 1.74 g/cm^3 (0.0629 lb/in.^{3}) for the HT fiber to 2.18 g/cm^3 (0.0788 lb/in.^{3}) for the UHM fiber. High-tenacity carbon fibers have the highest strength (7.1 GPa, or 1030 ksi) and specific strength (0.398 Mm) of any known reinforcing fiber. Ultrahigh modulus carbon fibers have the highest modulus (966 GPa, or 140×10^6 psi) and specific modulus (45.2 Mm) of any known reinforcing fiber. The ultrahigh specific modulus is an important property for aircraft and aerospace composites. Carbon fibers are electrically conductive. The temperature at which sustained use of carbon fibers is possible in oxidative environments is about 500 °C (930 °F).

CMC and MMC Reinforcing Fibers

This overview of CMC and MMC reinforcing fibers focuses primarily on the cost-considered value-in-use of the ultimate-use temperature of selected fibers in three fiber categories: metal fibers or wires, oxide ceramic fibers, and non-oxide ceramic fibers. The individual reinforcing fibers in each category were deliberately selected to represent those commercial products that have the highest, midpoint, and lowest values of specific modulus and ultimate-use temperature, respectively.

Metal Fibers or Wires. Steel, tungsten, beryllium, and other metal fibers are used (Ref 8). Due to their relatively high densities, their specific moduli are low and their reinforcing value is limited. They do offer high ultimate-use temperatures. Beryllium is a useful but toxic fiber. Steel fibers offer the lowest specific modulus (and value-in-use) among all known composite reinforcing fibers. The Brunswick Corporation sells a steel fiber under the trade name Brunsmet, as well as other metal fibers.

Oxide Ceramic Fibers. Increasing demand for fibers with a much higher ultimate-use temperature than that of oxide glass fibers has resulted in two families of ceramic fibers: oxide ceramics and non-oxide ceramics. These fibers are used in CMCs and MMCs. The 3M Company sells polycrystalline alumina and silica-alumina fibers under the trade name Nextel 610 and Nextel 720, respectively, and Saphikon sells a single-crystal alumina (sapphire) fiber under the trade name Saphikon.

The density of oxide ceramic fibers increases from 3.40 g/cm^3 (0.123 lb/in.^{3}) for Nextel 720, a polycrystalline fiber containing 85% alumina and 15% silica, to 3.96 g/cm^3 (0.143 lb/ in.^{3}) for Saphikon, a single-crystal sapphire fiber containing 100% α-alumina. Because of the high density of these fibers, their specific strength (0.063–0.090 Mm) is lower than those of carbon, aramid, non-oxide ceramic, and oxide glass fibers. It is comparable to that of steel and natural fibers. The specific modulus of ceramic oxide fibers, which increases from 7.80 Mm for Nextel 720 fibers to 12.1 Mm for sapphire fibers, is intermediate between that of carbon and aramid fibers. The temperature at which sustained use of these oxide ceramic fibers is possible is about 1200 °C (2200 °F).

Non-oxide Ceramic Fibers. Non-oxide and oxide ceramic reinforcing fibers have different properties and are aimed at different applications (Ref 4). Non-oxide fibers include polycrystalline silicon carbide and silicon nitride fibers. Ube sells a silicon carbide fiber that contains 9.8% O and 1.0% Zr under the trade name Tyranno LM. Textron sells a sheath/core fiber with a silicon carbide sheath and a carbon core under the designation SCS-6. Nippon Carbon sells a near-stoichiometric silicon carbide fiber under the trade name Hi-Nicalon-S. The properties of these fibers are shown in Table 1(a) and Fig. 1.

The density of silicon carbide fibers increases from 2.48 g/cm^3 (0.0896 lb/in.^{3}) for Tyranno ZM to 3.10 g/cm^3 (0.112 lb/in.^{3}) for Hi-Nicalon-S fibers. The specific modulus increases from 7.90 Mm for Tyranno ZM to 13.8 Mm for Hi-Nicalon-S fibers. It is comparable to that of oxide ceramic fibers. The highest temperature at which sustained use of SCS-6 and of Hi-Nicalon-S is possible is about 1400 °C (2550 °F).

Summary and Conclusions

Composite reinforcing fibers have high value- in-use in a wide range of commercial applications. Commercial glass fibers have high value- in-use in low-cost, high-volume, commodity PMCs where they offer satisfactory reinforcement at a fiber price ranging from $1.50/kg for first-quality products to $4.25/kg for multiaxial glass reinforcements. Commercial aramid, carbon, oxide ceramic and non-oxide ceramic reinforcing fibers have high value in high-cost, low-volume applications where the cost ranges from $20/kg for LM aramid and SM carbon fibers to $6,900/kg for Hi-Nicalon-S silicon carbide fibers. Commercial sapphire fibers have high value-in-use in extremely costly specialty applications where they offer otherwise unattainable reinforcing properties at $66,000/kg.

Glass Fibers

Frederick T. Wallenberger, James C. Watson, and Hong Li, PPG Industries, Inc.

Introduction

GLASS FIBERS are among the most versatile industrial materials known today. They are readily produced from raw materials, which are available in virtually unlimited supply (Ref 1). All glass fibers described in this article are derived from compositions containing silica. They exhibit useful bulk properties such as hardness, transparency, resistance to chemical attack, stability, and inertness, as well as desirable fiber properties such as strength, flexibility, and stiffness (Ref 2). Glass fibers are used in the manufacture of structural composites, printed circuit boards and a wide range of special-purpose products (Ref 3).

Fiber Forming Processes. Glass melts are made by fusing (co-melting) silica with minerals, which contain the oxides needed to form a given composition. The molten mass is rapidly cooled to prevent crystallization and formed into glass fibers by a process also known as fiberization.

Nearly all continuous glass fibers are made by a direct draw process and formed by extruding molten glass through a platinum alloy bushing that may contain up to several thousand individual orifices, each being 0.793 to 3.175 mm (0.0312 to 0.125 in.) in diameter (Ref 1). While still highly viscous, the resulting fibers are rapidly drawn to a fine diameter and solidify. Typical fiber diameters range from 3 to 20 μm (118 to 787 μin.). Individual filaments are combined into multifilament strands, which are pulled by mechanical winders at velocities of up to 61 m/ s (200 ft/s) and wound onto tubes or forming packages. This is the only process that is described in detail subsequently in the present article.

The marble melt process can be used to form special-purpose, for example, high-strength fibers. In this process, the raw materials are melted, and solid glass marbles, usually 2 to 3 cm (0.8 to 1.2 in.) in diameter, are formed from the melt. The marbles are remelted (at the same or at a different location) and formed into glass fibers. Glass fibers can also be down drawn from the surface of solid preforms. Although this is the only process used for manufacturing optical fibers, which are not discussed in this Volume, it is a specialty process for manufacturing structural glass fibers such as silica or quartz glass fibers. These and other specialty processes are highlighted wherever appropriate but not discussed in full. Additional details about fiber forming are provided in the section "Glass Melting and Fiber Forming" in this article.

Sizes and Binders. Glass filaments are highly abrasive to each other (Ref 4). "Size" coatings or binders are therefore applied before the strand is gathered to minimize degradation of filament strength that would otherwise be caused by filament-to-filament abrasion. Binders provide lubrication, protection, and/or coupling. The size may be temporary, as in the form of a starch-oil emulsion that is subsequently removed by heating and replaced with a glass-to-resin coupling agent known as a finish. On the other hand, the size may be a compatible treatment that performs several necessary functions during the subsequent forming operation and which, during impregnation, acts as a coupling agent to the resin being reinforced.

Glass Fiber Types

Glass fibers fall into two categories, low-cost general-purpose fibers and premium special-purpose fibers. Over 90% of all glass fibers are general-purpose products. These fibers are known by the designation E-glass and are subject to ASTM specifications (Ref 5). The remaining glass fibers are premium special-purpose products. Many, like E-glass, have letter designations implying special properties (Ref 6). Some have tradenames, but not all are subject to ASTM specifications. Specifically:

Letter designation	Property or characteristic
E, electrical	Low electrical conductivity
S, strength	High strength
C, chemical	High chemical durability
M, modulus	High stiffness
A, alkali	High alkali or soda lime glass
D, dielectric	Low dielectric constant

Table 1 gives compositions and Table 2 gives physical and mechanical properties of commercial glass fibers.

(a) The log 3 forming temperature is the temperature of a melt at a reference viscosity of 100 Pa · s (1000 P).
Source: Ref 2, 7, 8, 9, 10, and 11

General-purpose glass fibers (E-glass variants) are discussed in the following section of this article, which provides an in-depth discussion of compositions, melt properties, fiber properties (Ref 12), methods of manufacture, and significant product types. An in-depth discussion of composite applications can be found in other articles in this Volume.

Glass fibers and fabrics are used in ever increasing varieties for a wide range of applications (Ref 13). A data book is available (Ref 14) that covers all commercially available E-glass fibers, whether employed for reinforcement, filtration, insulation, or other applications. It lists all manufacturers, their sales offices, agents, subsidiaries, and affiliates, complete with addresses, and telephone and fax numbers. And it tabulates key properties and relevant supply details of all E-glass fiber grades, that are available in the market today.

Special-Purpose Glass Fibers. S-glass, D- glass, A-glass, ECR-glass, ultrapure silica fibers, hollow fibers, and trilobal fibers are special-purpose glass fibers. Selected special-purpose glass fibers are discussed in the subsequent section of this article. That section reviews compositions, manufacture, properties, and applications to an extent commensurate with their commercial use (Ref 15).

A companion data book (Ref 16) is available that covers all commercially available high- strength glass fibers including S-glass and, all silica or quartz glass fibers, including Astroquartz and Quartzel. It also lists a wide range of woven fabrics, that are commercially available in the market of today, ranging from S-glass/aramid, S-glass/carbon, silica/aramid, and silica/ carbon yarns to silica/boron yarns. In addition, it covers all commercially available carbon, ceramic, boron, and high-temperature polymer fibers and yarns. This data book also lists all yarn counts, fabric constructions, fabric weights, and commercial sources.

ASTM Test Methods. ASTM has published standard test methods for glass density (Ref 17), alternating current loss characteristics and dielectric constant (Ref 18), direct current conductance of insulating materials (Ref 19), dielectric breakdown voltage and dielectric strength (Ref 20), softening point of glass (Ref 21), annealing point and strain point of glass by fiber elongation (Ref 22), annealing point and strain point of glass by beam bending (Ref 23), viscosity (Ref 24), liquidus temperature (Ref 25), and coefficient of linear thermal expansion of plastics (Ref 26).

Some fiber properties (Ref 4), such as tensile strength, modulus, and chemical durability, are measured on the fibers directly. Other properties, such as relative permittivity, dissipation factor, dielectric strength, volume/surface resistivities, and thermal expansion, are measured on glass that has been formed into a bulk patty or block sample and annealed (heat treated) to relieve forming stresses. Properties such as density and refractive index are measured on both fibers and bulk samples, in annealed or unannealed form.

General-Purpose Glass Fibers

Types. Two generic types of E-glass (Ref 6) are known in the market today. The incumbent E-glass contains 5 to 6 wt% of boron oxide. Stringent environmental regulations require the addition of costly emission abatement systems to eliminate boron from the off-gases of boron- containing melts. Alternatively, the use of environmentally friendly boron-free E-glass is required. These melts do not contain, and therefore do not emit, boron into the environment during processing. As a result, a boron-free E-glass product was recently introduced into the market by Fiberglas (Owens Corning Corp., Toledo, OH) under the trademark Advantex.
Commercial boron-containing E-glass comes in two variants. One commercial variant is derived from the quaternary SiO_2-Al_2O_3-CaO- MgO (Ref 2, 4, 6, and 27), and the other is derived from the ternary SiO_2-Al_2O_3-CaO phase diagram (Ref 2, 4, 6, and 28). Commercial E-glasses in the ternary SiO_2-Al_2O_3-CaO system contain a small amount (<0.6 wt%) of MgO that is not deliberately added but obtained as by-product (or tramp) from other ingredients. On the other hand, commercially available boron-free E- glass is derived from the quaternary SiO_2- Al_2O_3-CaO-MgO phase diagram (Ref 2, 7, 8, and 29).
ASTM standards for E-glass (Ref 5) cover all three commercial E-glass variants, distinguishing E-glasses by end use. Compositions containing 5 to 10 wt% by weight of boron oxide are certified for printed circuit board and aerospace applications. Compositions containing 0 to 10 wt% by weight of boron oxide are certified for general applications. According to these standards, E-glass compositions for either type of application may also contain 0 to 2 wt% alkali oxide and 0 to 1 wt% fluoride. The more recent boron-free E-glass variants may also be fluorine- free.

Oxide Compositions. E-glasses of any type are general-purpose fibers because they offer useful strength at low cost. Table 1 presents the oxide components and their ranges for the two types of E-glass fibers that are currently being produced and used in composites. A range is given for each with regard to its oxide components because each manufacturer, and even different manufacturing plants of the same company, may use slightly different compositions for the same glass. These variations result mainly from differences in the available glass batch (raw materials). Tight control is maintained within a given production facility to optimize compositional consistency and maximize production efficiencies.

As shown in Table 1, commercial, boron-containing E-glass compositions (Ref 1, 2, 4, 6, 12, and 24) differ substantially from boron-free E-glass compositions. The silica content for commercial boron-containing E-glasses ranges from 52 to 56 wt% by weight, and for commercial boron-free E-glasses from 59 to 61 wt%. The alumina content generally ranges from 12 to 15 wt% for these boron-containing E-glasses and from 12 to 13.5 wt% for these boron-free E-glasses. The calcia content ranges from 21 to 23 wt% for these commercial boron-containing E-glasses and from 22 to 23 wt% for these boron-free E-glasses.

For commercial, boron-containing, ternary or quaternary E-glasses, the magnesia content ranges from 0.4 wt% (tramp only) to greater amounts if magnesia (dolomite) is deliberately added. For commercial boron-free E-glasses, it ranges from 3.1 to 3.4 wt% (see Table 1). The boron oxide content ranges from 5 to 6% for commercial boron-containing E-glasses, and it is zero for boron-free E-glasses. The titania content ranges from 0.4 to 0.6 wt% for commercial boron-containing E-glasses. For boron-free E- glasses, it ranges from 0.5 wt% (Ref 8) to 1.5 wt% (Ref 7) (see also Table 1).

Environmentally friendly E-glass melts are boron-free and fluorine-free. However, the log 3 fiber forming or fiberization temperature (T_F) of boron-free E-glass melts may be as much as 100 to 110 °C (180 to 200 °F) higher than that of boron-containing E-glass melts (Fig. 1). The log 3 forming temperature is the temperature of a melt at a reference viscosity of 100 Pa · s (1000 P). In addition, the softening point of boron-free E-glass is 60 to 90 °C (110 to 160 °F) higher also than that of a boron-containing E-glass. The higher process temperature requires more process energy, but the higher softening point facilitates higher use temperatures.

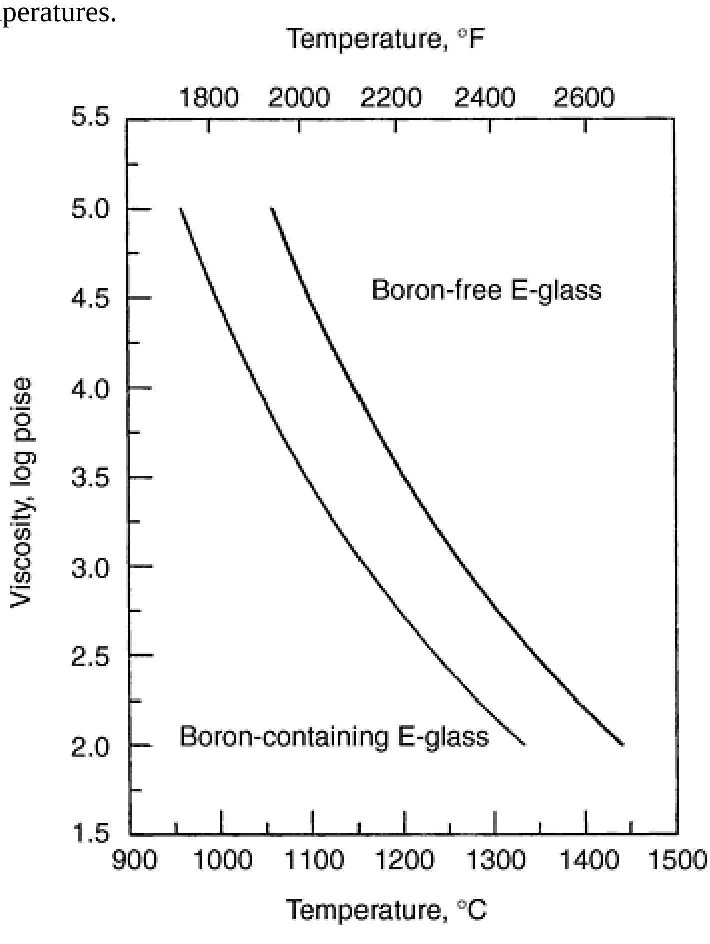

Fig. 1 Viscosity of boron-free and boron-containing E- glass

Melt Properties. According to Table 2, the log 3 forming temperature, T_F, of boron-containing E-glasses ranges from 1140 to 1185 °C (2085 to 2165 °F). The liquidus temperature (T_L) is the temperature below which solid (crystals) will form. It ranges form 1050 to 1064 °C (1920 to 1945 °F). The difference between forming and liquidus temperature (ΔT) ranges from 81 to 90 °C (146 to 162 °F). In contrast, the log 3 fiber forming temperature of boron-free E-glasses ranges from 1250 to 1264 °C (2280 to 2307 °F), the liquidus temperature from 1146 to 1180 °C (2095 to 2155 °F), and the difference between forming and liquidus temperature (ΔT) from 86 to 104 °C (155 to 187 °F) (Ref 7, 8, 9, and 10). Finally, the

softening point of boron-containing E- glasses ranges from 830 to 860 °C (1525 to 1580 °F); that of boron-free E-glasses is about 916 °C (1680 °F).

Mechanical Properties. Table 2 also compares the mechanical properties of the boron-free and boron-containing E-glasses. Elastic modulus (or fiber stiffness) of boron-free E-glasses is about 5% higher than that of boron-containing E-glasses, while pristine, virgin, or single-filament tensile strength is said to be about the same for both types of E-glasses when both are tested at room temperature (Ref 8, 9).

Physical Properties. In addition, Table 2 compares the physical properties of the boron- free and boron-containing E-glasses. Most importantly, the corrosion resistance of boron-free E-glasses was found to be seven times higher than that of boron-containing E-glasses when tested at room temperature for 24 h in 10% sulfuric acid. It approaches that of ECR glass fibers (Ref 9, 10).

Boron-free E-glasses have a slightly higher density (2.62 g/cm^3) than boron-containing E- glasses (2.55 g/cm^3), but the density of both fibers is lower than that of ECR glass (2.66 to 2.68 g/cm^3), a corrosion-resistant special-purpose fiber. Boron-free E-glasses have a higher refractive index and linear expansion coefficient than boron-containing E-glass fibers. The refractive index of both E-glasses is lower than that of ECR glass. The linear expansion coefficient of ECR glass fibers is midway between that of the two E-glasses.

Boron-free E-glasses have a slightly higher dielectric constant (7.0) than boron-containing E- glasses (5.9 to 6.6) when measured at room temperature and at a frequency of 1 MHz. As a result, boron-containing, but not boron-free, E- glass fibers are needed for electronic circuit boards and aerospace applications. On the other hand, boron-free and boron-containing E-glass fibers are used in structural composites where the dielectric constant is of no concern. Composite and laminate uses of all glass fibers are discussed in other articles in this Volume.

Special-Purpose Glass Fibers

Types. Special-purpose fibers, which are of commercial significance in the market today, include glass fibers with high corrosion resistance (ECR-glass), high strength (S-, R-, and Te- glass), with low dielectric constants (D-glass), high strength fibers, and pure silica or quartz fibers, which can be used at ultrahigh temperatures. These fibers will be discussed in the following paragraphs. Others special-purpose fibers include A-glass, C-glass, hollow fibers, bicomponent fibers, and trilobal fibers. These special- purpose glass fibers have recently been reviewed in detail (Ref 2).

ECR-Glass. The corrosion resistance of glass fibers is determined by their chemical structure. It has already been noted in the preceding section on general-purpose glass fibers that boron- free E-glass fibers derived from the quaternary SiO_2-Al_2O_3-CaO-MgO phase diagram have higher acid resistance than E-glass fibers that are derived from the ternary SiO_2-Al_2O_3-CaO phase diagram but have high boron levels. The ECR glass fibers offer enhanced long-term acid resistance and short-term alkali resistance (Ref 27).

The addition of high levels of ZnO and TiO_2 to the boron-free quaternary E-glass system further enhances the corrosion resistance of the resulting ECR glass fibers while at the same time reducing the log 3 forming temperature. The product and process advantage are obtained at a cost penalty. About 2% ZnO and two additional percent TiO_2 are required, and both materials are known to be costly batch ingredients.

S-Glass, R-Glass, and Te-Glass. The tensile strength of glass fibers is determined by the structure connectivity of the silicate network, notably, by the absence of alkali oxides, which are not readily integrated into the structure. The structure of boron oxide, though being a part of the network, is weaker than that of silicon oxide, and therefore, boron oxide serves as a flux. Several high-strength glass fibers are known, including S-glass, Te-glass, and R-glass (Ref 2). All offer 10 to 15% higher strength than E-glass at room temperature, but their real value is their ability to withstand higher in-use temperatures than E-glass. These fibers are used in military applications. Stringent quality-control procedures are necessary to meet military specifications.

S-glass and Te-glass are derivatives of the ternary SiO_2-Al_2O_3-CaO system. R-glass is a derivative of the quaternary SiO_2-Al_2O_3-CaO- MgO system. S-glass and S-2 glass fibers, a product variant, have the same glass composition (Ref 2) but different coatings. While internal structural uniformity (high strength) is achieved with these boron-free and alkali-free compositions, their forming temperatures are higher than that of E-glass. Attainment of high in-use temperatures is a definite product advantage, but higher melt temperatures, more process energy, and more costly bushing alloys are required.

Silica/Quartz Fibers. Glass fibers with increasing SiO_2 levels can be used in applications requiring increasingly high in-use temperatures. High-silica fibers (95% SiO_2) are amorphous glass fibers. They are obtained by acid leaching of borosilicate E-glass fabrics, which are, in turn, used as insulation blankets at temperatures up to 1040 °C (1900 °F). Pure silica fibers (99% SiO_2) are made by dry spinning from aqueous water- glass solutions. They are known by the tradename “Silfa” and mostly are used as yarns, for example, for wire insulation at temperatures up to 1090 °C (1990 °F). For details see Ref 2. They are not used in composite applications and are therefore not shown in Table 2.

Ultrapure silica glass fibers or quartz fibers (99.99% SiO_2), which are down-drawn from preforms (Ref 2) in a containerless process, are also amorphous, despite the fact that the trivial name “quartz” or trade names Quartzel and Astroquartz would imply the presence of the hexagonal crystal structure of quartz. Ultrapure silica (quartz) fibers combine superior high-temperature resistance with superior transparency to ultraviolet (UV) and longer wavelength radiation. For example, in a composite radome on the nose of an aircraft, they protect delicate radar equipment from flying objects, lightning and static discharge (Ref 30). The purest of all commercial silica glass or quartz fibers (99.999% SiO_2) are obtained by dry-spinning of a reagent grade tetraethylorthosilicate sol-gel (Ref 2).

All ultrapure silica glass or quartz fibers are used in yarn and in composite applications and are, therefore, shown in Table 2. Ultrapure and pure silica yarns and fabrics can be used at temperatures up to 1090 °C (1990 °F), high silica fabrics at up to 1040 °C (1900 °F), and S-glass, Te-glass, and R-glass yarns and fabrics at up to 815 °C (1500 °F) (for process and product details see Ref 2).

D-Glass. The electrical properties of glass fibers are determined by their volume resistivity, surface conductivity, dielectric constant and loss tangent (Ref 2). E-glass with its relatively high dielectric constant is the major reinforcing fiber for printed circuit board (PCB) laminates in the market today, but miniaturization drives the industry toward specialty fibers with lower dielectric constants and lower dielectric loss tangents.

Several low D-glass variants are known. All have very high B_2O_3 levels (20 to 26%) and, therefore, much lower dielectric constants than E-glass (4.10 to 3.56 versus 6.86 to 7.00). Those D-glass variants having low dielectric loss tangents as well (Ref 8) are said to offer the highest value in-use when used to reinforce PCB laminates. Because of their high cost, however, any D-glass version will remain a low volume specialty fiber. The very high boron-oxide levels, which are needed and in part emitted from the melt, may require an entirely different specialty process (see Ref 2 for details).

For very different reasons, ultrapure silica fibers, hollow E-glass fibers, S-glass, and other high-temperature fibers have lower dielectric constants than solid E-glass. They, too, can and are being used to reinforce printed circuit board (PCB) laminates. However, silica fibers have a low modulus and are, therefore, less effective as reinforcing fibers. Hollow fibers, although initially effective because of their low dielectric constant, lose their dielectric properties if moisture can seep into the laminate structure.

Important Commercial Products

Once the continuous glass fibers have been produced they must be converted into a suitable product form for their intended composite application. The major finished forms for E-glass fibers are continuous roving, woven roving, fiberglass mat, chopped strand, and yarns for textile applications.

Fiberglass roving is produced by collecting a bundle of strands into a single large strand, which is wound into a stable, cylindrical package. This is called a multiend roving process. The process begins by placing a number of oven- dried forming packages into a creel. The ends are then gathered together under tension and collected on a precision roving winder that has a constant traverse-to-winding ratio, and is called the waywind. This ratio has a significant effect on package stability, strand characteristics, and ease of payout in subsequent operations. The yield (meter per kilogram, or yard per pound) of the finished roving is determined by the number of input ends and the yield of the input strand or sliver. Final package weight and dimensions can be made to vary widely, depending upon the required end-use. Figure 4 shows the entire process.

Rovings are used in many applications. When used in a spray-up fabrication process, the roving is chopped with an air-powered gun that propels the chopped-glass strands to a mold while simultaneously applying resin and catalyst in the compact ratio. This process is commonly used for bath tubs, shower stalls, and many marine applications. In another important process, the production of sheet molding compound (SMC), the roving is chopped onto a bed of formulated polyester resin and compacted into a sheet, which thickens with time. This sheet is then placed in a press and molded into parts. Many fiber-reinforced plastic (FRP) automotive body panels are made by this process.

Filament winding and pultrusion are processes that use single-end rovings in continuous form. Applications include pipes, tanks, leaf springs, and many other structural composites. In these processes the roving is passed through a liquid resin bath and then shaped into a part by winding the resin-impregnated roving onto a mandrel or by pulling it through a heated die. Because of a property called *catenary* (the presence of some strands that have a tendency to sag within a bundle of strands), multiend rovings sometimes do not process efficiently. Catenary is caused by uneven tension in the roving process that results in poor strand integrity.

While providing desirable entanglement for transverse strength in pultrusion, the looser ends in the roving may eventually cause loops and breakouts in close-tolerance orifices, making reinforced plastics processing difficult. Consequently, the process of direct forming single-end rovings was developed by using very large bushings and a precision winder specially designed to operate in the severe forming environment. No subsequent step other than drying is required. Single-end rovings have become the preferred product for many filament-winding and pultrusion applications.

Woven roving is produced by weaving fiberglass rovings into a fabric form. This yields a coarse product that is used in many hand lay-up and panel molding processes to produce FRPs. Many weave configurations are available, depending on the requirements of the laminate. Plain or twill weaves provide strength in both directions, while a unidirectionally stitched or knitted fabric provides strength primarily in one dimension. Many novel fabrics are currently available, including biaxial, double-bias, and triaxial weaves for special applications.

Fiberglass mats may be produced as either continuous- or chopped-strand mats. A chopped- strand mat is formed by randomly depositing chopped fibers onto a belt or chain and binding them with a chemical binder, usually a thermoplastic resin with a styrene solubility ranging from low to high, depending on the application. For example, hand lay-up processes used to moderate corrosion-resistant liners or boat hulls require high solubility, whereas closed-mold processes such as cold press or compression molding require low solubility to prevent washing in the mold during curing.

Continuous-strand mat is formed in a similar manner but without chopping, and, usually, less binder is required because of increased mechanical entanglement, which provides some inherent integrity. Continuous-strand mat may be used in closed mold processes and as a supplemental product in unidirectional processes such as pultrusion, where some transverse strength is required. A number of specialty mats are also produced. Surfacing veil made with C-glass is used to make corrosion-resistant liners for pipes and tanks. Surfacing veils made from other glass compositions are used to provide a smooth finished surface in some applications. Glass tissue is used in some vinyl flooring products.

Combinations of a mat and woven roving have been developed for specific products in recent years. In many lay-up processes the laminate is constructed from alternate layers of fiberglass mat and woven roving. Fiberglass producers thus began to provide products that make this process more efficient. The appropriate weights of fiberglass mat (usually chopped- strand mat) and woven roving are either bound together with a chemical binder or mechanically knit or stitched together. This product can then be used as a significant labor saver by the fabricators.

Chopped strand products are produced by two major processes. In the first process, dried forming packages are used as a glass source. A number of strand ends are fed into a chopper, which chops them into the correct length, typically 3.2 to 12.7 mm ($\frac{1}{8}$to $\frac{1}{2}$in.). The product is then screened to remove fuzz and contamination and boxed for shipment (Fig. 5). The second process, used in recent years to produce many chopped-strand products, is the direct- chop process. In this process, large bushings are used in forming, and the strands are chopped in a wet state directly after sizing is applied. The wet, chopped strands are then transported to an area where they are dried, screened, and packaged. The direct-chop process has provided the industry with a wide variety of chopped reinforcements for compounding with resins.

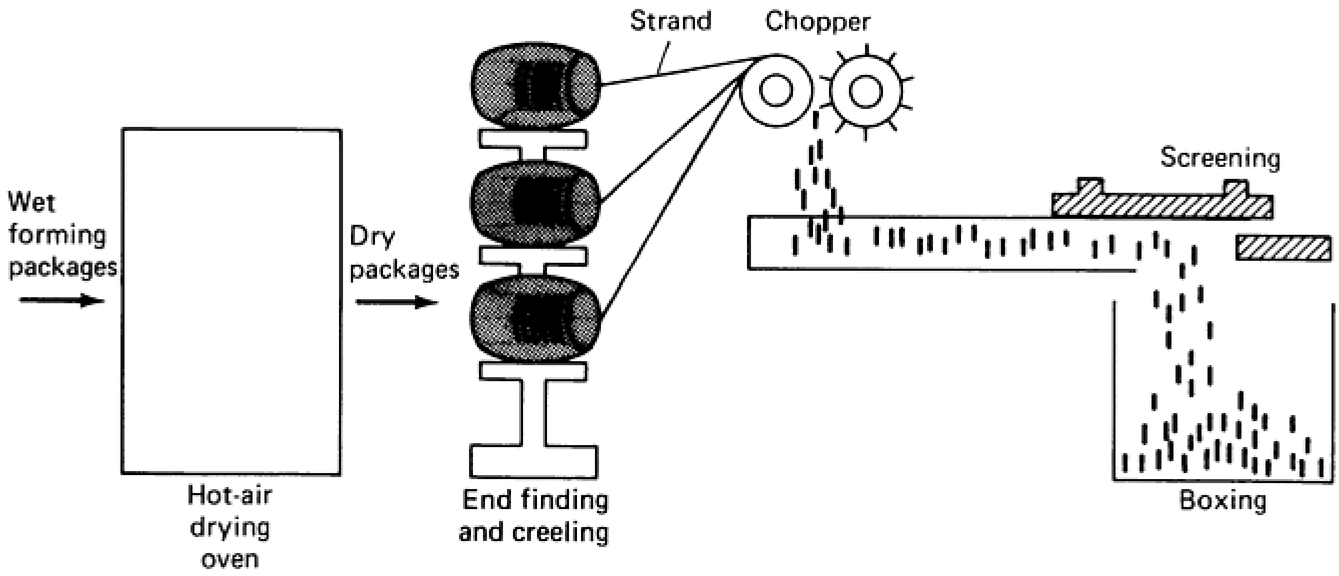

Fig. 5 Chopped-strand production

Chopped glass is widely used as a reinforcement in the injection molding industry. The glass and resin may be dry blended or extrusion compounded in a preliminary step before molding, or the glass may be fed directly into the molding machine with the plastic resin. Hundreds of different parts for many applications are made in this manner. Chopped glass may also be used as a reinforcement in some thermosetting applications, such as bulk molding compounds.

Milled fibers are prepared by hammer milling chopped or sawed continuous strand glass fibers, followed by chemically sizing for some specific applications and by screening to length. Fiber lengths typically vary from particulates to screen opening dimensions for the reported nominal length (0.79 to 6.4 mm, or $\frac{1}{32}$to $\frac{1}{4}$in.). As such, milled fibers have a relatively low aspect ratio (length to diameter). They provide some increased stiffness and dimensional stability to plastics but minimal strength. Their use is primarily in phenolics, reaction-injection molded urethanes, fluorocarbons, and potting compounds.

Fiberglass paper is the reinforcing element for fiberglass roofing shingles. Chopped strands of 25 to 50 mm (1 to 2 in.) length are usually used in making fiberglass paper or a thin fiberglass mat. In this process, chopped fibers are dispersed in water to form a dilute solution. The fiberglass strands filamentize during the mixing and dispersion process. The solution is pumped onto a continuously moving chain, where most of the water is removed by vacuum, leaving behind a uniformly distributed, thin fiberglass mat. A binding resin is added on-line, followed by drying and curing, to form the fiberglass paper. This paper is then combined with the appropriate resin system to form roofing shingles.

Textile yarns are fine-fiber strands of yarn from the forming operation that are air dried on the forming tubes to provide sufficient integrity to undergo a twisting operation. Twist provides additional integrity to yarn before it is subjected to the weaving process, a typical twist consisting of up to one turn per inch. The twisting operation is shown in Fig 6. In many instances, heavier yarns are needed for the weaving operation. This is normally accomplished by twisting together two or more single strands, followed by a plying operation. Plying essentially involves retwisting the twisted strands in the opposite direction from the original twist. The two types of twist normally used are known as S and Z, which indicate the direction in which the twisting is done. Usually, two or more strands twisted together with an S twist are plied with a Z twist in order to give a balanced yarn. Thus, the yarn properties, such as strength, bundle diameter, and yield, can be manipulated by the twisting and plying operations.

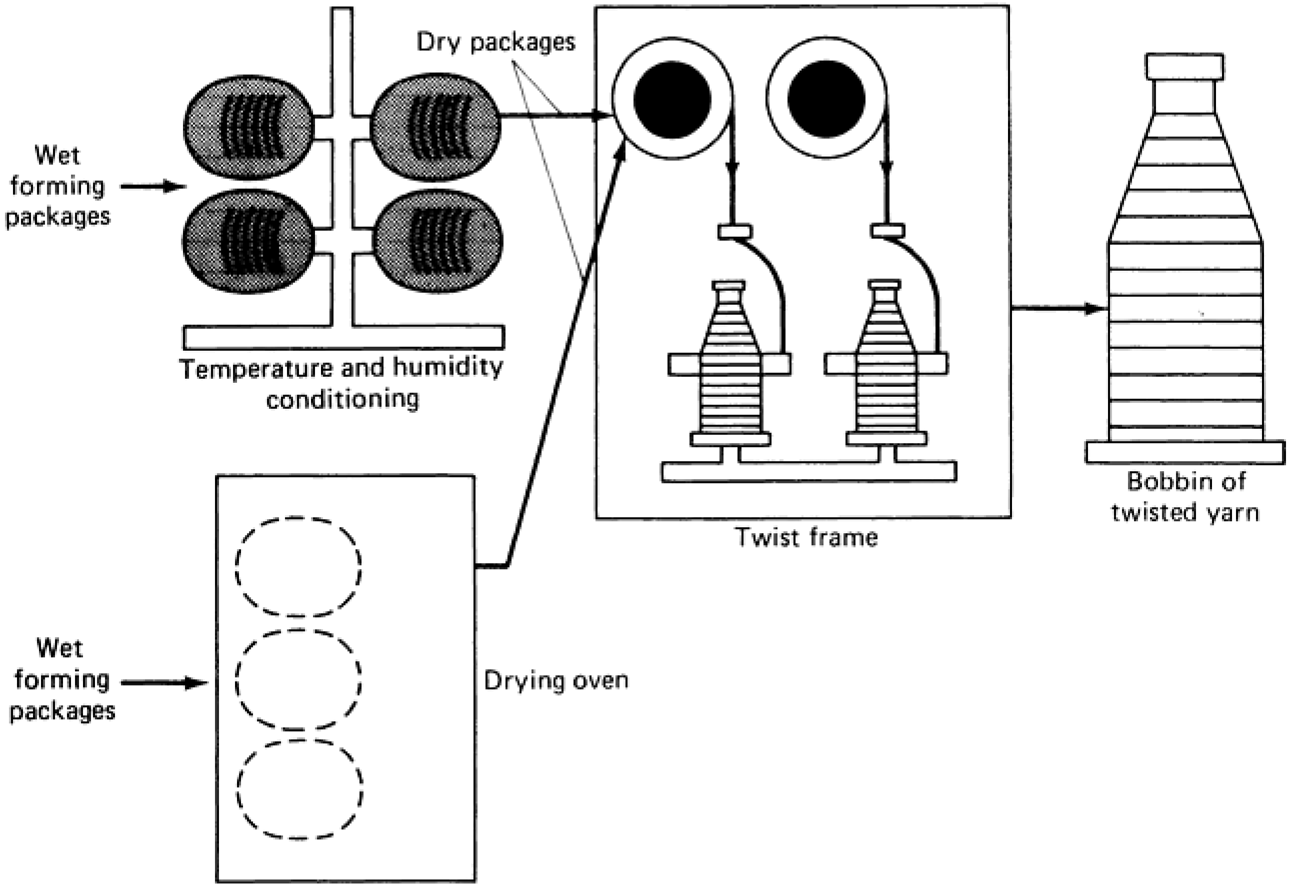

Fig. 6 Twisting

The yarn nomenclature for fiberglass yarns consists of both letters of the alphabet and numbers. For instance, in ECG 75 2/4:

- The first letter specifies the glass composition, in this case, E-glass.
- The second letter specifies the filament type (staple, continuous, texturized) (in the case, of ECG 75 2/4, continuous).
- The third letter specifies the filament diameter (in this case, G).
- The next series of numbers represents the basic strand yield in terms of 1/100th of the yield (in this case, 75 means 7500 yd/lb).
- The fraction represents the number of strands twisted together (numerator) to form a single end and the number of such ends plied together (denominator) to form the final yarn. In the above case, 2/4 means two basic strands are twisted together to form a single end, and four such ends are plied together (usually in the opposite direction) to form the final yarn.

The product brochures from various weavers as well as to Ref 4 should be consulted for details on commercially available fabrics. The *Glass- Fibre Dictionary and Databook* (Ref 14) should be consulted for even greater detail and/or for a summary of all commercially available yarns.

Fiberglass Fabric. Fiberglass yarns are converted to fabric form by conventional weaving operations. Looms of various kinds are used in the industry, but the air jet loom is the most popular. The major characteristics of a fabric include its style or weave pattern, fabric count, and the construction of warp yarn and fill yarn. Together, these characteristics determine fabric properties such as drapability and performance in the final composite. The fabric count identifies the number of warp and fill yarns per inch. Warp yarns run parallel to the machine direction, and fill yarns are perpendicular.

There are basically four weave patterns: plain, basket, twill, and satin. Plain weave is the simplest form, in which one warp yarn interlaces over and under one fill yarn. Basket weave has two or more warp yarns interlacing over and under two or more fill yarns. Twill weave has one or more warp yarns floating over at least two fill yarns. Satin weave (crowfoot) consists of one warp yarn interfacing over three and under one fill yarn to give an irregular pattern in the fabric. The eight-harness satin weave is a special case, in which one warp yarn interlaces over seven and under one fill yarn to give an irregular pattern. In fabricating a composite part, the satin weave gives the best conformity to complex contours, followed in descending order by twill, basket, and plain weaves.

Texturized Yarn. Texturizing is a process in which the textile yarn is subjected to an air jet that impinges on its surface to make the yarn "fluffy" (Fig. 7). The air jet causes the surface filaments to break at random, giving the yarn a bulkier appearance. The extent to which this occurs can be controlled by the velocity of the air jet and the yarn feed rate. The texturizing process allows the resin-to-glass ratio to be increased in the final composite. One of the major applications of texturized yarns is as an asbestos replacement.

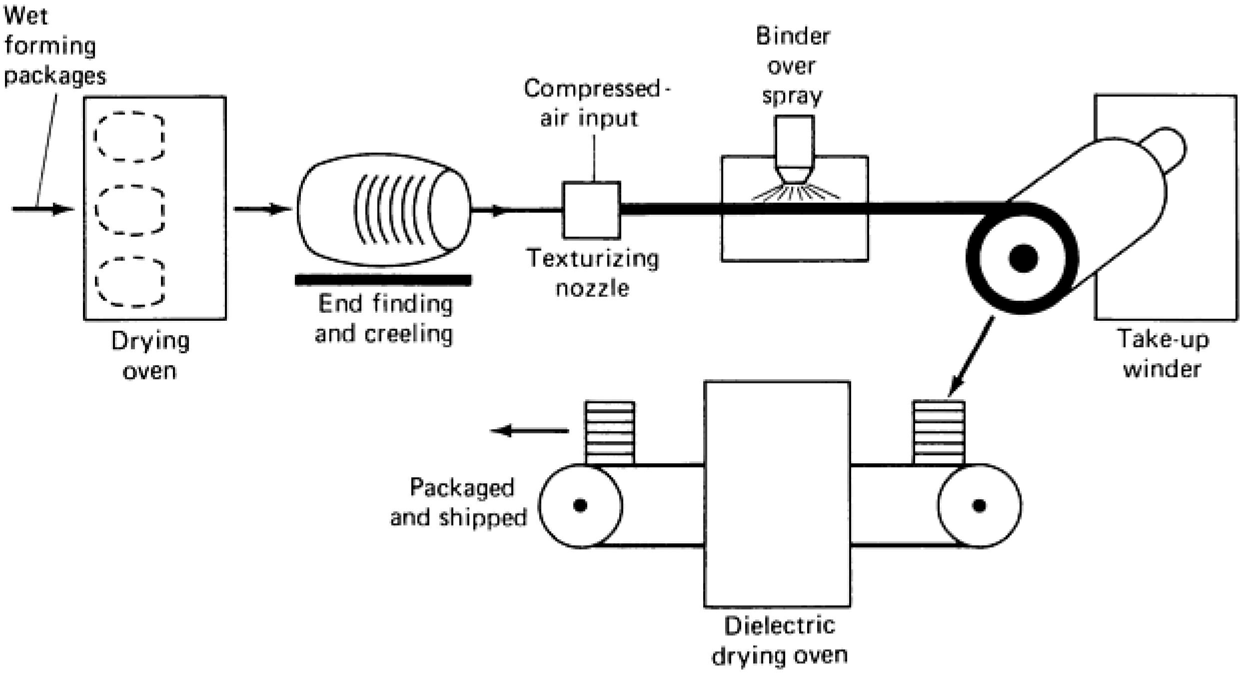

Fig. 7 Texturizing

Carded Glass Fibers. Carding is a process that makes a staple fiberglass yarn from continuous yarn. The continuous yarn is chopped into 38 to 50 mm (1.5 to 2.0 in.) lengths, and then aligned in one direction in a mat form. It is finally converted to a staple yarn. The yarn produced by this process can absorb much more resin than texturized yarn. Carded glass fibers are also used as an asbestos replacement in friction applications, such as automotive brake linings.

Carbon Fibers

Paul J. Walsh, Zoltek Corporation

Introduction

CARBON FIBERS, after a 40 year period of development and use in specialized applications, are now on the brink of broad commercialization. Their use is growing rapidly, fueled by significant price reductions during the 1990s and increasing availability. Changes in the performance/price ratio have resulted in the increased penetration of composites into applications formerly held by metals and has enabled their use in other applications previously not possible with existing materials. Additionally, market conditions increasingly favor designs for commercial products that are lighter, stronger, faster, and more fuel efficient—designs that are possible with carbon fibers. No longer relegated to aerospace, carbon fiber composites are now being adopted in fields such as automotive, civil infrastructure, offshore oil, and paper production.

History

The earliest commercial use of carbon fibers is often attributed to Thomas Edison's carbonization of cotton and bamboo fibers for incandescent lamp filaments (Ref 1). However, practical commercial use of carbon fibers for reinforcement applications began in the late 1950s with the pursuit of improved ablative materials for rockets (Ref 2). Union Carbide marketed a carbonized rayon based fabric in the early 1960s (Ref 3). DuPont's work with “black Orlon” in the late 1950s showed that acrylics could be thermally stabilized, while Shindo in Japan and Watt et al. in the United Kingdom demonstrated that, by using tension through the carbonization process, high mechanical properties could be realized (Ref 4).

Activity increased rapidly during the 1960s and 1970s to improve the performance/price ratio of carbon fibers. Much of this effort focused on evaluation of various precursors, since carbon fiber can be made from almost anything that yields a quality char upon pyrolysis. Donnet and Bansal (Ref 5) present a good overview of various researchers' efforts to evaluate different precursors, including PAN (polyacrylonitrile), pitch, rayon, phenol, lignin, imides, amides, vinyl polymers, and various naturally occurring cellulosic materials.

Overall carbon fiber demand grew to approximately 1000 metric tons by 1980, fueled primarily by the aerospace industry, with the sporting goods industry taking some excess capacity and off-specification fiber. Polyacrylonitrile- based carbon fiber usage had exceeded all other precursors at that time. This was a surprise to some, since the anticipation in the late 1970s had been that the significantly lower raw material price and higher char yield of pitch would result in the winning combination. However, higher processing costs are required to

make a spinnable pitch, so better overall properties for PAN fibers resulted in their dominance. Rayon was relegated to third place, despite having a lower raw material cost, because inferior properties and a low char yield (20 to 25%) after carbonization made for a higher overall cost. Properties can be improved by stress graphitization at high temperatures, but this increases cost further, making the fiber even less desirable. Rayon is still used today for insulating and ablative applications but not for structural applications.

By the mid-1990s, a new cost-effective, PAN- based carbon fiber made from a modified textile precursor was being aggressively promoted by companies like Zoltek and Fortafil for commercial applications. In 1995, one manufacturer announced the goal of reaching a price level of $5/ lb ($11/kg) by the year 2000, which brought alot of attention to and greatly accelerated application development (Ref 6). An overall trend of improved performance/price ratio for both pitch and PAN fiber manufacturers has sustained this growth.

Carbon fiber demand has grown to an estimated 16×10^6 kg (35×10^6 lb) per year (Ref 7). Usage in 1997 was estimated at 30% aerospace, 30% sporting goods, and 30% commercial/industrial applications, with the industrial applications poised for the greatest growth (Ref 8).

Manufacture of Carbon Fibers

Precursor sources used, in order of volume, are PAN, pitch, and rayon. Although the specific processing details for each precursor is different, all follow a basic sequence involving spinning, stabilization, carbonization, and application of a finish or sizing to facilitate handling, as shown in Fig. 1. Discontinuous carbon fiber whiskers are also now produced in a batch process from hydrocarbon gases using a vapor-liquid-solid growth mechanism.

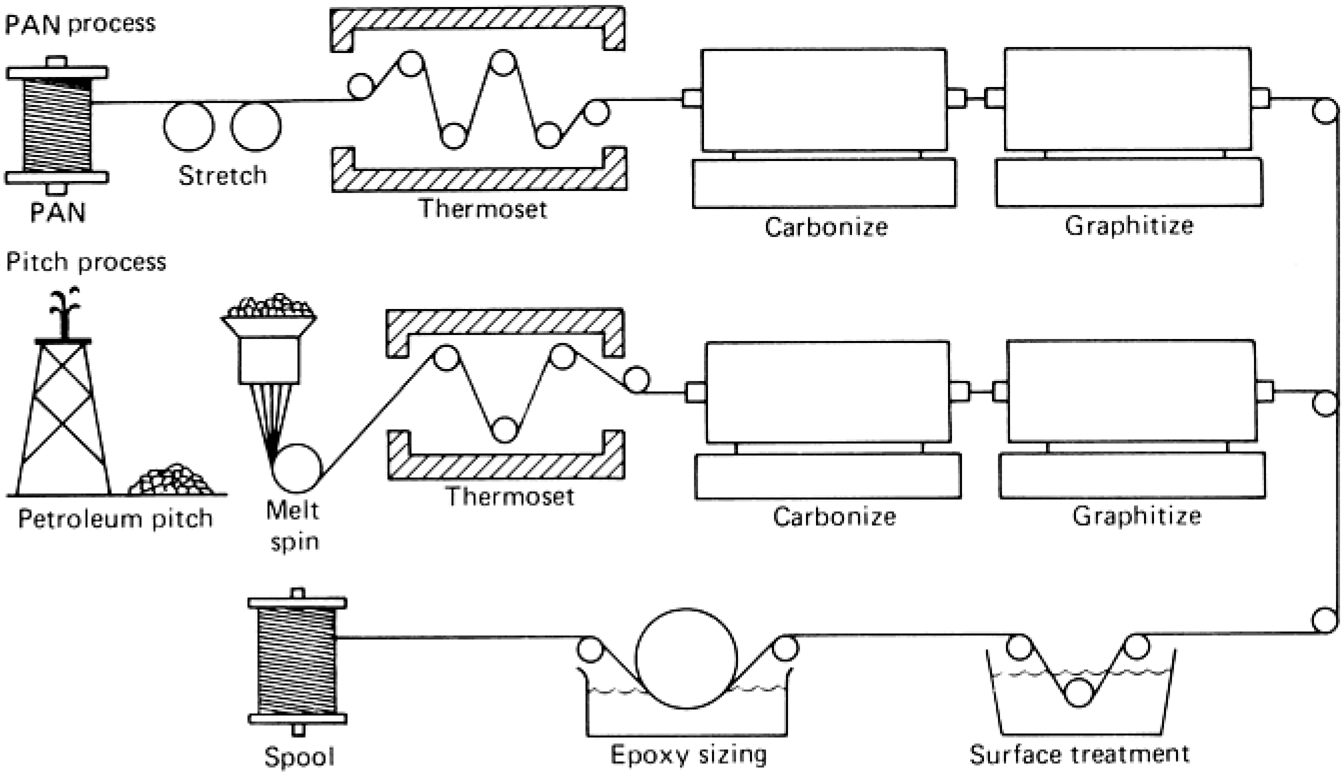

Fig. 1 The processing sequence for polyacrylonitrile (PAN) and mesophase-pitch-based precursor fibers shows the similarities for the two processes. Highly oriented polymer chains are obtained in PAN by hot stretching, while high orientation in pitch is a natural consequence of the mesophase (liquid crystalline) order.

PAN-based Carbon Fibers. The majority of all carbon fibers used today are made from PAN precursor, which is a form of acrylic fiber. Precursor manufacture is accomplished by spinning the PAN polymer into filaments using variants of standard textile fiber manufacturing processes. The PAN fibers are white in color, with a density of approximately 1.17 g/cm^3 (0.042 lb/ in^3) and a molecular structure comprised of oriented, long chain molecules. Stabilization involves stretching and heating the PAN fibers to approximately 200 to 300 °C (390 to 570 °F) in an oxygen-containing atmosphere to further orient and then crosslink the molecules, such that they can survive higher-temperature pyrolysis without decomposing. Stretching after spinning and during stabilization helps develop the highly oriented molecular structure that allows development of a high tensile modulus and improved tensile strength upon subsequent heat treatment.

Carbonization of standard and intermediate modulus fiber typically involves pyrolyzing the fibers to temperatures ranging from 1000 to 1500 °C (1800 to 2700 °F) in an inert atmosphere, typically to a 95% carbon content. An additional high heat treatment step is included just after carbonization for some very high-modulus fibers. During carbonization, the fibers shrink in diameter and lose approximately 50% in weight. Restraint on longitudinal shrinkage helps develop additional molecular orientation, further increasing mechanical properties.

After carbonization, the fibers may be run through a surface treatment step designed to clean and attach functional groups to the fiber surface, which increases bond strength with matrix resins. Most manufacturers use an electrolytic oxidation process that creates carboxyl, carbonyl, and hydroxyl groups on the surface for enhanced bonding. A sizing or finish is then applied to minimize handling damage during spooling and enhance bonding with matrix resins. The fiber is then spooled.

Today, there is differentiation among manufacturers between those who use a modified textile-type PAN precursor and those who use an aerospace-type precursor. The textile-type precursor is made on a very large scale in modified- acrylic textile fiber plants in tows or rovings consisting of >200,000 filaments. The tows are then split down into smaller bundles (approximately 48,000 filaments) after carbonization for spooling. Aerospace precursor is made in smaller specialty plants and processed in 3000 (3K) to 12K filament tows that can be assembled into 24K or larger tows after carbonization. Manufacturing cost is lower for the textile-type precursor, due to higher line throughputs, larger economies-of- scale, and less handling of smaller tow bundles. This type fiber is more targeted for industrial applications. The aerospace-type precursor, because it is processed in smaller tow sizes, is less fuzzy and available in the small tow sizes favored by the aerospace industry, for whom it was originally developed. Physical properties can be similar for both types.

Pitch-Based Fibers. Pitch is a complex mixture of aromatic hydrocarbons and can be made from petroleum, coal tar, asphalt, or PVC (Ref 9). Starting raw material selection is important to the final fiber properties. Pitches must be processed through a pre-treatment step to obtain the desired viscosity and molecular weight in preparation for making high-performance carbon fibers. The pre-processed pitch contains “mesophase”, a term for a disk-like liquid crystal phase (Ref 10) that develops regions of long-term ordered molecules favorable to manufacture of high-performance fibers. Without this step, the result is an isotropic carbon fiber with low strength and low modulus of less than 50 GPa (7×10^6 psi) (Ref 11). Process details of the final composition and method of spinning mesophase pitch are generally held secret by the manufacturers.

Once spun, the stabilization, carbonization, surface treatment, application of sizing, and spooling of pitch-based fibers follows a sequence similar to the manufacture of PAN-based fibers, as shown in Fig. 1. Actual process parameters, such as temperatures, ramp rates, and time at temperature for stretch and stabilization, are different for pitch than for PAN. Gas species evolved during pyrolysis and their onset of evolution are very different for PAN and pitch. The response to heat treatment is also greater for mesophase-pitch-based fibers at higher temperatures, a consequence of their more ordered starting molecular structure. For example, a mesophase-pitch-derived fiber processed to the same temperature as a PAN fiber will exhibit higher density and thermal and electrical conductivity, all else being equal.

Other Precursors. Rayon is processed in similar fashion to PAN, as shown in Fig. 1; the difference is the actual process parameters used.

Carbon fiber “whiskers” can be formed from gas-phase pyrolysis via catalyzed cracking of hydrocarbon gases like methane. One process involves growth of a thin carbon tube of 10 to 50 nm from a submicron iron particle in a hydrocarbon-rich atmosphere, followed by a secondary process of thickening the tube by chemical vapor deposition of carbon on the surface (Ref 12). Others have discussed similar processes, some capable of longer length fibers (Ref 13). Although only discontinuous fibers are fabricated, they have unique properties approaching those of single crystal graphite in some cases.

Available Formats for Fibers. Commercially available carbon fibers are produced by a multitude of manufacturers with a wide range of properties and tow sizes. Carbon fibers are available in many of the same formats as glass fiber. These formats include continuous filament- spooled fiber, milled fiber, chopped fiber, woven fabrics, felts, veils, and chopped fiber mattes. Most fiber today is spooled, and then processed into other formats in secondary operations. The size of the carbon fiber tow bundle can range from 1000 filaments (1K) to more than 200K. Generally, aerospace carbon fibers are available in bundles of 3K, 6K, 12K, and 24K filaments, while most commercial-grade fibers are available in 48K or larger filament counts. Composite fabrication equipment, such as filament winders and weaving machines, must be adapted to handle the larger cross section of commercial grade fiber.

Properties and Characteristics of Carbon Fibers

Composites made from carbon fiber are five times stronger than grade 1020 steel for structural parts, yet are still five times lighter. In comparison to 6061 aluminum, carbon fiber composites are seven times stronger and two times stiffer, yet 1.5 times lighter. Carbon fiber composites have fatigue properties superior to all known metals, and, when coupled with the proper resins, carbon fiber composites are one of the most corrosion resistant materials available. Certain mesophase-pitch-based carbon fibers possess thermal conductivity three times greater than copper. The electrical conductivity of PAN and pitch-based carbon fibers is used to dissipate static electricity in a wide variety of computer-related products. They do not melt or soften with heat, allowing them to be used in such high temperature applications as

rocket nozzles and aircraft brakes. In fact, their strength actually increases with temperature in non-oxidizing atmospheres. These unique properties are the result of the fiber microstructure, in both the axial and transverse directions.
Axial Structure. Envision a single carbon filament as a long cylinder with a diameter of approximately 7 μm. Packed within this cylinder are tiny undulating ribbon-like crystallites which are intertwined and oriented more or less parallel to the axis of the cylinder (Ref 14, 15, 16). The length and straightness of these crystallite "ribbons" determines the modulus of the fiber. A model of the axial structure of a PAN-based carbon fiber is shown in Fig. 2.

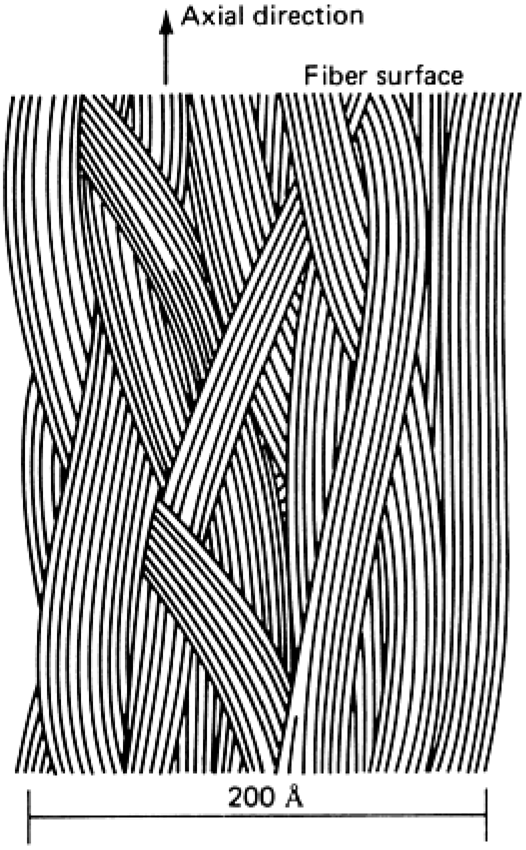

Fig. 2 The undulating ribbon structure of the graphene layers for a PAN-based carbon fiber with a 400 GPa (600 × 10^6 psi) modulus. The ribbons at the surface have lower amplitude than in the core. There are about 20 graphene layers in the ribbons in the core and about 30 near the surface.

On a finer scale, each ribbon-like crystallite is comprised of multiple wrinkled layers. Each layer is made of carbon atoms arranged like chicken wire in a hexagonal structure characteristic of graphite, called a graphene plane. Strong covalent C-C bonds within the layer plane give the potential for high strength and stiffness. Weak van der Waals bonding between the layer planes gives rise to poor shear resistance, but also allows thermal and electrical conductivity. Loose electrons and thermal energy in the form of phonons take advantage of the weak bonding between layer planes and use the inter-plane space as a corridor to travel. The width of the ribbons, the number of graphene layers comprising their thickness, and the length of the ribbons help determine the electrical and thermal characteristics of the carbon fiber, as well as contribute to fiber modulus. Typically, larger and more oriented graphene planes result in higher thermal and electrical conductivity.
Improving the orientation of the microstructure can also increase filament tensile modulus, thermal conductivity, electrical conductivity, and density. This can be accomplished by plastic deformation (for example, stretching the fiber) and/ or heat treatment. Figure 3 shows x-ray diffraction results relating heat treatment temperature to the degree of preferred orientation of the microstructure (Ref 17, 18). The degree of preferred orientation represents the average angle at which the crystallites lie relative to the fiber axis; a zero degree angle means that the crystallites are perfectly aligned with the fiber axis. Transmission electron microscopy shows that the ribbons undulate, such that their amplitude is greater than their wavelength. Any reported measurement of preferred orientation is therefore only an average. The data clearly shows improved orientation with increasing heat treatment temperature. Figure 3 also shows that for heat treatment temperatures above 1600 °C (2900 °F) the mesophase pitch-based fiber will orient more than the PAN fiber, a result of larger crystallite sizes that PAN precursors are not able to achieve. The relationship between preferred orientation of the microstructure and modulus is illustrated in Fig. 4. Increased orientation results in increased fiber modulus, as expected.

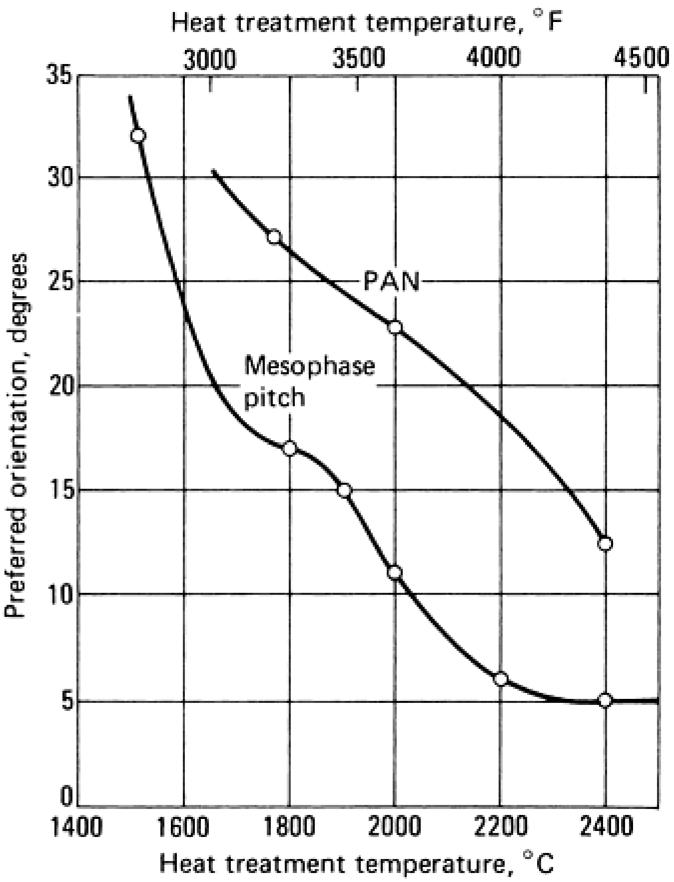

Fig. 3 The preferred orientation of the graphene planes is determined by the heat treatment temperature and the precursor type. Source: Ref 14, 18

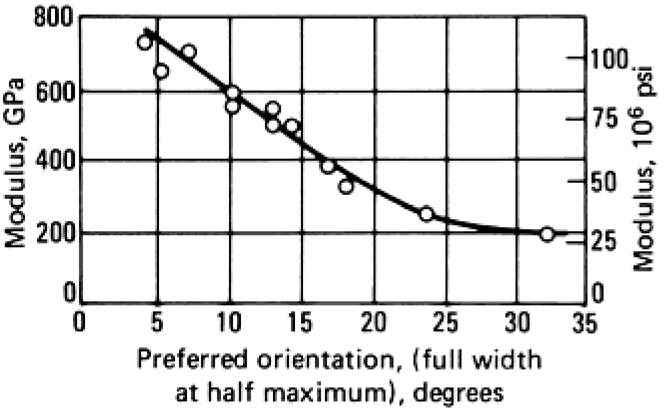

Fig. 4 The modulus of a carbon fiber is determined by the preferred orientation, microstructure, and elastic constants. The relationship between modulus and preferred orientation for a pitch-based carbon fiber is shown.

Increases in fiber tensile modulus can also be obtained by stretching the fiber during stabilization and carbonization. In this case, mechanical rather than thermal energy provides the impetus for molecular realignment.

Transverse Structure. While axial orientation determines modulus, fiber strength is determined by the number and size of flaws and by the transverse and axial orientation. A variety of transverse textures are possible (Ref 19), including a common one described as “onion skin”. In this structure, the graphene layer planes at the fiber surface align like the layers of an onion. In the center core region of the fiber, the layers are randomly oriented. Most of the microstructural pores and flaws are found in either the transition from the skin to the random core region, or in the core region; flaws resulting from damage induced during precursor or carbon fiber processing are observed on the surface. Some pitch fibers have very large graphene layers in a flat orientation reminiscent of the old Pan-Am Airlines insignia. Some of the ultra-high modulus fibers >900 GPa (130 $\times 10^6$ psi) have a radial structure like the spokes of a wheel.

Unlike the axial structure, the radial structure of the carbon filament depends upon precursor type and processing (Ref 20, 21, 22, 23, and 24).

Flaw size and flaw density reduce the strength of a carbon fiber. However, because the fiber is bundled with thousands or millions of other fibers in a composite, the strength is an average effect. Fiber manufacturers control the strength of the overall fiber bundle through rigorous process control.

Effect of Structure on Properties. Fibers made from PAN precursors generally exhibit higher tensile and compressive strength, higher strain at failure, and lower modulus as compared to mesophase-pitch-based fibers. The structure of PAN-based carbon fibers leads to a good balance in properties and is responsible for their dominance in structural applications. Relatively good layer alignment and small crystallite stack heights minimize interlayer shear failure, which improves compressive strengths while maintaining good tensile strength (Ref 25). A model of a 400 GPa (58 × 10^6 psi) PAN-based carbon fiber is shown in Fig. 5 (Ref 26).

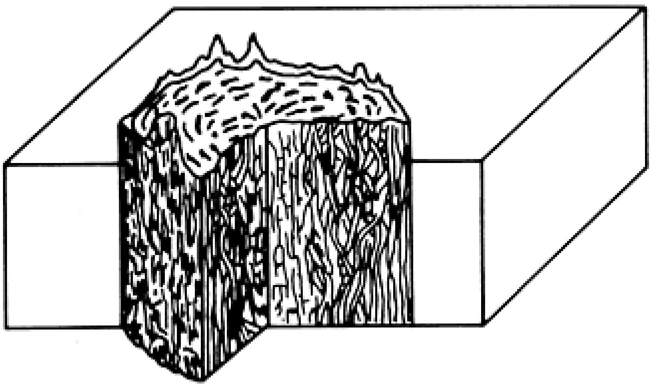

Fig. 5 A 400-GPa (60 × 10^6 psi) modulus PAN-based fiber. Source: Ref 26

PAN fibers used to be categorized into standard modulus, intermediate, and high modulus. New offerings by fiber producers have blurred these categories somewhat. The differences between the three categories for fibers made from a particular precursor are due to combinations of mechanical stretching, heat treatment, and/or precursor spinning. Distinctions are also made between aerospace and commercial-grade carbon fibers. The difference relates to the type of precursor used; commercial grades use a lower cost, modified textile-type PAN. Polyacrylonitrile chemistry is similar between the two, and differences relate more to processing. Generalized properties for PAN-based fibers are presented in Table 1.

Table 1 Properties of PAN-based carbon fibers

Property	Commercial, standard modulus	Aerospace		
		Standard modulus	Intermediate modulus	High modulus
Tensile modulus, GPa (10^6 psi)	228 (33)	220–241 (32–35)	290–297 (42–43)	345–448 (50–65)
Tensile strength, MPa (ksi)	380 (550)	3450–4830 (500–700)	3450–6200 (600–900)	3450–5520 (600–800)
Elongation at break, %	1.6	1.5–2.2	1.3–2.0	0.7–1.0
Electrical resistivity, μΩ· cm	1650	1650	1450	900

Larger crystallite size and greater orientation of mesophase-pitch-based fibers give them superior modulus, thermal conductivity, and lower thermal expansion characteristics as compared to PAN-based fibers. Satellite applications make extensive use of pitch-based fibers and take advantage of all three properties. Table 2 lists general properties of mesophase-pitch-based fibers.

Table 2 Properties of mesophase pitch-based carbon fibers

Property	Low modulus	High modulus	Ultra-high modulus
Tensile modulus, GPa (10^6 psi)	170–241 (25–35)	380–620 (55–90)	690–965 (100–140)
Tensile strength, MPa (ksi)	1380–3100 (200–450)	1900–2750 (275–400)	2410 (350)
Elongation at break, %	0.9	0.5	0.4–0.27
Electrical resistivity, μΩ· cm	1300	900	220–130
Thermal conductivity, W/m · K (Btu/ft · h ·°F)	…	…	400–1100 (230–635)
Coefficient of thermal expansion in axial direction, 10^{-6} K	…	–0.9	–1.6

Carbon content, %	+97	+99	+99
Filament diameter, μm	11	11	10
Manufacturers	BPAmoco, Mitsubishi Kasei		BPAmoco

One of the most beneficial properties of all carbon fibers is their superior fatigue resistance in composites. Unlike glass or aramid fibers, carbon fibers do not suffer from stress rupture, and demonstrate complete elastic recovery upon unloading (Ref 27, 28, and 29). Creep is not observed in carbon fibers at temperatures below 2200 °C (3990 °F) (Ref 30).

The carbon content of low-modulus carbon fibers is less than 99%, largely because of retained nitrogen (Ref 31). Increasing carbon contents and densities are achieved through higher heat treatment temperature, which removes nitrogen and provides greater crystalline perfection.

Electrical and thermal conductivity also increase with increasing crystalline perfection and purity (Ref 32). The electrical conductivity of carbon fibers must be taken into account when processing, since free-floating fibers can short out electrical equipment. Dust-proof, gasketed NEMA 12 enclosures (as specified by the National Electrical Manufacturers Association) are recommended for electrical cabinets, as are covers over electrical outlets (Ref 33).

Room temperature coefficients of thermal expansion (CTE) in the axial direction are slightly negative for low modulus carbon fibers, and grow increasingly negative for the higher modulus fibers. At temperatures above 700 °C (1290 °F), the axial CTE of all fibers turns positive (Ref 34). Composite designers are able to couple the negative CTE of high modulus fibers with appropriate matrix materials to make composites with a CTE of zero over limited temperature ranges.

Interfacial Bonding. Resins and molten metals do not easily wet carbon fibers, due to the relatively inert, non-polar fiber surface. Glass fibers depend upon coupling agents to chemically bond with resins; carbon fibers never achieve strong bonds. Instead, carbon fiber depends upon a combination of mechanical and weak chemical bonding with the matrix material. Surface treatments used by carbon fiber manufacturers populate the fiber surface with active chemical groups such as hydroxyls, carboxyls, and carbonyls (Ref 35). These form bridges between the fiber and resin, and depend upon the number of bonds rather than the strength of the bonds to achieve a strong interface.

Reactivity with Other Compounds. As an inorganic material, carbon fibers are not affected by moisture, atmosphere, solvents, bases, and weak acids at room temperature (Ref 36). However, oxidation becomes a problem at elevated temperatures. For low-modulus PAN-based fibers and high-modulus PAN- or pitch-based fibers, the threshold for oxidation for extended operating times is 350 °C (660 °F) or 450 °C (840 °F), respectively (Ref 37). Impurities tend to catalyze oxidation at these low temperatures and somewhat improved oxidation resistance can be expected with higher-purity fibers (Ref 38).

Typical Applications of Carbon Fibers

Carbon fiber usage is growing in a variety of applications, including aerospace, sporting goods, and a variety of commercial/industrial applications. Growth is fastest in the commercial/ industrial applications. In many instances, carbon composites have displaced metal parts, despite being more expensive on a direct-replacement purchased cost basis. Where successful, carbon composites have lowered total system costs through reduced maintenance, faster processing speeds, and improved reliability. Many new uses under development are enabling, meaning applications that were not practical with metal or other materials are now possible with carbon composites.

Aerospace. Perhaps nowhere is the need to save weight greater than in the aerospace industry. Early growth of the carbon fiber industry was driven almost exclusively by the desire for higher performance aircraft made possible with carbon fiber composites. Today, carbon fiber is used on aircraft for primary and secondary structures. Use is growing, having already established a strong track record in primary structures on military aircraft. All of these applications use carbon fiber for its high specific strength and specific stiffness. Fiber formats used include prepreg for layup processes and fabrics for resin transfer molding and similar processes.

Satellites incorporate very high modulus pitch-based carbon fibers, partly for the high stiffness-to-weight ratios and partly for their negative axial coefficient of thermal expansion.

Sporting Goods. Golf club shafts are presently the largest sporting goods application for carbon fibers. Lighter weight and higher stiffness shafts, made possible with carbon fiber, allow club manufacturers to place more weight in the clubhead, which increases club head speed for improved distance. Most golf shaft manufacturing today is done with unidirectional prepregged sheets of carbon fiber in a roll wrapping operation. Some shafts are filament wound.

Carbon fiber fishing rods are favored by fisherman for their lightweight and sensitive touch. The rods are manufactured via a roll-wrapping process similar to golf shafts, using unidirectional prepreg. Most racquets for tennis, racquetball, and squash are made from prepregged carbon fiber that is sheeted, wrapped around a bladder, and cured. Carbon composite arrows are fabricated by either of two processes: pultrusion or roll wrapping. Skis and bicycle components tend to use fabrics made from carbon fiber.

Commercial and Industrial Applications. Large volumes of milled and chopped carbon fiber are used to impart static dissipating properties to trays for processing semiconductors, and for computer printer and copier machine parts. Parts are injection molded from thermoplastics that have been pre-blended with carbon fiber in a compounding extruder. The carbon fiber is used for its electrical conductivity and ability to provide lightweight reinforcement to thermoplastics.

Carbon fiber drive shafts and couplings have replaced steel shafts for cooling towers and many other torque-transmitting applications. Properties that favor carbon composites include corrosion resistance, light weight, and high stiffness, which reduces vibration. Filament winding processes are used to fabricate the shafts and incorporate fiber into various angles tailored for the torque and vibrational characteristics required of the application.

The desire for faster processing in the papermaking and film casting industry has encouraged growth of carbon composite rollers, which spin faster and have less deflection than steel rollers. Roller diameters up to one meter are now routinely fabricated with carbon fibers on automated filament winding machines.

Speed and precision are also drivers for weaving machine components, such as rapiers, that are made from pultruded carbon composite shapes.

Injection of liquids into oil wells to stimulate production is currently being performed with spoolable carbon composite pipe. The pipe is made in a continuous process whereby a thermoplastic liner is pulled through multiple sets of rotating creels containing carbon fiber spools. The fiber is wetted with resin and wrapped onto the liner, which serves as the mandrel. The tube is cured in-line, and spooled at the other end. Although spoolable carbon composite pipe is more expensive than spoolable steel pipe, its usage is increasing because of superior fatigue performance, which results in improved reliability. Stress corrosion during unspooling and respooling is responsible for premature failure of steel spoolable pipe.

Depletion of shallow water oil fields and the move into deeper water has raised oil company interest in carbon composites. Development programs are underway to moor large oil platforms to the ocean bottom via tethers

constructed from pultruded carbon fiber rods. Carbon fiber tethers are the leading contender for use in water depths beyond 1500 m (5000 ft); this shift is based on its lightweight and high stiffness, which minimize the natural frequency of the platform due to wave motion. Steel tethers used in shallower depths are impractical in deeper water, because they cannot support their own weight hanging from the platform.

Pultrusion companies that are eyeing the tether application are also pursuing carbon composite tendons for pre- and poststressing of precast concrete. Unlike glass fiber, carbon composite rods are inert to alkaline attack and corrosion and satisfy the increased useful life requirement imposed by many municipalities for infrastructure projects. Another pultrusion application, carbon composite rebar, is being developed for use along the waterfront to combat the high costs of corrosion induced structural damage.

Seismic retrofitting of bridge columns and walls has been extensively performed in Japan with sheets of carbon fiber “wallpaper” or fabrics that are saturated with resin and applied to the concrete structure. The high stiffness of the carbon minimizes movement of the concrete and the inertness to corrosion insures long term protection.

The electrical properties of carbon fiber and the ability to configure the material into a semipermeable membrane with defined mass transport properties make carbon the material of choice as the electrode in polymer electrolyte fuel cells to power next generation engines.

Anticipated Developments in Carbon Fibers

Much of the effort expended for carbon fibers today is directed at cost reduction. It appears that the prospects for cost reduction have stimulated interest in many new applications. Certainly, as prices come down, opportunities for new applications grow.

Future funding and technology development for carbon fibers will most likely be directed towards application development, a trend experienced in the glass fiber industry. Areas of opportunity include lowering cost and improving speed of manufacturing processes.

Education and familiarity with composite materials are increasing, but are still well below that of metals. We can expect the demand for carbon fibers to grow in large steps as more engineers learn how to design with carbon fibers.

Property standardization is another expected trend. Glass fiber is easy for a designer to design with, since E-glass and S-glass are standards by which many suppliers produce. Carbon fiber suppliers have many grades to choose from, with little commonality among producers. As large applications for carbon fiber develop, customers will demand standardization among carbon fiber producers.

Aramid Fibers

Karl K. Chang, E.I. Du Pont de Nemours & Company, Inc.

Introduction

ARAMID FIBERS held the distinction of having the highest strength-to-weight ratio of any commercially available reinforcement fiber at the time of their first commercial introduction in the early 1970s. The earliest aramid fibers, produced by E.I. Du Pont de Nemours & Company, Inc., under the tradename of Kevlar, were initially targeted at reinforcement of tires and plastics. The characteristics of light weight, high strength, and high toughness have led to the development of applications in composites, ballistics, tires, ropes, cables, asbestos replacement, and protective apparel. Since those early days other para-aramid fibers have been developed, including Twaron by Accordis BV, Technora by Teijin, Ltd, and improved variations of Kevlar fibers.

Aramid Fibers

Karl K. Chang, E.I. Du Pont de Nemours & Company, Inc.

Fiber Forms and Applications

The major fiber forms are continuous filament yarns, rovings, and woven fabrics, and discontinuous staple and spun yarns, fabrics, and pulp. Aramid is also available as textured yarn, needle- punched felts, spunlaced sheets, and wet-laid papers.

Yarns and Rovings. Kevlar 49 is a high- modulus aramid fiber that is available in 11 yarn sizes and four roving sizes, as shown in Table 1. Yarns are multifilament products that are spun directly during fiber manufacture and range from a very fine, 25-filament yarn to 1333-filament yarns. Rovings are produced by combining ends of yarns in a process similar to that used to produce glass fibers. For example, four ends of 1140-denier yarn are combined to make 4560- denier roving. Denier, a textile unit of linear density, is the weight in grams of 9000 m of yarn or roving (1 denier = 1.111×10^{-7} kg/m). Table 2 lists the yarn and roving sizes of Kevlar 29, which has a lower tensile modulus than Kevlar 49 and is used extensively in ballistic armor, asbestos replacement, and certain composites when greater damage tolerance is desired. Kevlar 149, with a tensile modulus 25 to 40% higher than Kevlar 49, is available as 1420-denier yarn.

Table 1 Kevlar 49 yarn and roving sizes

Denier	**Yield**		Number of filaments
	m/kg	**yd/lb**	
55	163,636	81,175	**25**

Because aramid yarns and rovings are relatively flexible and nonbrittle, they can be processed in most conventional textile operations, such as twisting, weaving, knitting, carding, and felting. Yarns and rovings are used in the filament winding, prepreg tape, and pultrusion processes. Applications include missile cases, pressure vessels, sporting goods, cables, and tension members.

Fabrics and Woven Rovings. Conventional woven fabric is the principal aramid form used in composites. Of the wide range of fabric weights and constructions available, those most commonly used are identified in Table 3 (Ref 10). Many of these aramid fabrics of Kevlar were designed and constructed to be the volume equivalent to the same style number of fiberglass fabric. Generally, fabrics made of a very fine size of aramid yarn are thin, lightweight, and relatively costly, and they are used when ultralight weight, thinness, and surface smoothness are critical. Fabrics are available from weavers worldwide. Plain, basket, crowfoot, and satin weave patterns are available. Generally, crowfoot and satin weaves are recommended when a high degree of mold conformability is required. Heavy, woven roving fabrics are also available and are used in marine applications where hand lay-up is appropriate and for hard ballistic fabrics. Unidirectional fabrics are used when maximum properties are desired in one direction. Applications for high-modulus aramid fabrics include commercial aircraft and helicopter secondary composite parts, particularly facings of honeycomb sandwich constructions, boat hulls, electrical and electronic parts, ballistic systems, and coated fabrics.

Table 3 Kevlar 49 fabric and woven roving specifications

Style No.	**Weave**	**Basis weight**		**Fabric construction**		**Yarn denier**	Fabric thickness	
		g/m^2	**oz/yd^2**	**ends/cm**	**ends/in.**		**mm**	10^{-3} in.

(a) Only available on special order; custom fabric will be woven to specifications.

Textured aramid can be processed through a high-velocity air jet to attain filament loops in the continuous filament yarn. This produces a bulkier yarn that has more air space between the filaments and a drier, less slick, tactile characteristic. The yarn is used in asbestos replacement to give the composite a higher resin-to-aramid ratio and in protective apparel to achieve superior textile aesthetics.

Although continuous filament forms dominate composite applications, the use of aramid in discontinuous or short fiber forms is rapidly increasing. One reason for the increase is that the inherent toughness and fibrillar nature of aramid allows the creation of fiber forms not readily available with other reinforcing fibers.

Staple and Spun Yarns. Staple or short aramid fiber is available in crimped or uncrimped form in lengths ranging from 6.4 to 100 mm (0.25–4.0 in.). Crimped versions that are 25 mm (1.0 in.) or longer are used to make spun yarns on conventional cotton, woolen, or worsted system equipment. Spun yarns formed in this way are not as strong or as stiff as continuous aramid filament yarns, but are bulkier, pick up more resin, and have tactile characteristics similar to cotton or wool. They are used in asbestos replacement (for example, clutch facings) and as sewing thread. The shorter aramid fibers, crimped and uncrimped, are used to reinforce thermoset, thermoplastic, and elastomeric resins. Applications include automotive and truck brake and clutch linings, gaskets, electrical parts, and wear-resistant thermoplastic parts. Selection of a crimped or uncrimped form usually depends on the resin-fiber mixing method or on equipment used for the specific application. Special mixing methods and equipment are usually necessary to achieve uniform dispersion of the aramid fiber.

Fabrics and Felts. Woven and knit fabrics made from aramid spun yarns are available. They are used in asbestos replacement and in protective apparel because of their resistance to cutting, puncture, abrasion, or thermal exposure. Aramid staple is also processed into needle- punched felts, which are used in asbestos replacement, ballistic armor, and marine laminates.

Pulp. Kevlar is available in a unique short fiber form known as pulp (Fig. 5). It is a very short fiber (2–4 mm, or 0.08–0.16 in.) with many attached fibrils. These fibrils are complex in that they are curled, branched, and often ribbonlike. They are a direct result of the inherent fibrillar structure of this fiber. The large surface area (40 times standard fiber) and high aspect ratio of the fibrils (greater than 100) can provide very efficient reinforcement. In general, pulp is more easily mixed into resin formulations than is staple fiber and is now used extensively in replacing asbestos in gaskets, friction products, sealants, caulks, and coatings (Ref 11, 12).

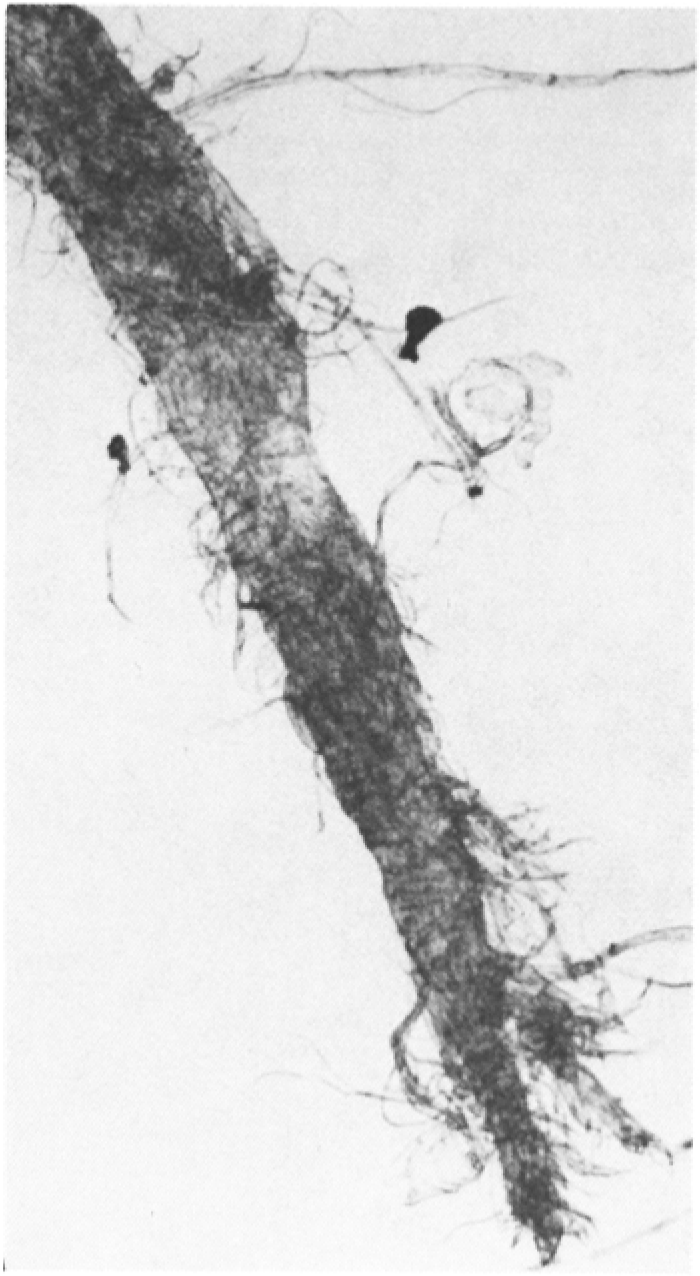

Fig. 5 Aramid pulp

Spunlaced Sheets. Aramid staple fibers can be processed into lightweight, nonwoven sheet structures. One of the available forms is spunlaced sheet, in which webs of staple fibers are entangled by high-pressure water jets. No binder resin is used. These sheets are low-density (0.008–0.16 g/cm^3), lightweight (0.02–0.07 kg/ m^2, or 0.5–2.0 oz/yd^2) structures that are very drapable and readily impregnated. Applications include surfacing veil, printed circuit boards, and fire-blocking layers in aircraft seating.

Papers. The dominant aramid paper used in advanced composites in honeycomb sandwich constructions is made from Nomex aramid fiber (Ref 13). It is chemically related to Kevlar, but its tenacity and modulus are considerably lower and are more like those of conventional textile fibers. A range of Nomex papers in varying thicknesses and weights are available. Honeycomb cores of Nomex are also available; densities range from 0.24 to 0.14 g/cm^3 (Ref 14).

Aramid chopped fibers and pulp can be processed into wet-laid papers on conventional fourdrinier machines. Applications include asbestos replacement, such as in gasketing and automatic transmissions. Straight, uncrimped fibers can be used to maximize stiffness and mechanical properties of the wet-laid papers. These thin, lightweight papers are readily impregnated and can be cost competitive with expensive, lightweight, thin, continuous filament fabrics. Composites that use these papers are being developed for printed circuit boards, aerospace, and industrial applications (Ref 15). Proprietary papers based on para-aramid floc and meta-aramid fibrids are also available.

Aramid Fibers

Karl K. Chang, E.I. Du Pont de Nemours & Company, Inc.

Materials Properties

Key representative properties of para-aramid fibers are given in Table 4. Kevlar 49 is the dominant form used today in structural composites because of its higher modulus. Kevlar 29 is used in composites when higher toughness, damage tolerance, or ballistic stopping performance is desired. An ultrahigh-modulus fiber, Kevlar 149, is also available.

Table 4 Properties of para-aramid fibers

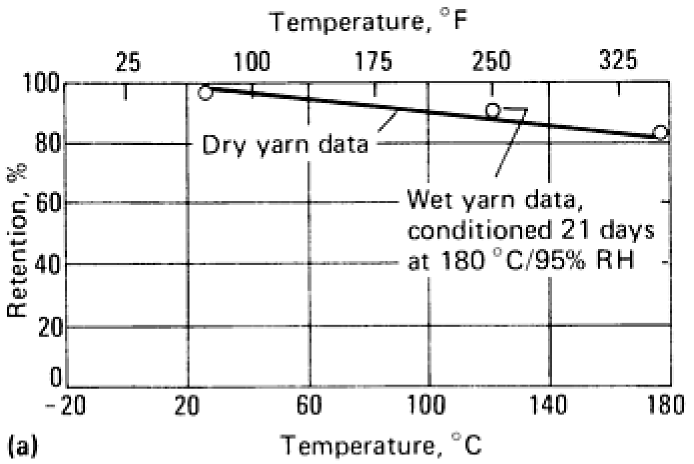
Material	Density, g/cm^3	Filament diameter		Tensile modulus(a)		Tensile strength(a)		Tensile elongation, %	Available yarn count, No. filaments
		µm	µin.	GPa	10^6 psi	GPa	10^6 psi		
Kevlar 29 (high toughness)	1.44	12	470	83	12	3.6	0.525	4.0	**134–10,000**
						2.8(b)	0.400(b)		
Kevlar 49 (high modulus)	1.44	12	470	131	19	3.6–4.1	0.525–0.600	2.8	**25–5,000**
Kevlar 149 (ultrahigh modulus)	**1.47**	**12**	**470**	**179**	**26**	**3.4**	**0.500**	**2.0**	**1,000**

(a) ASTM D 2343, impregnated strand (Ref 16).
(b) ASTM D 885, unimpregnated strand (Ref 17).

Tensile modulus of para-aramid fibers is a function of the molecular orientation. As a spun fiber, Kevlar 29 has a modulus of 62 GPa (9×10^6 psi). In composite form, it has a modulus (83 GPa, or 12×10^6 psi) that is slightly higher than that of E-glass (69 GPa, or 10×10^6 psi). Heat treatment under tension increases crystalline orientation, and the resulting fiber, Kevlar 49, has a modulus of 131 GPa (19×10^6 psi). Kevlar 149 has an even higher modulus (179 GPa, or 26×10^6 psi) and is available on special order. This modulus approaches the theoretical maximum predicted for para-aramid fibers (Ref 18).

The tensile strength of para-aramid fiber is in the range of 3.6 to 4.1 GPa ($0.525–0.600 \times 10^6$ psi). This is more than twice the strength of conventional organic fibers such as nylon 66 and is 50% greater than the strength of E-glass roving. It is believed that tensile failure initiates at fibril ends and propagates via shear failure between the fibrils.

Tensile Properties in Hot/Wet Conditions. High-modulus para-aramid yarns show a linear decrease of both tensile strength and modulus when tested at elevated temperatures in air (Fig. 6). More than 80% of these properties are retained at 180 °C (355 °F). Figure 7 shows retention of room-temperature yarn strength after long exposures at elevated temperatures. More than 80% of strength is retained after 81 h at 200 °C (390 °F).



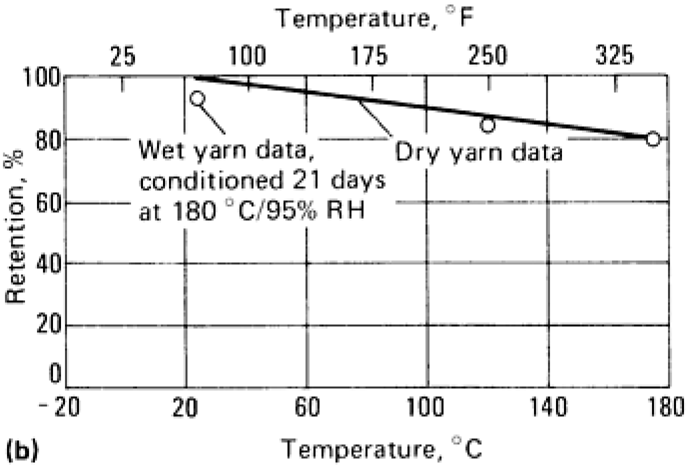


Fig. 6 Effect of temperature on tensile strength and modulus of dry and wet Kevlar 49 aramid yarn. (a) Tensile strength. (b) Tensile modulus

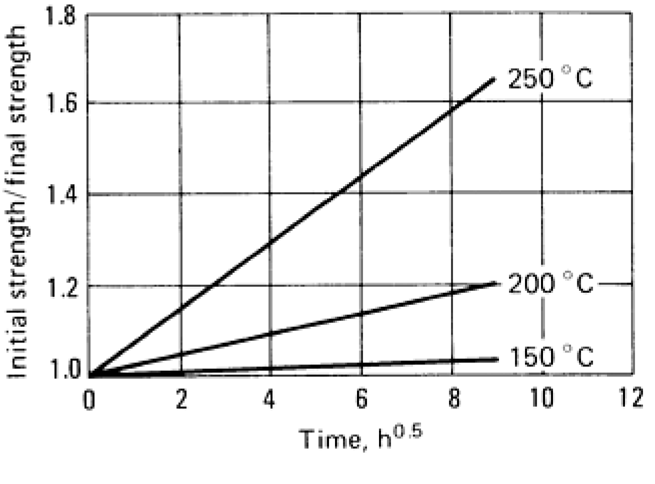

Fig. 7 Room-temperature tensile strength retention after air aging of Kevlar 49 aramid yarn at various temperatures

At room temperature, the effect of moisture on tensile properties is <5%. At elevated temperature, the effect of moisture appears to be reversible: yarn conditioned for 21 days at 180 °C (355 °F)/95% relative humidity tested at high temperature had essentially the same behavior as dry yarn (Fig. 6). Tests of yarn while immersed in hot water suggest a loss of 10% due to the water alone (Ref 19, 20).

Creep and Fatigue. Para-aramid is resistant to dynamic and static fatigue (Fig. 8 and 9). Creep rate is low and similar to that of fiberglass, but unlike glass, para-aramid is less susceptible to creep rupture (Ref 21).

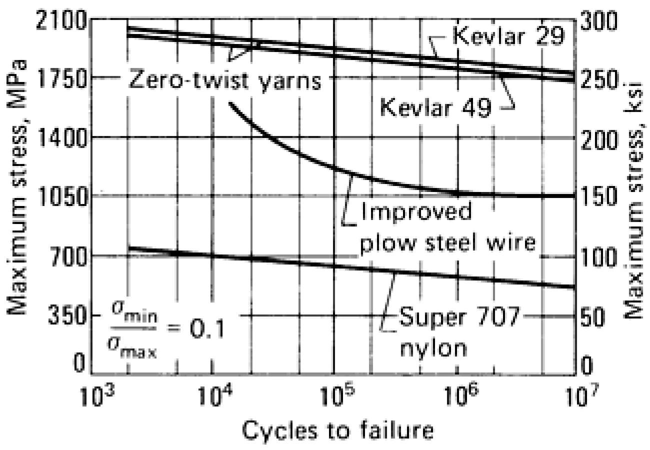

Fig. 8 Comparative tension-tension fatigue for yarns and wire

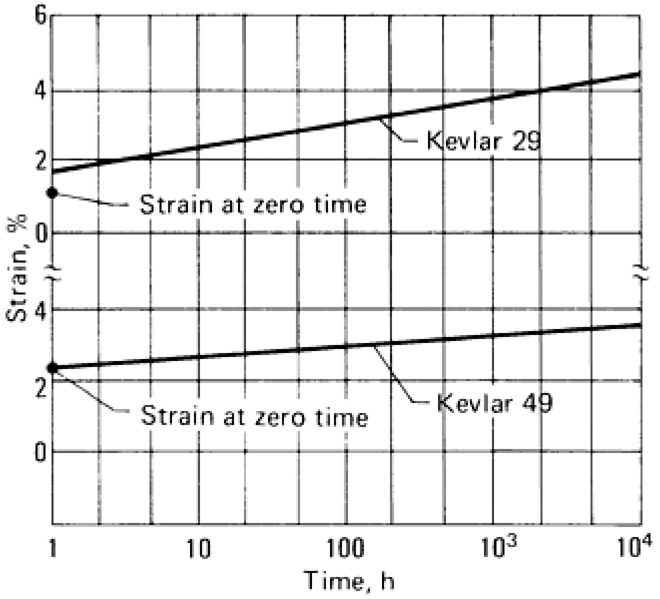

Fig. 9 Creep of Kevlar 29 and Kevlar 49 aramid yarns at 50% of ultimate strength

Compressive Properties. Although para- aramid fiber responds elastically in tension, it exhibits nonlinear, ductile behavior under compression. At a compression strain of 0.3 to 0.5%, a yield is observed (Fig. 10). This corresponds to the formation of structural defects known as kink bands (Fig. 11), which are related to compressive buckling of para-aramid molecules. As a result of this compression behavior, the use of para-aramid fibers in applications that are subject to high strain compressive or flexural loads is limited. The compressive buckling characteristics have also led to developments of crashworthy structures that rely on the fail-safe behavior of aramid composites under sustained high compressive loads (Ref 23).

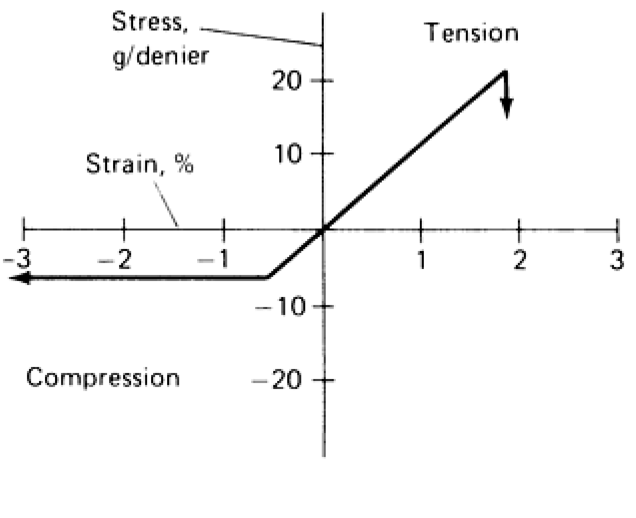

Fig. 10 Para-aramid stress-strain behavior in tension and compression

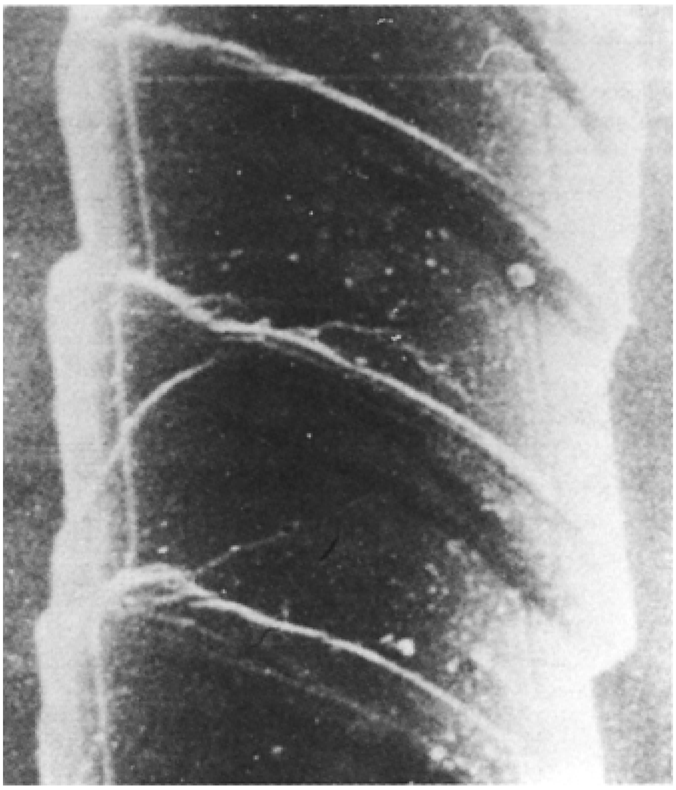

Fig. 11 Kink bands from severe compression. Source: Ref 22

Toughness. Para-aramid fiber is noted for its toughness and general damage tolerance characteristics (Ref 24). In part, this is related directly to conventional tensile toughness, or the area under the stress-strain curve. Toughness is also related to composite impact resistance and ballistic stopping power (Ref 25, 26). The para- aramid fibrillar structure and compressive behavior contribute to composites that are less notch sensitive (Ref 27) and that fail in a ductile, nonbrittle, or noncatastrophic manner, as opposed to glass and carbon (Ref 28).

Thermal Properties. The aromatic chemical structure of para-aramid imparts a high degree of thermal stability (Fig. 12). Fibers from PPD- T do not have a literal melting point or a glass transition temperature (T_g) (estimated at ≥375 °C, or 710 °F), as normally observed with other synthetic polymers. They decompose in air at 425 °C (800 °F) and are inherently flame resistant (limiting oxygen index of 0.29). They have utility over a broad temperature range of about–200 to 200 °C (–330 to 390 °F), but are not generally used long term at temperatures above 150 °C (300 °F) because of oxidation (Fig. 7). Para-aramid fiber has a slightly negative longitudinal coefficient of thermal expansion of–2 × 10^{-6}/K and a positive transverse expansion of 60 × 10^{-6}/K.

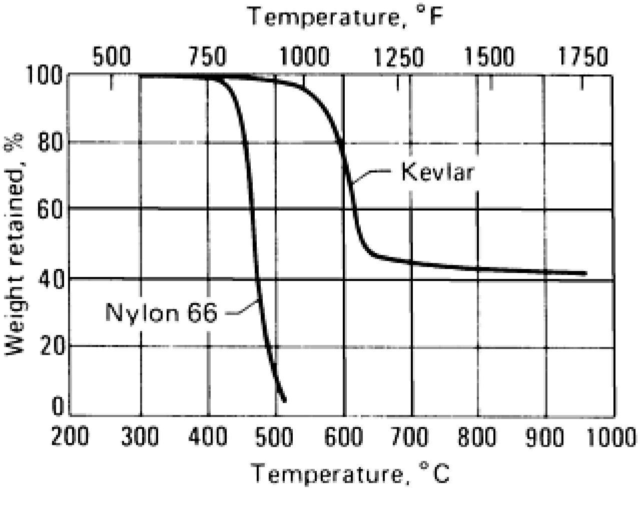

Fig. 12 Thermal stability; thermogravimetric analysis done at 20 °C (70 °F)/min in nitrogen

Para-aramid fiber has a low thermal conductivity that varies by about an order of magnitude in the longitudinal versus transverse direction. Heat of combustion is about 35 MJ/kg (15000 Btu/lb). The specific heat versus temperature is shown in Fig. 13.

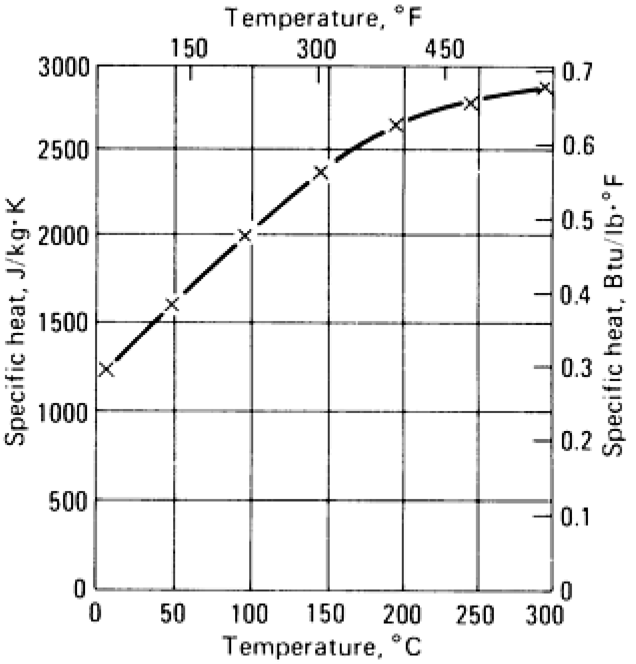

Fig. 13 Effect of temperature on the specific heat of Kevlar 49 aramid

Electrical and Optical Properties. Para- aramid is an electrical insulator. Its dielectric constant of ~4.0, measured at 10^6 Hz, is lower than that of fiberglass and about the same as that of quartz. The index of refraction of para-aramid fiber is 2.0 parallel to the fiber axis and 1.6 perpendicular to the fiber axis. E-glass is 1.55 in both directions.

Environmental Behavior. Para-aramid fiber has an equilibrium moisture content that is determined by the relative humidity, as shown in Fig. 14. At 60% RH, equilibrium moisture of Kevlar 49 is about 4%. Kevlar 149 has a corresponding value of about 1.5%. Physically, the diameter of an aramid filament changes by 0.5% with a corresponding 1% change in fiber moisture content.

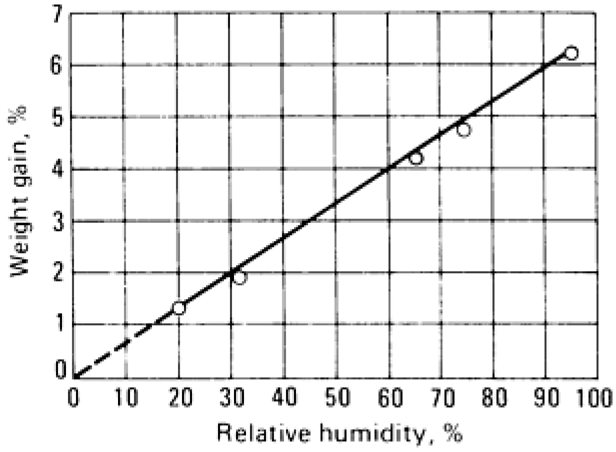

Fig. 14 Equilibrium moisture content versus relative humidity for Kevlar 49 at room temperature

Para-aramid fiber can be chemically degraded by strong acids and bases. It is resistant to most other solvents and chemicals (Ref 6). Ultraviolet radiation also can degrade para-aramid. The degree of degradation depends on material thickness because para-aramid is self-screening. In polymeric composites, strength loss of para- aramid has not been observed (Ref 29).

Para-aramid is resistant to electron radiation, as shown in Table 5. Vacuum outgassing has been performed on para-aramid yarn that had been predried at 125 °C (257 °F) for 24 h under a vacuum of 1.3×10^{-4} Pa (10^{-6} torr). With a colorless deposit of 0.02 wt% micro volatile condensible materials (VCM), there was a 2.28% weight loss.

Table 5 Effect of electron radiation on Kevlar 49

Using resonant transformer and filament wrapped in aluminum foil over dry ice, conditions of exposure were 1 Mrad every 13.4 s, 0.5 mA, 2 MV, and 30 cm (10 in.) distance.

Mrad exposure	Single-filament properties				
	Tenacity		**Tensile modulus**		Elongation, %
	MPa	**ksi**	**GPa**	**10^6 psi**	
0	2860	415	128	18.6	**2.4**
100	2940	426	130	18.8	**2.4**
200	**3010**	**436**	**133**	**19.3**	**2.5**

Future Developments

The most promising new market opportunity for composite materials today is infrastructure. Composite solutions for repair and strengthening of bridges and buildings can be considerably less expensive and faster than conventional steel and reinforced concrete. Major earthquakes in California, Japan, and Italy since 1994 have accelerated the adoption of composite materials in infrastructure applications. Aramid systems were developed and commercialized in Japan for seismic retrofit of railway and highway bridge columns after the Kobe earthquake in 1995. In addition to structural properties, the damage tolerance and impact-resistant properties of aramid fibers also make them the fiber of choice for strengthening bridge supports to resist vehicular impact and for strengthening masonry walls to resist blast loads (Ref 30).

Introduction

CONTINUOUS-LENGTH CERAMIC FIBERS are commercially available in two general classes for the reinforcement of ceramic-matrix composites (CMC): (1) oxide fibers, based on the alumina-silica (Al_2O_3-SiO_2) system and on α-alumina (α-Al_2O_3), and (2) nonoxide fibers, based primarily on β-phase silicon carbide (SiC). These fibers are typically produced with small diameter (<20 μm) and in polycrystalline form with small grain size (<1 μm). When compared to single-crystal fibers or whiskers of the same compositions, the polycrystalline fibers are easier to handle and offer significantly lower production costs, but reduced creep resistance and temperature capability. Thermostructural capability is degraded further with the presence of amorphous or creep-enhancing second phases in the grain boundaries. Nevertheless, a variety of oxide and nonoxide polycrystalline-ceramic fibers exist today with sufficient crystallinity, purity, and performance capability to reinforce metal- and ceramic-matrix composites that can compete with metallic alloys at low and high temperatures. Literature reviews detail the process methods, properties, and applications for numerous ceramic-fiber types that have been developed since the 1970s (Ref 1, 2, 3, 4, and 5). However, only certain types have reached the stage in which they have been used to reinforce different CMC systems with composite-property databases available in the open literature. For the sake of brevity, this article focuses only on these commercial types because they have demonstrated their general applicability as CMC reinforcement.

Fiber Production

The most common approach for producing polycrystalline-ceramic fibers is by spinning and heat treating chemically derived precursors. For oxide fibers, sol-gel processing is used. The sol- gel process uses chemical **sol**utions or colloidal suspensions, which are shaped into fibers, then **gel**led (usually by drying) and heat treated to convert the gelled precursor to ceramic. In the case of fibers based on SiC and silicon nitride, fibers are spun from organometallic "preceramic" polymer precursors, followed by cross- linking (curing) and heat treatment steps to convert the fibers to ceramic materials (Ref 5). The use of chemical precursor technology allows the commercial preparation of ceramic fibers with properties not accessible by traditional fiber- forming technology, such as spinning of molten glasses. A key characteristic of ceramic fibers is their ultrafine microstructure, with grain sizes sometimes in the nanometer range. Fine grains are required for good tensile strength (>2000 MPa, or 300 ksi), but can be detrimental to creep resistance (Ref 6). The precursor processes also allow fiber production in the form of continuous- length multifilament tows or rovings, which are typically coated with a thin polymer-based sizing and then supplied to customers on spools. These sized tows are flexible and easily handled so that they can be woven or braided into fabrics, tapes, sleeves, and other complex shapes. Most small- diameter fiber manufacturers also supply fibers in fabric form since composite-fabrication processes generally require an initial step of fabric stacking and near-net shaping into final product forms. Continuous-length monofilaments of single-crystal Al_2O_3 and polycrystalline SiC with diameters >50 μm are also commercially available. Although employed to reinforce both metal and ceramic composites, they are limited in their flexibility, shapeability, and affordability, and thus are considered here mainly for property comparison.

Composite Applications

Applications for oxide-based fibers take advantage of their oxidation resistance, moderate temperature capability (to 1100 °C, or 2000 °F), chemical stability, and relatively low cost. Many oxide-fiber CMC do not require interfacial fiber coatings or composite overcoatings for debonding; instead, composite toughness is generated by crack deflection in porous oxide matrices. This provides an additional cost benefit, but may limit temperature capability in order to avoid matrix sintering. Although displaying a lower toughness to surface flaws and surface coatings, oxide-based fibers are preferred over nonoxide reinforcements in corrosive environments such as in waste incineration, hot gas filtration, certain heat exchanger applications, and metal-matrix composites (especially aluminum). In addition, oxide fibers have major commercial uses in high-temperature thermal insulation applications requiring flexible, lightweight, and oxidation-resistant continuous

fibers, such as sleeves for pipes and electrical cables, high-temperature shielding, belts, blankets, and gasket seals. The cost of most small-diameter oxide fibers ($200–1000/kg) is higher than that of glass and carbon fibers, but lower than that of SiC fibers ($1,000–13,000/kg).

Applications for nonoxide SiC-based fibers typically center on CMC for high-temperature structural applications (>1100 °C, or 2000 °F), where lower creep and grain-growth rates in comparison to oxide fibers allow better dimensional stability and strength retention under the combined conditions of temperature and stress. The SiC-based fibers can also provide greater thermal and electrical conductivity, higher as- produced strength, and lower density. However, under oxygen-containing environmental conditions, the exposed surfaces of silicon-based fibers will degrade slowly due to silica growth and surface recession. However, silica is among the most protective of scales, so that, in a general sense, SiC has very good oxidation resistance. It follows then that SiC-based fibers are generally preferred for CMC applications that require both long-term structural service under environmental conditions that minimally expose the fibers to oxygen, and upper-use temperatures higher than possible with oxide/oxide CMC and state of the art metallic superalloys. Minimal oxygen exposure is typically achieved by incorporating the fibers in dense protective matrices of similar composition and thermal expansion, such as in SiC/SiC composites. Extensive developmental efforts are underway to use these SiC/SiC CMC in land- and aero-based gas turbine engines for hot-section components that require service for thousands of hours under combustion gas environments.

Ceramic Fibers

Properties of Commercial Fibers

Commercial oxide fibers can be divided into two compositional classes: (1) alumina-silica fibers, that is, those consisting of a mixture of transition alumina and amorphous silica, and (2) alumina fibers consisting primarily of α- Al_2O_3. As indicated in Table 1, these two classes contain a variety of fiber types from different manufacturers, with substantially different as- produced microstructures and properties. In general, the alumina-silica fiber types display lower strength, modulus, thermal expansion, and density than the fibers based on α-Al_2O_3. The higher strength and modulus plus the superior thermochemical stability of the more crystalline α- Al_2O_3 fibers make them the preferred oxide candidates for the reinforcement of metal- and ceramic-matrix composites. However, the moderate strength and lower stiffness of the alumina- silica fibers allow better strain to failure and flexibility, both very important properties for the use of textile-grade fibers in thermal insulation applications.

RT, room temperature.

(a) A, alumina; S, silica

In the alumina-silica fibers, alumina is present as transition aluminas (η-Al_2O_3 or γ-Al_2O_3). Because transition aluminas have very fine grain size (10–100 nm), these fibers have good strength. Commercial alumina-silica fibers contain SiO_2 to preserve the submicrometer transition alumina microstructure and therefore fiber strength and flexibility for extended periods above 1100 °C (2000 °F). However, SiO_2 remains as an amorphous glassy phase; this can compromise chemical stability and creep properties at high temperature. Above 1200 °C (2200 °F), alumina-silica fibers will crystallize over time to form either mullite ($3Al_2O_3{\cdot}2SiO_2$) or α- Al_2O_3, which commonly results in large grains and low fiber strength. Nextel 440 ceramic oxide fibers, which contain 2 wt% B_2O_3, do not degrade during the crystallization to mullite. B_2O_3 promotes the formation of fine-grained mullite via a $9Al_2O_3{\cdot}2B_2O_3$ intermediate phase. However, B_2O_3 increases fiber creep rate and can also increase reactivity and therefore strength degradation with certain matrices.

In comparison to fibers containing transition aluminas and amorphous silica, fibers containing crystalline α-Al_2O_3 are more resistant to shrinkage at high temperatures caused by crystallization and sintering and can have higher creep resistance under load at high temperatures. The chemical stability of α-Al_2O_3 fibers reduces reactivity with oxide matrices, providing much higher strength in porous matrix composites. Nextel 720 fiber, although it contains 15 wt% SiO_2, can be considered to be based on α-Al_2O_3 because it contains greater than 50 vol% of α-Al_2O_3. Thus it has a much higher modulus, chemical stability, and creep resistance compared with the alumina-silica fibers discussed previously. Saphikon, which is a melt-grown single-crystal Al_2O_3 monofilament, has the highest as-produced strength (3500 MPa, or 500 ksi) and does not creep until well above 1400 °C (2600 °F). However, unlike polycrystalline fibers, the strength of Saphikon fiber decreases substantially at moderate temperatures (e.g.,

below 500 °C, or 900 °F) due to environmentally assisted slow crack growth. For applications with thermal gradients, one disadvantage of the α-Al_2O_3 fibers is their high thermal expansion and low thermal conductivity (<5 W/m · K), which can result in high thermal stresses.

Commercial Nonoxide (SiC-Based) Fibers. Table 2 lists some key technical details related to the microstructure and properties of a variety of SiC-based fiber types of interest for CMC reinforcement. These types range from fibers with very high percentages of oxygen and excess carbon, such as Nicalon and Tyranno Lox M, to the near-stoichiometric (atomic C/Si ≈ 1) fibers, such as Sylramic. These large compositional differences not only impact chemical and thermostructural properties, but also result in a large variation in electrical properties (Ref 5). Because of their high production costs and need to be protected from oxidizing environments, SiC- based fibers have yet to reach the market status enjoyed by oxide fibers, which also have applications outside of structural composites (e.g., high-temperature thermal insulation). For sake of completeness, Table 2 also includes some nonoxide carbon-based fibers that also have been used for CMC reinforcement. Typically the carbon fibers are very low in cost and display the best intrinsic behavior of all fiber types, particularly regarding intrinsic thermal stability, creep resistance, and as-produced tensile strength. However, under oxidizing conditions, the exposed surfaces of carbon fibers quickly convert to gas at temperatures as low as 400 °C (750 °F). Thus these fiber types have only been considered for CMC that are well protected from oxidizing service conditions by matrices and/or external composite coatings and that are required to experience these conditions for relatively short times. Ceramic composites such as C/SiC are typically targeted for high-temperature applications of short duration in oxygen, such as brake pads and structural components in advanced space-propulsion systems.

RT, room temperature

The primary process methods used to produce SiC-based fibers with small (<20 μm) and large (>50 μm) diameters are polymer pyrolysis and chemical vapor deposition (CVD), respectively. For the polymer route, precursor fibers typically based on polycarbosilane are spun into multifilament tows, which are then cured and pyrolzed to form strong fibers at process temperatures up to ~1200 °C (2200 °F). This maximum process temperature is dictated by the fact that during the early fiber production steps, a small amount of oxygen can be unwontedly introduced into the fiber microstructure. This results in oxide-based impurity phases that, in the presence of carbon and carbides, tend to decompose into gases that leave the fiber above 1200 °C (2200 °F), thereby creating porosity and less than optimal fiber tensile strength (Ref 5). Because it is often desirable to fabricate and use CMC for long times above 1200 °C (2200 °F), advanced process methods that limit the oxide phases have recently been developed. In one method, the oxygen pickup is reduced, for example, by curing under electron irradiation (Hi-Nicalon and Hi-Nicalon-S). In another method, any oxide-based impurities are allowed to decompose at higher temperatures, and then the remaining SiC grains are sintered into strong fibers that are dense, oxygen-free, and nearly stoichiometric. For example, to form the Tyranno SA and Sylramic fiber types, aluminum and boron sintering aids are introduced, respectively, into the fibers prior to pyrolysis in order to facilitate fiber densification during excursions to process temperatures greater than 1700 °C (3100 °F). In comparison to the pyrolyzed fibers, the final sintered fibers usually contain larger grains that are beneficial for improved fiber creep resistance and thermal conductivity. For the Sylramic fiber, creep and oxidation resistance are further improved when the boron sintering aids are reduced by a postprocess thermal treatment to form the Sylramic-iBN fiber that contains a thin in situ BN coating on the fiber surface (Ref 7).

Stoichiometric SiC fibers with high strength, thermal conductivity, and creep resistance can also be produced by the CVD route, which typically uses methyl-trichlorosilane to vapor deposit fine columnar-grained (~100 nm long) SiC onto a small-diameter (~30 μm) continuous- length carbon monofilament (Ref 1). Chemical vapor deposited-SiC fibers on small-diameter (~13 μm) tungsten monofilaments are also commercially available, but due to high-temperature reactions between the SiC and tungsten, these fibers are more suitable as reinforcement of metal-matrix composites for low- and intermediate-temperature applications. Although the CVD-SiC fibers have displayed very high strengths (~6000 MPa, or 900 ksi, for the Ultra SCS fiber), the final fibers are monofilaments with diameters greater than 50 μm. Laboratory attempts have been made to reduce their diameters and to produce multifilament tows, but issues exist concerning finding substrate filaments with the proper composition and diameter, methods for spreading these filaments during deposition to avoid fiber-to-fiber welding, and low- cost gas precursors for the CVD-SiC.

Fibers for High-Temperature CMC Applications

With increasing temperature, ceramic fiber properties such as elastic modulus and thermal conductivity decrease slowly in a monotonic manner, so that the room-temperature values for these properties in Tables 1 and 2 represent, in a relative manner, how these fiber types differ across a wide temperature range. Fiber strength follows the same trend of a slow monotonic decrease with temperature up to about 800 and 1000 °C (1500 and 1800 °F) for polycrystalline oxide and SiC-based fibers, respectively. However, above these temperatures, factors such as composition, grain size, impurity content, and prior thermostructural history have a significant impact on rate of fiber strength degradation with time and temperature. This strength behavior is typical of the time-dependent fracture of monolithic ceramics in which as-produced flaws grow slowly in size (slow crack growth) at elevated temperatures; whereas creep mechanisms aid in the more rapid growth of the same flaws or in the nucleation and growth of new microcracks and cavities at higher temperatures.

Currently, pure and stoichiometric SiC fiber types with grain sizes of ~0.2 μm provide the best combination of low- and high-temperature tensile strength (Ref 6).

To better understand fiber thermostructural capability over a long time period, one can examine literature data that show the effects of temperature, time, stress, and environment on the creep and fracture behavior of various fiber types of CMC interest (Ref 7, 8, 9, 10, and 11). In general, the maximum temperature/time/stress capability of the more creep-prone fibers is limited by the fiber tendency to display excessive creep strains (>1%) before fracture. On the other hand, the temperature/time/stress capability of the more creep-resistant fibers is limited by fiber fracture at low creep strains (<1%), the values of which are often dependent on the environment. These limitations are illustrated in Tables 3 and 4, which show the approximate upper-use temperatures of some commercial oxide and SiC fibers, respectively, as determined from simple stress- rupture measurements on single fibers. These upper-use temperatures were determined by using the available data for fiber creep and fracture time versus stress and temperature, and the assumption that the maximum temperature-limiting condition occurred either when the fiber creep strain exceeded 1% in 1000 hours or when the fiber fractured in 1000 hours. Fiber stresses of 100 and 500 MPa (15 and 70 ksi) were assumed, which are typical of the range of stresses experienced by fibers within structural CMC. A "not applicable" (NA) notation in the tables indicates that the more creep-resistant fibers fractured before reaching a creep strain of 1%. Figure 1 compares the estimated 1000 h upper-use temperatures for all the ceramic fibers based on single fiber fracture as measured at 500 MPa (70 ksi) in air.

(a) For ~25 mm (1 in.) gage length.

Source: Ref 6, 7, 8, and 9

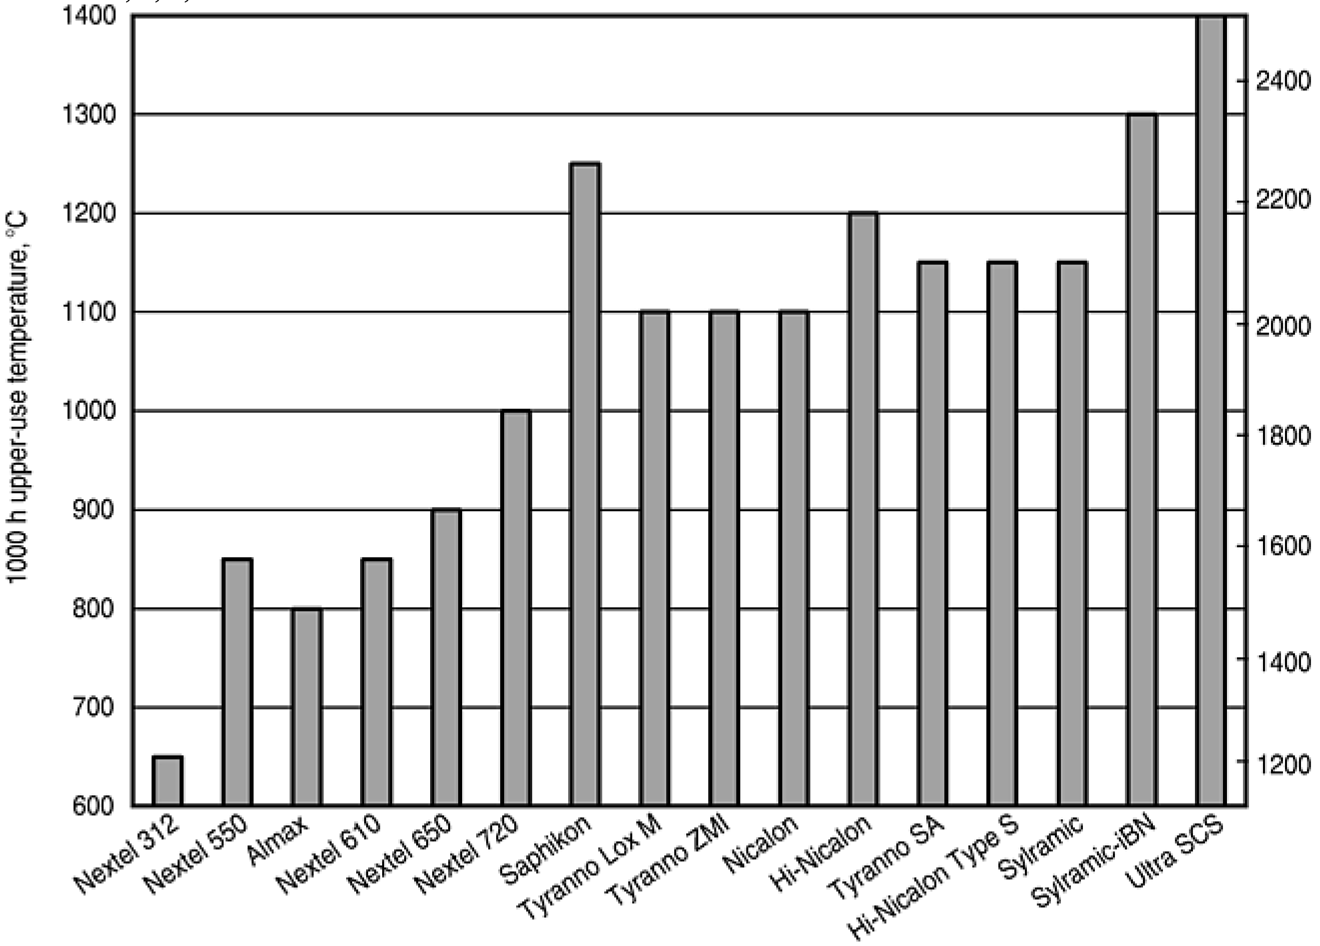

Fig. 1 Estimated 1000 h upper-use temperatures for small- and large-diameter ceramic fibers based on the fracture of single fibers measured at 500 MPa (70 ksi) in air at 25 mm (1 in.) gage length

For the oxide fibers tested in air, Table 3 shows Nextel 312 has the lowest thermostructural capability due to its high content of noncrystalline phases. The maximum capability of the Altex and Nextel 550 fibers, both alumina- silica fibers, and the α-Al_2O_3 Nextel 610 and Almax fibers are similar; while Nextel 650 fiber and Nextel 720 fiber display the best thermostructural capability of all the commercially available polycrystalline types. Nextel 650 fiber, which contains yttria-stabilized zirconia as a second phase, benefits primarily from the Y^{3+} dopant, which has been shown to slow diffusion and creep in Al_2O_3 (Ref 12, 13). Nextel 720 fiber, on the other hand, benefits from a high content of mullite, a highly creep-resistant oxide compound, and from a unique crystalline structure of interpenetrating phases that reduces creep by grain boundary sliding (Ref 14). The highest- performing oxide fiber is the Saphikon single crystal fiber, which has no measurable creep in the *c*-axis orientation below 1400 °C (2600 °F), but suffers from high-temperature diffusion-controlled crack growth (Ref 9).

Table 4 shows the approximate upper-use temperatures for commercial SiC fibers as determined from single fiber testing up to 1400 °C (2600 °F) under air and argon environments. These upper-use temperatures, when compared to those of Table 3, clearly indicate the greater thermostructural capability of the SiC fibers over the oxide-based fibers (see also Fig. 1). Although the stoichiometric and purer SiC fiber types display the best capability, some of these fiber types display better behavior in air than argon, with the Sylramic fiber types showing the largest difference. The improved capability in air can be attributed in part to a measurable reduction in intrinsic creep rate for some fiber types (Ref 7), andin part to the formation of a thin silica layer on the fiber surface. This layer minimizes vaporization of thermally unstable phases and, by blunting surface flaws, increases the creep-rupture strain of all fiber types by ~100%. For CMC service under oxidizing conditions, this environmental effect can be important, because air may be the effective fiber environment if the CMC matrix is cracked and inert gas the environment if the matrix is uncracked. Another important observation from Tables 3 and 4 and Fig. 1 is that the fracture-limited upper-use temperatures of the more creep-resistant fibers are not measurably better than those of their more creep-prone counterpart fibers; for example, compare Nextel 650 versus Nextel 610, Hi-Nicalon type S versus Hi-Nicalon, and Tyranno SA versus Tyranno Lox M.

Future Directions

Because of their low atomic diffusion and high thermal conductivity, pure stoichiometric SiC fibers are the preferred reinforcement for CMC products that are required to operate for long times at temperatures greater than state of the art metal alloys (>1100 °C, or 2000 °F). While reduction in production costs and improvement in high-temperature thermal conductivity and fracture life are high-priority developmental issues for future SiC-based fibers, another important issue is improvement of the fiber surfaces against oxygen attack. In this area, possibilities exist for the development of oxidation-resistant fiber coatings that are deposited on tows after fiber processing, or better yet in terms of cost reduction, are formed in situ during fiber production or service. Some of the developmental fibers, such as the Hi-Nicalon-type fibers coated with CVD-BN from Nippon Carbon (Ref 15) and the in situ BN-coated fibers from the University of Florida (Ref 16) and Bayer Company (Ref 17), are moving in these directions. These coating approaches should also be beneficial for reducing fiber abrasion and strength degradation during the complex weaving and braiding processes typically needed for some CMC products.

Although the creep resistance of oxide fibers is inferior to SiC-based fibers, recently developed oxide fibers have demonstrated adequate creep resistance for use in structural composites up to 1100 °C (2000 °F). Further increases in temperature capability are possible. The use of dopants (e.g., Y^{3+} in Nextel 650 fibers) has been shown to provide a promising route to improved high-temperature capability in oxide fibers. Another fertile area for research is the development of fine-grained, fully crystalline fibers of creep- resistant multicomponent oxides such as yttrium-aluminum-garnet (YAG) and mullite. Both YAG and mullite fibers have been developed at several laboratories (Ref 8, 18) and have exhibited even better creep resistance than Nextel 720 fibers. The

advantages of environmental stability and low cost will continue to provide incentive for further improvements in high-temperature properties of oxide fibers.

Discontinuous Reinforcements for Metal-Matrix Composites

Cory A. Smith, DWA Aluminum Composites

Introduction

DISCONTINUOUSLY REINFORCED METAL-MATRIX COMPOSITES (DRMMCs) are commonly used today in many aerospace and industrial applications. They offer a wide range of attractive material properties, both mechanical and physical, that cannot be achieved using conventional engineering alloys. These enhanced materials properties are the direct result of the interaction between the metallic matrix and the reinforcement. This article focuses on the production of particulate reinforcements used in DRMMC materials systems, their physical and materials properties, and the particle shape and overall morphology.

Cory A. Smith, DWA Aluminum Composites

Reinforcement Roles

In a DRMMC materials system, the reinforcement strengthens the metal matrix both extrinsically, by load transfer to the ceramic reinforcement, and intrinsically, by increasing dislocation density (Ref 1). The interaction between the particulate reinforcement and the metallic matrix is the basis for the enhanced physical and materials properties associated with DRMMC materials systems. Composite materials properties can be tailored to meet specific engineering requirements by selecting a particular reinforcement and varying the amount added to the metal matrix. In this fashion, the physical and mechanical properties of the composite materials system can be controlled with some independence. Increasing the reinforcement volume in a composite system increases mechanical properties, such as elastic modulus, ultimate strength, and yield strength, while reducing the thermal expansion and, in some cases, the density of the composite system. Unfortunately materials properties such as ductility and fracture toughness typically decrease with increasing reinforcement volume.

The increase in both the elastic modulus and strength (ultimate and yield) is believed to be due to the difference in thermal expansion between the ceramic reinforcement particles and the metallic matrix during processing. During the production of these composites, both the reinforcement and matrix are heated to processing temperature, brought to thermomechanical equilibrium, and then allowed to cool. The thermal contraction of the metallic matrix during cooldown is typically much greater than that of the reinforcement, which leads to a geometric mismatch. At the ceramic-metal interface, this geometrical disparity creates mismatch strains that are relieved by the generation of dislocations in the matrix originating from sharp features on the ceramic reinforcement.

Discontinuously reinforced metal-matrix composite materials systems are commonly used in applications that require high specific materials properties, enhanced fatigue resistance, improved wear resistance, controlled expansion, or the ability to absorb neutron radiation (boron carbide). Additionally, DRMMC may be designed to yield a materials system that offers multiple roles. Some examples of multiple roles are DRMMC materials systems that offer high strength and fatigue resistance for aerospace and mechanical applications, thermal management coupled with expansion control for space-borne applications, moderate strength and neutron absorption capabilities for nuclear applications, high strength and wear resistance for heavy equipment applications, and impact/energy dissipation for armor applications. The correct selection of reinforcement is very important in yielding desired resultant materials properties. An improper reinforcement selection may lead to less-than-desirable composite materials properties, difficulty in fabrication of end product, and high cost.

DRMMC Reinforcements

The most common DRMMC materials systems used for current aerospace structural applications are silicon carbide (SiC) and boron carbide (B_4C) particulate reinforcement in an aluminum alloy matrix. Aluminum oxide particles are a lower-cost alternative most commonly used for casting applications. Titanium carbide is being investigated for high-temperature applications. Table 1 lists the mechanical and physical properties of various ceramic reinforcements commonly used in

the manufacture of modern DRMMC materials systems. Table 2 lists the characteristics for commonly used reinforcements.

FEPA, Federation of the European Producers of Abrasives

Silicon Carbide. Discontinuously reinforced metal-matrix composite materials systems based on SiC are the most commonly used and most mature at this time. The benefits of using SiC as reinforcement are improved stiffness, strength, thermal conductivity, wear resistance, fatigue resistance, and reduced thermal expansion. Additionally, SiC reinforcements are typically low- cost and are relatively low-density. Figure 1 shows the size distributions for commonly used SiC grits ranging from F1500 to F360. The "F" nomenclature is defined by Federation of the European Producers of Abrasives (FEPA) standards, which govern abrasive grit-size distributions in Europe.

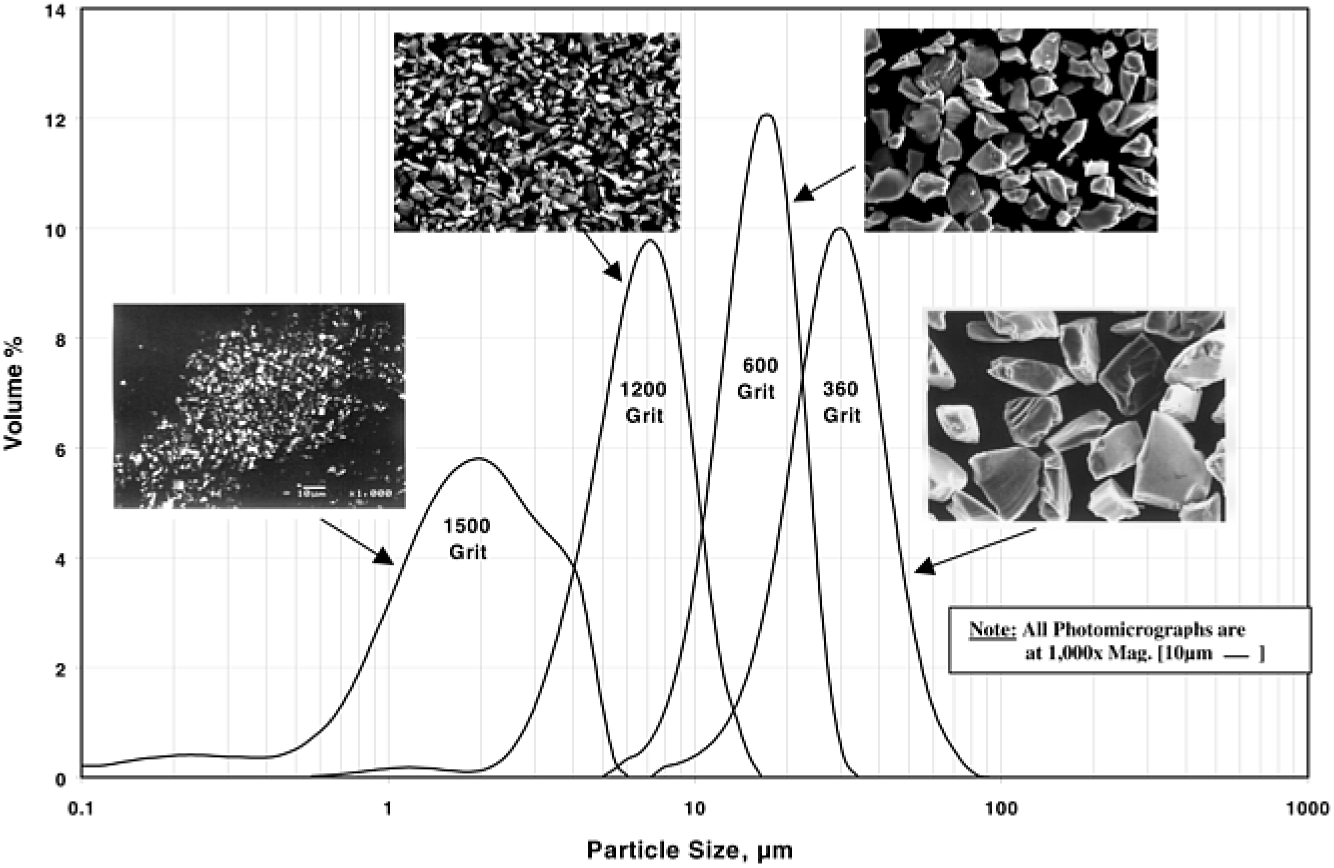

Fig. 1 Variation in particle size distribution and morphology as a function of grit size for F1500, F1200, F600, and F360 grit SiC powders

The production of SiC was first reported by Berzelius in 1810 and again in 1821. It was later rediscovered during various electrothermal experiments by Despretz in 1849 and Marsden in 1881. However, Acheson was the first to recognize its potential industrial importance. Acheson applied electric current through a mixture of powdered coke and clay and found that the carbon electrode was covered in hard, shiny crystals. Acheson later discovered that these crystals had much better abrasive properties than the emery powder that was in general use at the time. As a result, he founded the Carborundum Company in 1891 for the production of SiC. An important development in the production of SiC in resistance furnaces came in 1972 to 1974, when Elektroschmelzwerk Kempten (ESK) developed a furnace that collected reaction-produced gases and used them for energy production and, in doing so, contributed to environmental protection (Ref 2).

Silicon carbide is produced industrially from silicon dioxide and carbon, which reacts as follows:

$$SiO_2 + 3C \rightarrow SiO + 2CO \qquad \text{(Eq 1)}$$

The reaction is strongly endothermic, with the enthalpy change, ΔH= 618.5 kJ/mol (4.28 kW · h/kg) (Ref 3). The reaction takes place in several stages:

$$SiO_2 + C \rightarrow SiO + CO \qquad \text{(Eq 2)}$$

The initiation reaction follows Eq 2 and is thermodynamically possible above 1700 °C (3100 °F), beginning when the SiO_2 melts. The next stages are:

$$SiO + C \rightarrow Si + CO \quad \text{(Eq 3)}$$

$$Si + CO \rightarrow SiC \quad \text{(Eq 4)}$$

The SiC is formed as an encrustation on the carbon grains, ultimately causing the reaction to cease. The SiC then further reacts:

$$SiC + 2SiO \rightarrow 3SiO + CO \quad \text{(Eq 5)}$$

$$SiC + SiO \leftrightarrow 2Si(g) + CO \quad \text{(Eq 6)}$$

where Eq 6 is the equilibrium reaction and is mainly responsible for the formation of large SiC crystals. The yield and quality of the SiC are seriously affected by any impurities present in the raw materials. Therefore, high-purity raw materials must be used.

Particle size and shape are important factors in determining materials properties. Fatigue strength is greatly improved with the use of fine particles, and the uniform distribution of reinforcement is improved by matching the size of the reinforcement to the size of the matrix particles. Figure 2 illustrates the benefit to uniformity of particle distribution of selecting the proper reinforcement size for the matrix powder being used. Figure 3 summarizes the effect of variation in particle size on several composite properties.

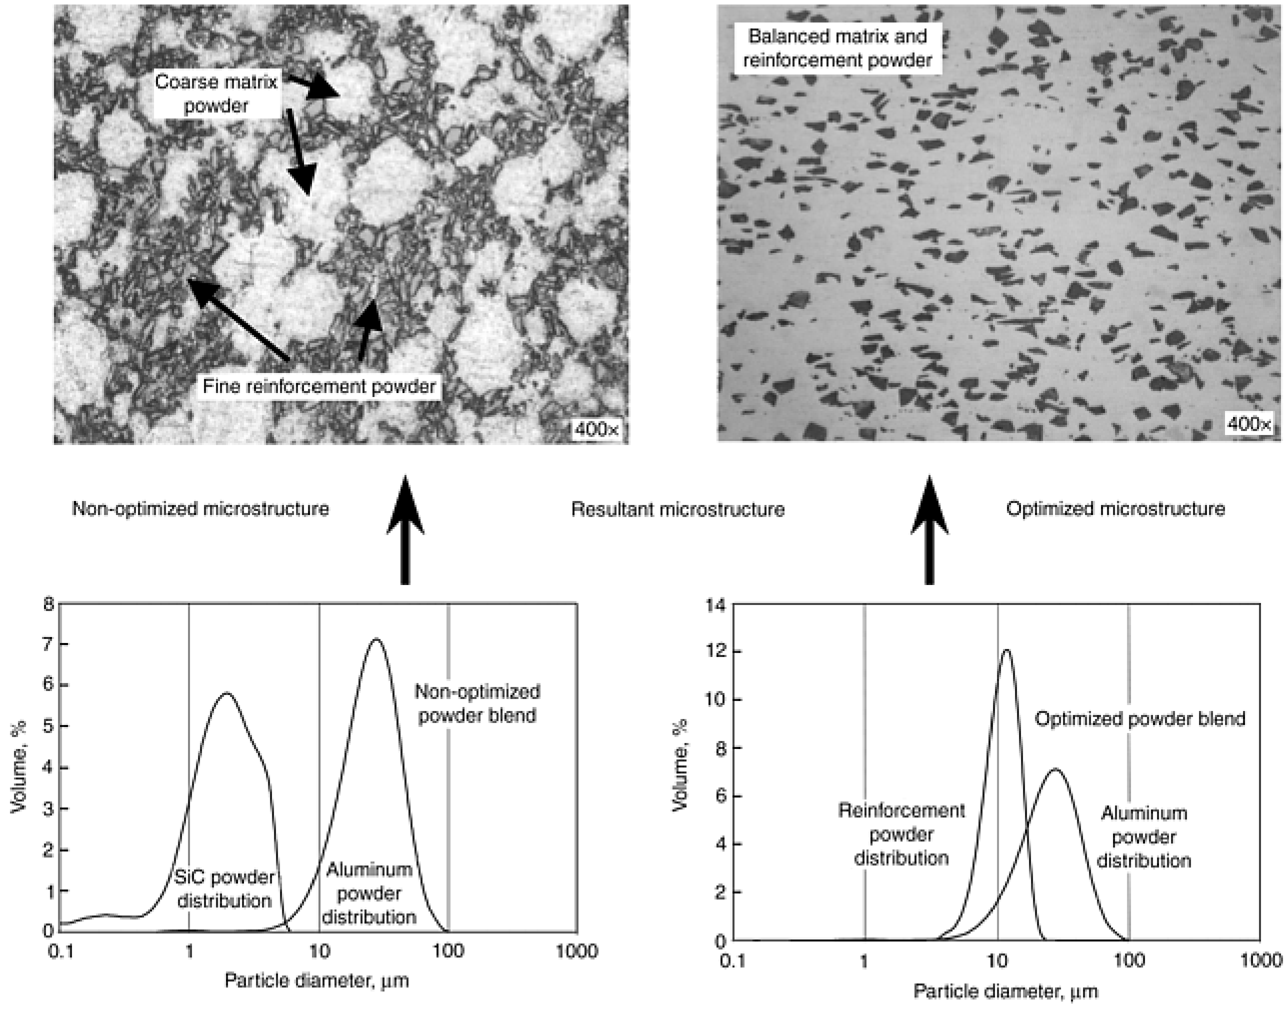

Fig. 2 Effect of microstructure optimization for 20 vol% SiC discontinuously reinforced aluminum metal-matrix composites

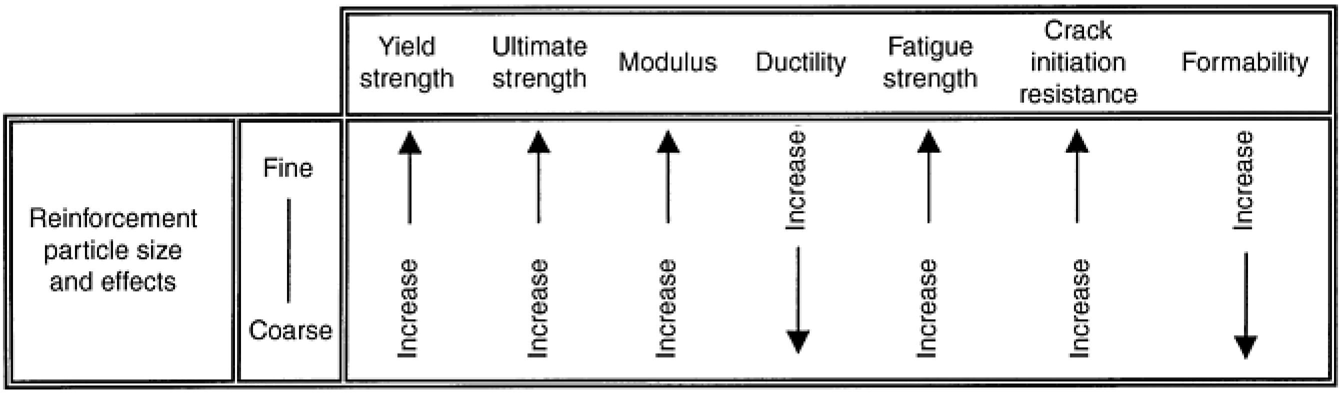

Fig. 3 Materials properties and formability as a function of reinforcement particle size

The shape of a particle is characterized by its aspect ratio, the ratio of its longest to shortest linear dimension. Most ceramic reinforcement particles have a low aspect ratio, being blocky with sharp edges. They are easy to produce by simple milling and therefore comparatively inexpensive, yielding composites with approximately isotropic properties. Whiskers and platelets are particles with higher aspect ratios. Figure 4 shows a high-aspect-ratio SiC particle. Although they are typically more expensive and harder to work with than the blocky particles, high-aspect-ratio particles are used when anisotropic properties are desired, concentrating the benefits of the reinforcement into a limited direction.

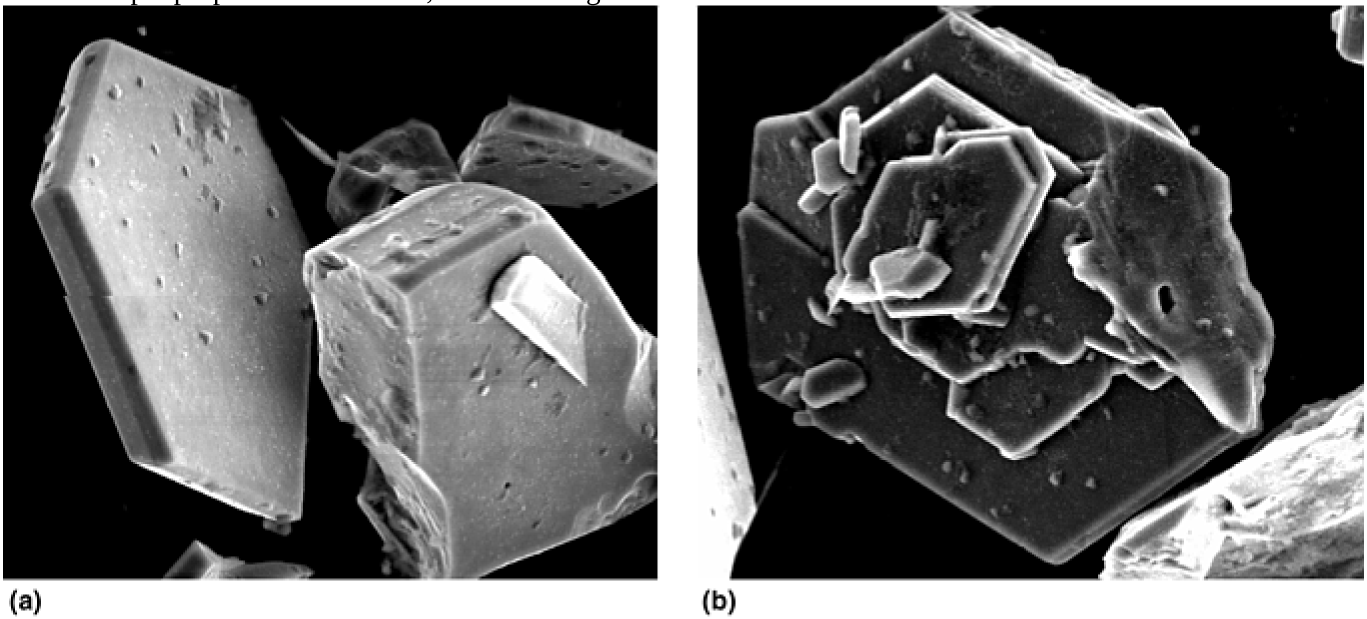

Fig. 4 Silicon carbide platelet reinforcement showing the basal plane morphology in the β phase. 1000×

Boron carbide is a commonly used reinforcement when low composite density is important, when low reactivity with the matrix is needed, and when neutron absorption is required. Figure 5 shows the morphology for B_4C particulates at 1000× (Fig. 5a) and at 5000× (Fig. 5b). When anisotropic composite properties are necessary, B_4C whiskers are used (Fig. 6). This form is expensive and rarely used. Some naturally occurring boron atoms (B^{10}) have a high neutron-absorption cross-section area. Consequently, B_4C, having four boron atoms per structural unit, is an important reinforcement for use in nuclear containment applications. Boron carbide is more inert in the presence of aluminum at high temperatures than is SiC. Its nonreactivity makes it more suitable for applications involving welding or casting.

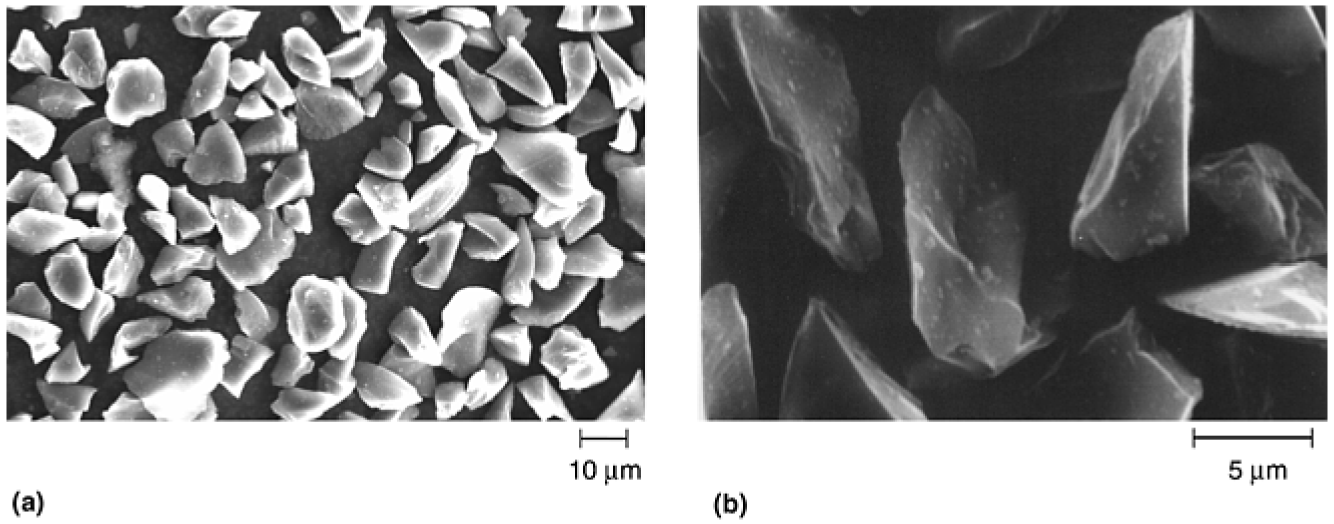

Fig. 5 Inherent morphology of B_4C particulate. (a) 1000×. (b) 5000×

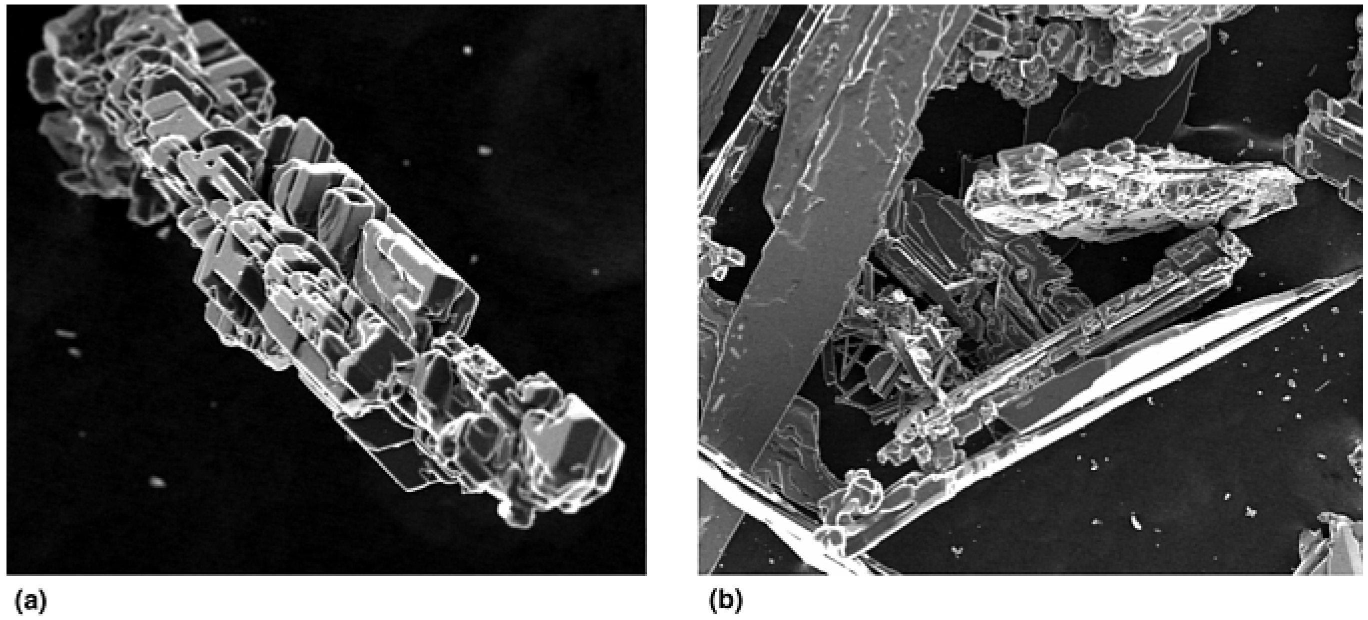

Fig. 6 Boron carbide whisker reinforcement, showing polycrystalline microstructure for different whisker morphologies. (a) 200×. (b) 100×

The large-scale production of B_4C is based on the carbothermic reaction of boric acid:

$$2B_2O_3 + 7C \rightarrow B_4C + 6CO \quad \text{(Eq 7)}$$

The reaction is strongly endothermic, producing 1812 kJ/mol (9.1 kW · h/kg), and is usually carried out at 1500 to 2500 °C (2700 to 4500 °F) in an electric furnace, as in the case of SiC. The starting mixture is an intimate mixture of boric acid and carbon (petroleum coke or graphite). Large quantities of carbon monoxide (2.3 m^3/kg) are generated, and boron can be lost to evaporation of boric acid at high temperatures. In an electrothermic process used by ESK, the product is cooled and the unreacted outer-zone material is removed to leave a fused coarse-grained B_4C of high purity. This B_4C is obtained in the form of regular blocks, which are broken up and milled to produce the B_4C grain size appropriate for final use. Additionally, B_4C of high purity is produced by other methods. These include the magnesiothermic reaction of magnesium and boric acid in the presence of carbon:

$$2B_2O_3 + 6Mg + C \rightarrow B_4C + 6MgO \quad \text{(Eq 8)}$$

synthesis from elements:

$$(4 + x)B + C \rightarrow B_{4+x}C + C \quad \text{(Eq 9)}$$

the reduction of boron trichloride by hydrogen in the presence of carbon:

$$4BCl_3 + 6H_2 + C \rightarrow B_4C + 12HCl \quad \text{(Eq 10)}$$

and by chemical vapor deposition:

$4BCl_3(BBr_2) + CH_4 \rightarrow B_4C + 12HCl(Br)$ (Eq 11)

The B_4C whiskers shown in Fig. 6 were produced by chemical vapor deposition.

Aluminum oxide particulate is another ceramic powder commonly used in reinforcement of DRMMC materials systems. The resultant benefits are not as great as some of the previously mentioned reinforcements, that is, SiC and B_4C. Aluminum oxide (Al_2O_3) reinforcement powders possess very low reactivity in molten metal baths (casting) and are relativity low-cost. The resultant composite properties, such as stiffness, strength, and fracture toughness, are not as high as those of either the SiC or B_4C reinforcement. However, the low reactivity and low cost make this reinforcement very attractive for the production of cast metal-matrix composites (MMCs) that require moderate strengths and stiffness improvements while retaining good wear resistance.

Titanium carbide (TiC) is not a widely used ceramic reinforcement powder. However, its inherent high-temperature stability is attractive for use in elevated-temperature applications, where high strength, stiffness, and creep resistance are required. This reinforcement is used primarily in titanium- and nickel-base alloy MMC materials systems that require stability at very high temperatures (up to 1100 °C, or 2000 °F). In these applications, all previously discussed reinforcements would rapidly react into brittle intermetallics, leading to less-than-desirable MMC properties. The use of this reinforcement comes at a price: TiC is very dense when compared to SiC, B_4C, and Al_2O_3 and, as a result, tends to be used only when very demanding high-temperature composites are necessary. The tensile strength of 20 vol% TiC in a matrix of nickel- base 718 alloy has been shown by DWA Aluminum Composites to be greatly improved over that of the monolithic 718 alloy between temperatures of 650 and 1100 °C (1200 and 2000 °F). It is also believed by current investigators to provide enhanced creep resistance. Iron-base materials systems reinforced with TiC are the best candidates for extrusion dies, where extremely high strength and wear resistance are necessary at elevated temperatures, such as extrusion of DRMMC materials systems.

Reinforcement Chemistry

When designing DRMMC materials systems, care must be taken to distinguish between the bulk chemistry and the surface chemistry of the reinforcement. The bulk chemistry describes the crystalline interior and controls the overall resultant materials properties. Typically, higher- purity ceramic powder yields higher composite performance, usually with higher raw material costs. In the case of surface chemistry, the composite designer must consider the contribution of incidental elemental additions to the overall DRMMC system. For example, SiC powders typically possess both silicon dioxide (SiO_2) and elemental silicon (Si) on their surfaces. If the concentration of these two species is high enough, the targeted DRMMCs chemistry may exceed alloy composition limits. Boron carbide reinforcements are affected in the same manner with contributions of free carbon, boron, and boric acid. The same is true for most available ceramic reinforcements widely used today.

Discontinuous Reinforcements for Metal-Matrix Composites

Continuous Fiber Reinforcements for Metal-Matrix Composites

Colin McCullough, 3M Company, Electrical Products Division

Introduction

FOR THE REINFORCEMENT of metal- matrix composites (MMCs), four general classes of materials are commercially available: oxide fibers based primarily on alumina and alumina- silica systems, nonoxide systems based on silicon carbide, boron fibers, and carbon fibers. Two general fiber forms are available: tow-based fibers that are typically small diameter (<20 μm) multifilament rovings or tows and monofilaments that are generally large diameter. The final choice of fiber for any composite system is governed not only by performance aspects, but also by the compatibility of the fiber with the matrix metal, the composite fabrication process, the handling character of the fiber and the mechanical requirements of the fiber/matrix interface. Note that metal fibers such as steel and tungsten are also used for reinforcing metals, but that in this article the topic is limited to nonmetallic fibers.

Composite applications take advantage of various properties of the fiber. The most common are high tensile strength, high tensile modulus, low coefficient of thermal expansion, and low density. The four general classes of fibers are discussed in the sections that follow.

Aluminum Oxide Fibers

Today the most common approach for producing polycrystalline tow-based ceramic fibers is by spinning and heat treating chemically derived precursors, which in the case of oxide fibers are sol-gel precursors. The use of chemical precursor technology allows the commercial preparation of ceramic fibers with properties not accessible by traditional fiber-forming technology, such as spinning of molten glasses. Traditional slurry processing methods can also be used to spin fibers (Almax, FP). A key characteristic of ceramic fibers is their ultrafine microstructure with grain sizes sometimes in the nanometer range. Fine grains are required for good tensile strength (>2 GPa, or 290 ksi). These processes also allow fiber production in the form of continuous-length multifilament tows or rovings, which are typically coated with a thin polymer-based sizing and then supplied to customers on spools. These sized tows are flexible and easily handled so that they can be woven or braided into fabrics, tapes, sleeves, and other complex shapes. Most small-diameter fiber manufacturers also supply fibers in fabric form. Further discussion of these tow-based alumina fibers can be found in the article “Ceramic Fibers” in this Volume.

Monofilament alumina is available as a 125 μm diam single-crystal fiber, which is grown directly from the molten oxide (Ref 1). This fiber has been studied for reinforcing some of the intermetallic-matrix composites such as titanium aluminides and nickel aluminides (Ref 1).

Key properties of commercially available fibers are listed in Table 1. Tow-based alumina fibers are used extensively for aluminum alloy reinforcement, and while generally nonreactive with molten aluminum there is the danger of a degrading reaction with alloying elements in some aluminum alloys (e.g., those containing magnesium) (Ref 2). These fibers are used principally where low density, high tensile and compression strengths, and high stiffness are desired in the composite. Additionally, good off-axis properties result from the strong bonding between aluminum and alumina, and the chemical stability of the fiber aids in producing good elevated-temperature properties (Ref 3).

Silicon Carbide Fibers

For fibers based on silicon carbide (SiC), the most common approach for producing polycrystalline tow-based ceramic fibers is by spinning and heat treating chemically derived precursors based on polymer precursors. As with the alumina-based tow materials, fine grain sizes are produced that promote high strength, and the ability to make multifilament rovings permits woven, braided, and fabric fiber forms. The multifilament form of SiC has been used to reinforce aluminum alloys (Ref 4). Further discussion of these tow-based fibers can be found in the article "Ceramic Fibers" in this Volume.

There are also commercially available forms of monofilament SiC. These are made using a continuous chemical deposition process in which a mixture of hydrogen and chlorinated alkyl silanes are reacted at the surface of a heated substrate wire. The substrate (fiber core) can be either tungsten or a spun carbon filament (see Table 2). The bulk fiber then consists of fine- grained β-SiC. Key properties are listed in Table 1. These fibers are used principally to reinforce titanium alloys where the low density, high tensile strength, high stiffness, and elevated-temperature capability offer the potential of great weight savings in high-speed-rotating jet-engine structures. However, to promote good load sharing between fibers in the composite and thus a high tensile strength, a low-strength, lubricious fiber coating is needed to create a "weakly bonded" interface system and additionally to act as a protective diffusion barrier. Table 2 summarizes the coatings for the SiC monofilaments.

Table 2 Coating schemes for SiC monofilament fibers

Fiber	**Diameter, μm**	**Fiber core**	Fiber coating
SCS-6	140	33 μm carbon core	**3 μm carbon layer + graded C-Si layer**
Ultra SCS	140	33 μm carbon core	**3 μm carbon layer + graded C-Si layer**
Trimarc	125	12.5 μm W + C layer	**3 μm carbon layer + $(H\text{-}S\text{-}H)^2$ layer**
Sigma 1140+	100	14 μm tungsten core	**3–5 μm carbon layer**
Sigma 1240	**100**	**14 μm tungsten core**	**1 μm carbon layer + TiB_x layer**

Boron Fibers

Boron fibers are made using chemical vapor deposition. A fine tungsten wire provides a substrate, and boron trichloride gas is the boron source. Continuous production provides for boron filaments of 100 and 140 μm diameter. Key properties are listed in Table 1. Boron fibers have been used principally in reinforcing aluminum alloys where low density, high tensile and compression strengths, and high stiffness result. The bare fiber may be used with solid-state composite forming, but with liquid processing routes the fiber needs to be coated with either B_4C or SiC in order to eliminate reaction with the fiber and the accompanying loss of fiber properties. More expansive coverage of these fibers is provided in the article "Ceramic Fibers" in this Volume.

Continuous Fiber Reinforcements for Metal-Matrix Composites

Colin McCullough, 3M Company, Electrical Products Division

Carbon Fibers

Two classes of carbon fiber, polyacrylonitrile (PAN) and pitch-based fibers, derive quite different structures and properties: the PAN being higher strength, lower modulus with little graphitization of the fiber surface, and the pitch being moderate strength, high modulus with greater levels of surface graphitization. The article "Carbon Fibers" discusses the characteristics of carbon fibers in more detail. Key properties of some carbon fibers are shown in Table 1. The combination of high strength, modulus, low coefficient of thermal expansion, low density, and low cost seemingly make them a desirable choice to reinforce metals. However, structural carbon fibers are still not widely used in MMCs, for example, aluminum and magnesium alloys, despite much research and development activity. Several technical issues remain to be solved, including: the reactivity during composite processing, the reactivity at elevated temperatures, the oxidation resistance of the fiber at elevated temperatures, the corrosion resistance due to the inherent galvanic coupling between carbon and the metal matrix (aluminum or magnesium), and the corrosion resistance related to the leaching of any fiber- matrix reaction products (e.g., aluminum carbide) (Ref 5, 6, 7, and 8).

Carbon fibers have also been used to reinforce copper for thermal-management applications, but the difficulties encountered relate to both the poor bond strength and high wetting angle between carbon and copper, necessitating the use of coatings or reactive elements to increase the bond strength. Generally, the low bond strength between carbon fibers and any of the common metals (aluminum, magnesium, copper) is a difficulty because poor off-axis properties result. In aluminum the pitch fibers appear to be less reactive, but their handling characteristics (high modulus, brittle) make fabrication a more difficult task. Additionally, the high-modulus fibers also have a high thermal conductivity, which makes them attractive for use in combined structural/thermal-management applications.

Continuous Fiber Reinforcements for Metal-Matrix Composites

Colin McCullough, 3M Company, Electrical Products Division

Future Outlook

Future developments in fibers for MMCs are intimately tied up with the successful commercialization of MMCs in general. The properties and performance of the fibers are already good, and wider commercial use of MMCs would help drive the price down by increasing the demand for volume. Technical activity is needed in addressing the interface behavior for system-specific applications and would include both mechanical behavior and chemical stability. This can include surface chemistry of the fiber, fiber coatings, and so on.

Fabrics and Preforms

Introduction

WOVEN MATERIALS, in laminate form, are currently displacing more traditional structural forms primarily because of the availability of fibers (such as carbon and aramid) whose enhanced mechanical properties in composite form surpass the property values of corresponding hardware in aluminum or steel on a strength-to-weight basis.

Woven broad goods, considered to be intermediate forms, present these fibers in a more convenient format for the design engineer, resin coater, and hardware fabricator. The many variations of properties made possible by combining different yarns and weaves allow the structural engineer a wide range of laminate properties. The designer should understand the operation of weaving hardware and textile design details in order to select the best fabric style.

This article describes the types of fabrics and preforms that are used in the manufacture of advanced composites and related selection, design, manufacturing, and performance considerations.

Unidirectional and Two-Directional Fabrics

The fabric pattern, often called the construction, is an *x*, *y* coordinate system. The *y*-axis represents warp yarns and is the long axis of the fabric roll (typically 30 to 150 m, or 100 to 500 ft). The *x*-axis is the fill direction, that is, the roll width (typically 910 to 3050 mm, or 36 to 120 in.). Basic fabric weaves are few in number, but combinations of different types and sizes of yarns with different warp/fill counts allow for hundreds of variations.

The most common weave construction used for everything from cotton shirts to fiberglass stadium canopies is the plain weave, shown in Fig. 1. The essential construction requires only four weaving yarns: two warp and two fill. This basic unit is called the pattern repeat. Plain weave, which is the most highly interlaced, is therefore the tightest of the basic fabric designs and most resistant to in-plane shear movement. Basket weave, a variation of plain weave, has warp and fill yarns that are paired: two up and two down. The satin weaves represent a family of constructions with a minimum of interlacing. In these, the weft yarns periodically skip, or float, over several warp yarns, as shown in Fig. 2. The satin weave repeat is *x* yarns long and the float length is *x*–1 yarns; that is, there is only one interlacing point per pattern repeat per yarn. The floating yarns that are not being woven into the fabric create considerable looseness or suppleness. The satin weave produces a construction with low resistance to shear distortion and is thus easily molded (draped) over compound curves, such as an aircraft wingroot area. This is one reason that satin weaves are preferred for many aerospace applications. Satin weaves can be produced as standard four-, five-, or eight-harness forms. As the number of harnesses increases, so do the float lengths and the degree of looseness and sleaziness, making the fabric more difficult to control during handling operations. Textile fabrics generally exhibit greater tensile strength in plain weaves. This distinction fades in the composites field.

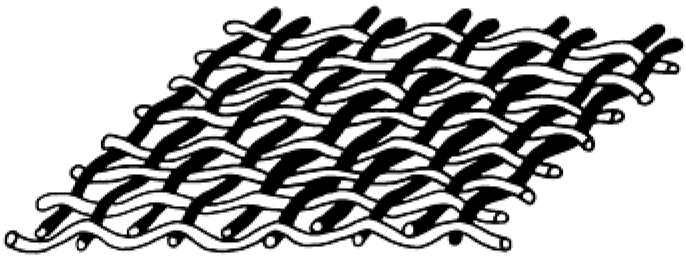

Fig. 1 Plain weave, yarn interlacing

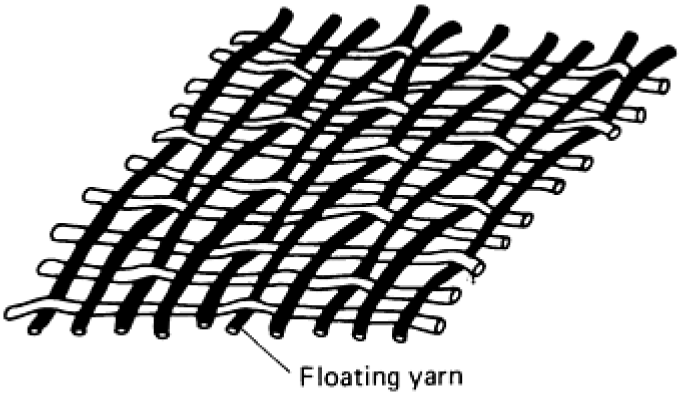

Fig. 2 Five-harness satin weave, interlacing

The ultimate laminate mechanical properties are obtained from unidirectional-style fabric (Fig. 3), where the carrier properties essentially vanish in the laminate form. The higher the yarn interlacing (for a given-size yarns), the fewer the number of yarns that can be woven per unit length. The necessary separation between yarns reduces the number that can be packed together. This is the reason for the higher yarn count (yarns/in.) that is possible in unidirectional material and its better physical properties. Unidirectional material has the most "unbalanced" weave and is usually reserved for special applications involving hardware with axial symmetry (such as a carbon-fiber-reinforced shuttle motor case) fabricated using a tape-wrapping operation.

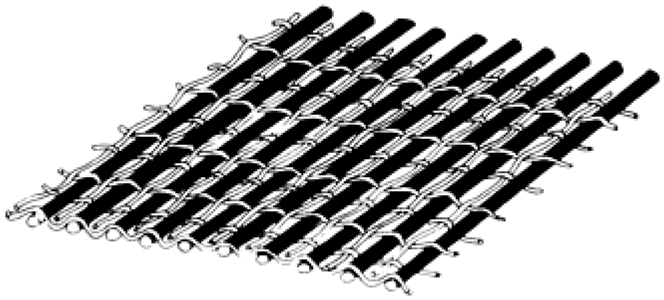

Fig. 3 Unidirectional weave

A weave construction known as locking leno (Fig. 4), which is used only in special areas of the fabric, such as the selvage, is woven on a shuttleless loom. The gripping action of the intertwining leno yarns anchors or locks the open selvage edges produced on rapier looms. The leno weave helps prevent selvage unraveling during subsequent handling operations, but is unsatisfactory for obtaining good laminate physical properties. However, it has found applications where a very open (but stable) weave is desired.

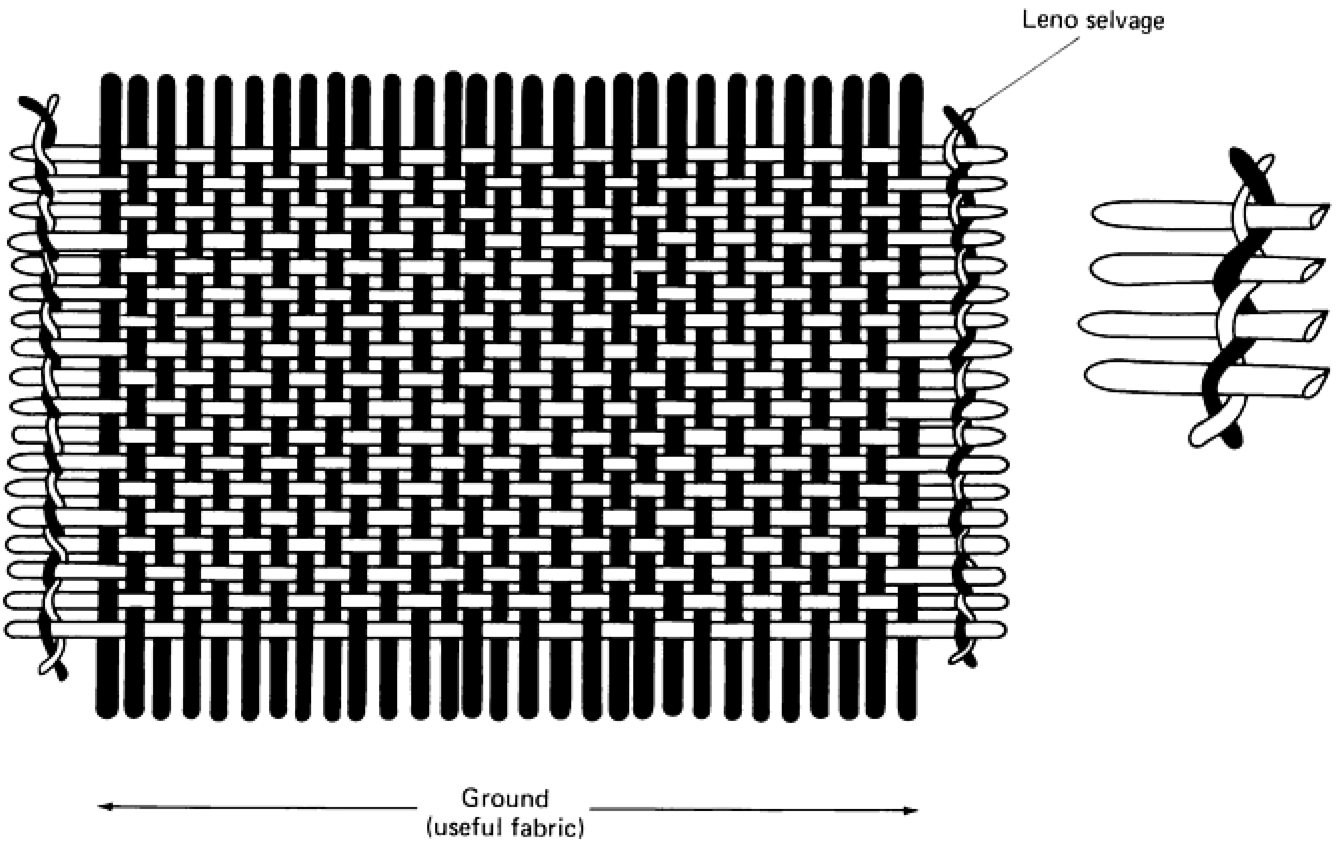

Fig. 4 Full-width plain weave with leno selvage

The textile designer is concerned with only a few fabric parameters: type of fiber, type of yarn, weave style, yarn count, and areal weight. Standard methods for measuring such parameters are well documented in Ref 1.

The verification of quality is an important aspect of the aerospace materials business. Quality is usually governed by military specification as part of the purchasing requirements. Typical quality defects, such as missing or broken warp or fill yarns, fabric misorientation (pucker), and misweaves in the pattern due to equipment failure or foreign material on the fabric, are documented in Ref 1 and 2.

Weave construction is the realm of the textile engineer, but fabric mechanical properties and how they translate into the laminate are concerns of the composite design engineer. Maximum directional properties for the minimum material (thickness) are attained with unidirectional-style material. The more usual goal of balanced properties requires two-directional styles. The fiber obviously dominates those properties carried by the fabric into a structural composite.

The fiberglass industry has these well-established fabric styles and categories:

Fabric weight	**Areal wt, kg/m^2 (oz/yd^2)**	**Thickness, μm (mil)**
Light	0.10–0.35 (3–10)	25–125 (1–5)
Intermediate	0.35–0.70 (10–20)	125–250 (5–10)
Heavy	0.50–1.0 (15–30)	250–500 (10–20)

The newer carbon and aramid fiber industries are somewhat oriented to custom design, but as the aerospace market matures, a few fabric constructions may become standards. Table 1 provides a sampling of styles that have found uses, along with corresponding order-of-magnitude epoxy resin composite properties.

Table 1 Typical fabric styles and composite properties

Weave	Yarns/in., warp × fill	Weight		Thickness at 25 kPa (3.4 psi)	
		kg/m^2	**oz/yd^2**	**mm**	**in.**
Typical fabric weaves					
Eight-harness satin	24 × 23	0.370	10.9	0.46	0.018
Eight-harness satin	24 × 23	0.370	10.9	0.48	0.019
Plain	12½× 12½	0.190	5.6	0.30	0.012

Five-harness satin	24 × 24	0.125	3.7	0.20	0.008
CFS	24 × 12	0.20	6.0	0.23	0.009
Plain	11½× 11½	0.19	5.7	0.25	0.010
Five-harness satin	11 × 11	0.370	10.9	0.50	0.020
Plain	8 × 8	0.525	15.5	0.81	0.032
Eight-harness satin	10½× 10½	0.755	22.2	1.0	0.040

Hybrid Fabrics

Hybrid fabrics are those woven from several different types of fibers, in contrast to fabrics woven from a single type of fiber. Table 2 shows typical properties of one hybrid graphite/aramid fabric. Combining fiber reinforcements allows the designer considerable flexibility. Among the reasons for the hybridization of graphite composites are (1) adding another fiber to a predominantly graphite composite in order to overcome the inherent disadvantages of graphite, (2) adding graphite fibers to a predominantly nongraphite composite or structure in order to take advantage of the benefits of graphite, and (3) producing a lower-cost structure. Normally, the impact resistance of graphite fiber composites can be improved by adding high-strength fibers with a greater strain-to-failure ratio than graphite. Several energy-absorbing mechanisms that have been proposed include interlacing resin layers to absorb energy and using fillers to stop cracks. Table 3 shows typical hybrid graphite/ aramid and graphite/glass impact properties.

Table 2 Properties of graphite, aramid, and hybrid fabric composites compared to 0°/90° laminates made from unidirectional layers (data normalized to 65 vol% fiber)

Ratio of aramid to graphite fiber	Tensile modulus, 0°/90°		Tensile modulus, fabric		Fabric efficiency, %	Tensile strength, 0°/90°		Tensile strength, fabric		Fabric efficiency, %	Compressive strength, 0°/90°		Compressive strength, fabric		Fabric efficiency, %

Graphite hybrid composites can be fabricated using conventional techniques and can be combined with boron, glass, aramid fibers, or metals in a laminated structure. Hybrids usually have the same matrix and can be fabricated by the co- curing process.

Multidirectionally Reinforced Fabrics

With the emergence of carbon-carbon composites and the resultant increased use of composite materials for high-temperature aerospace applications, the anisotropic nature of two-directionally oriented fabric presented a design problem: Although mechanical properties were satisfactory in the two directions containing reinforcement fabric, the mechanical properties in the third direction were matrix dominated and typically more than an order of magnitude less than in the reinforced direction. This problem was especially critical in applications involving high thermal stresses, such as carbon-carbon composite ballistic reentry nose tips and solid rocket throats. The obvious solution was to add fiber reinforcement in the third direction, and additional directions when necessary, to provide composite materials with isotropism approaching that of metals.

Early work in multidirectional reinforcement, preformed in the late 1960s, emphasized the development of geometric principles for a variety of fiber orientations, ranging from orthogonal, three-directional to eleven-directional reinforcement.

By the mid 1970s, it became apparent that the high cost of hand-assembled preforms (a preshaped fibrous reinforcement) would severely limit the application of multidirectionally reinforced composites to a very few aerospace applications. As a result, development activities began to de-emphasize the more complicated reinforcement geometries and concentrate on three-directional reinforcements, seeking to narrow the program scope and to optimize the three- directional configuration for specific applications, such as reentry nose tips and solid rocket motor throats. This optimization included fiber selection, heat treatment variations, and wave balance.

With the scope of multidirectional reinforcement development this reduced, it became possible to design and fabricate semiautomated equipment to reduce preform costs while increasing quality by eliminating the human error potential associated with hand assembly. As a result of these activities, semiautomated weavers were developed by the late 1970s and used to produce propulsion hardware for strategic weapon systems. At the present time, fully automated computer-controlled three-directional weavers are operational.

Reinforcement Materials

There are few limits on the composition of reinforcement fibers that can be woven into three-dimensional preforms; if a material can be made into a fiber, it can probably be woven into some type of three-directional preform. Fibers that have been woven into three-directional preforms include carbon-graphite, glass, silica, alumina, aluminosilicates, silicon carbide, cotton, and aramid. When design requirements necessitate, it is possible to weave a three-directional preform with a combination of fibers, as illustrated by the silica/carbon cylinder in Fig. 5.

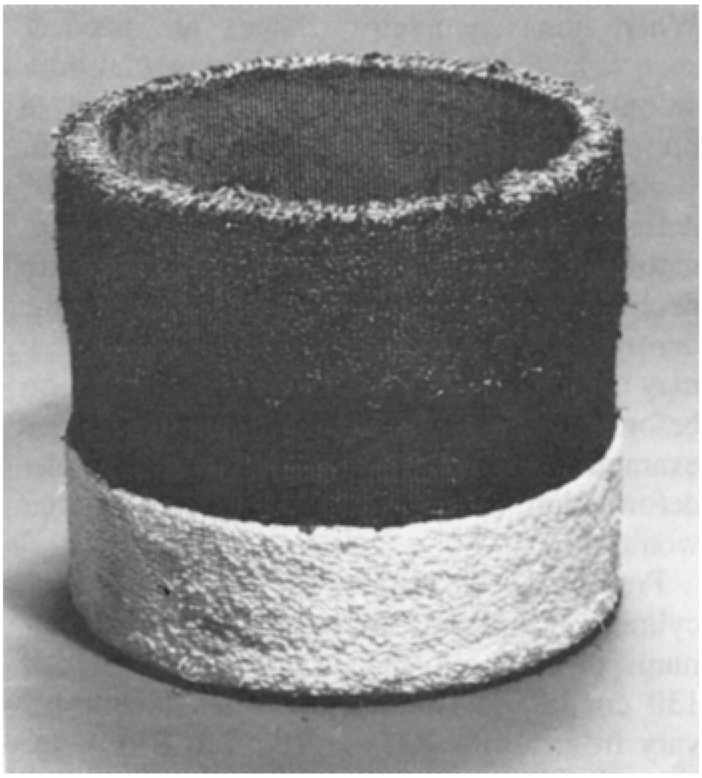

Fig. 5 Cylinder showing the combined use of silica and carbon fibers

Generally, the only limitation to fiber selection is the combination of brittle fibers and small yarn bend radii, the latter being caused by either weave geometry or the yarn delivery system of the automated weaving machine. This is particularly true of carbon and graphite fibers, which account for about 90% of all three-directional woven preforms. High-modulus graphite fiber is particularly prone to fracture during preform construction.

Weave Geometry

There are more than 20 varieties of multidirectionally reinforced preforms. Only the three variations of three-directional preforms that are most widely used and best characterized are described here, however.

Polar weave three-directional preforms have reinforcement yarns in the circumferential, radial, and axial (longitudinal) directions, as shown in Fig. 6. Preforms of this geometry normally contain 50 vol% fibers that can be introduced equally in the three directions. Some variation in relative yarn distribution can be accomplished when a specific application requires unbalanced properties. For example, if high-hoop tensile strength is required, additional fibers can be added in the circumferential direction, at some sacrifice of radial and longitudinal properties.

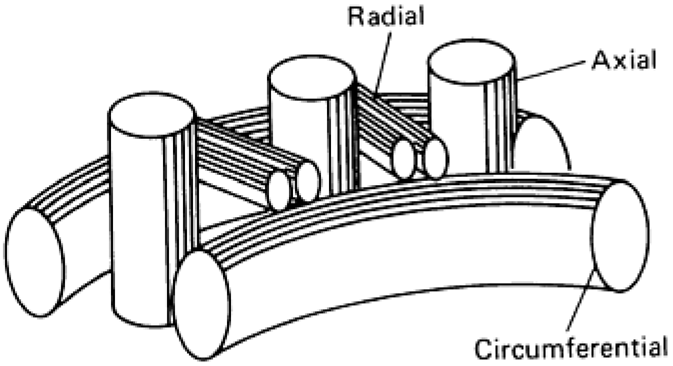

Fig. 6 Geometry of 3-D polar weave preform

Although originally developed as 305 to 510 mm diam (12 to 20 in. diam) thick-walled cylinders, polar weave three-directional preforms are presently fabricated in a number of body-of- revolution shapes, including

cylinders, cylinders/cones, and convergent/divergent sections. When nonaxisymmetric shapes are needed, such as leading edges or conic/rectangular transitions, a two-step process is used. First, preform of appropriate geometry is woven. Next, the preform is placed in a metal die, deformed into the required shape, and impregnated with a suitable resinous material to ensure geometric stability during the remainder of the densification process, as shown in Fig. 7. It may or may not be necessary to slit the preform before deformation; although the leading-edge example in Fig. 7 required slitting, a simpler deformation from conic to conic/rectangular would not.

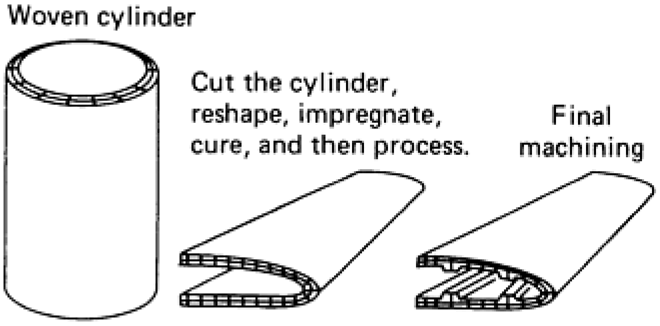

Fig. 7 Deformation of three-dimensional cylindrical preform to form a leading edge

Present size limitations for three-directional polar weave cylindrical preforms are an approximate maximum of 210 cm (84 in.) in diameter and 130 cm (50 in.) in length. Wall thicknesses vary from 6.4 to 200 mm (0.25 to 8 in.). Inside diameters are limited to 75 mm (3 in.) because of space requirements for the weaving mechanism.

Although yarn spacing is not discussed in specific quantitative terms because of the large number of variables, some general observations are appropriate. In a polar weave three-directional preform, the angular spacing of the radial fibers is a critical factor. The number and diameter of the radial yarn bundles remain constant as they move from the inside diameter to the outside diameter of the part, forming a pie-shaped “corridor” of increasing width. The volume percentage of radial fibers is therefore lower at the outside diameter than at the inside diameter. To account for this and to maintain a uniform fiber volume throughout the preform, the fiber bundle size of both the circumferential and longitudinal yarns is increased.

Orthogonal weave three-directional preforms have reinforcement yarns arranged in an orthogonal (Cartesian) geometry, with all yarns intersecting at 90° angles, as shown in Fig. 8. Typical yarn content varies from 45 to 55%, similar to that of a polar weave preform. These fibers can be introduced uniformly in each of the three directions to provide isotropic properties or in unbalanced amounts when design considerations require anisotropic properties. Unlike polar weave preforms, they are rarely woven to near- net configuration. Instead, they are woven as blocks, and parts are machined to the requisite size and shape.

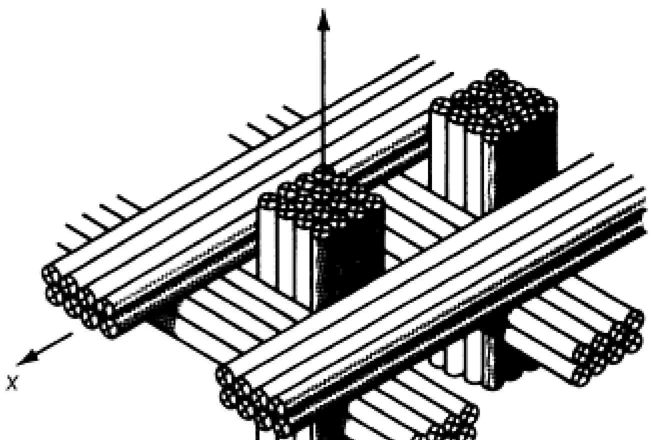

Fig. 8 Geometry of three-dimensional orthogonal weave preform

In regard to yarn spacing, it is worth noting that orthogonally woven three-directional preforms generally have a much finer unit cell size than their polar weave counterparts, resulting in superior mechanical properties and erosion resistance after densification into a composite.

Angle interlock, also known as warp interlock is a multilayered fabric in which the warp yarns travel from one surface of the fabric to the other, holding together up to eight layers of fabric, thus creating a thick, two-directional fabric, as shown in Fig. 9(a). When higher in-plane strength is needed, additional stuffer yarns can be added to create a quasi three-directional fabric, as shown in Fig. 9(b).

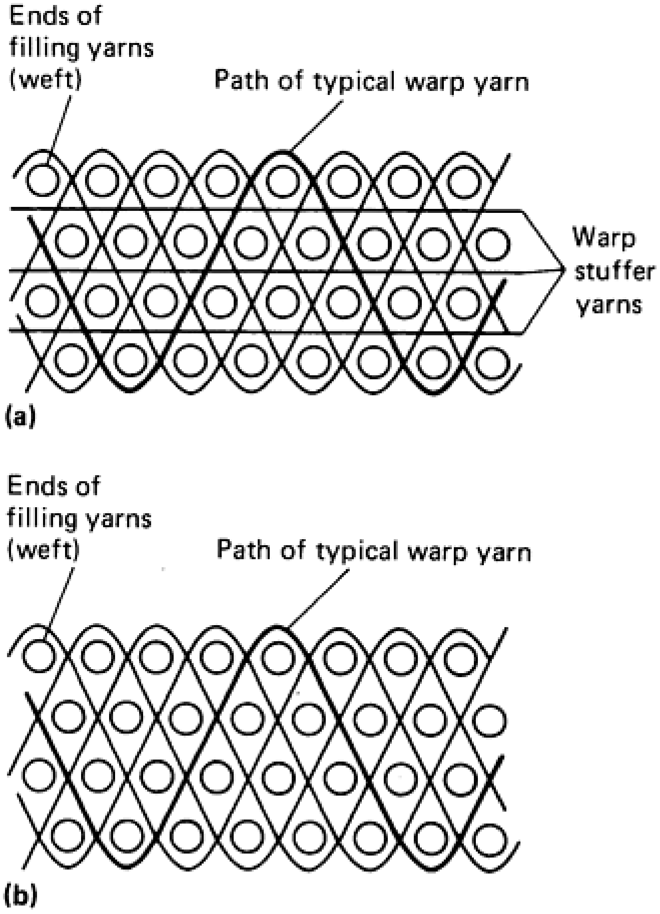

Fig. 9 Geometry of angle-interlock fabric (a) with and (b) without added stuffer yarns

Although angle interlock fabric is economical to produce on commercially available weaving equipment, its use has been limited. Because it is unavailable in closed shapes, its use when closed cones/cylinders are required necessitates the use of joints and their attendant plane of weakness.

Stitched fabric and needled felt can be marginally included in a summary of three-directional preforms and fabrics. Although both materials have reinforcement fibers in all three directions, the amount of fiber in the cross-ply direction is frequently such a small fraction of the total fiber volume that the cross-ply mechanical properties are only slightly better than the matrix dominated properties of two-directional materials.

Fabrics and Preforms

Prepreg Resins

Fibers that are preimpregnated with matrix resin in the uncured state are known as prepregs. Either continuous- or chopped-fiber prepregs are supplied to a part fabricator to the laminated or molded. The laid-up part is then subjected to heat and pressure to cure (chemically react) the resin. Prepreg has become an article of commerce because it frees the end user from having to develop resin formulations and impregnate fiber. The composite

material can be bought with resin content, resin type, and fiber type already made to order. Handling characteristics such as curing time and temperature can be controlled to precise levels to meet user requirements. Prepregs can be divided into at least two classes: those suitable for high-preformance applications (including aerospace applications) and those to be used in lower-performance molding compounds. Aerospace applications demand high-performance, high-quality composites and moldings. The lower-performance applications use sheet molding prepregs for automotive components and appliance housings. The two general classes differ widely in composition, handling, part manufacture, and use.

Prepreg Resins for High-Performance Applications

The reinforcement in prepregs supplied for aerospace application is typically carbon fiber. The high strength and stiffness of carbon, coupled with its low density, result in composites with higher performance/weight ratio than is possible in either metals or composites using glass fiber. The prepreg consists of resin-impregnated fiber in either uniaxial or woven form.

The part fabricator requires a prepreg with tack, drape, and a certain tack life and out time. Tack is the tendency of two plies or layers to adhere sufficiently to allow laying-up of complex parts yet allow a clean strip-back if layers are applied incorrectly. Too low an adhesion level will allow layers to slip, while too aggressive a level will not allow repositioning. Drape is the ability of the prepreg to bend and conform to mold curvature. Tack life refers to the amount of time that the prepreg can be at room temperature and still retain enough tack for lay-up. Out time is the total amount of time that the prepreg can be left at room temperature before curing and still make a good part. Fabricators must consider all of these handling characteristics, in addition to the cured properties generated by certain resin and fiber combinations.

Epoxy Resins. A resin chemistry that satisfies both manufacturing and composite property requirements is based on epoxy resins with a latent curative system. The cure system will be slow, at room temperature, to prevent reactions that reduce tack, drape, and out time, but sufficiently rapid at elevated temperatures to permit reasonably short curing times. Even the most latent systems in use do not completely eliminate room-temperature reaction. After the fiber is impregnated with resin, it is stored and shipped at low temperatures. The material is allowed to warm to room temperatures for lay-up. Typically, a one-year storage life at–20 °C (0 °F) is provided.

The epoxide group is well known and is a mature technology (Ref 5, 6, and 7). A wide range of epoxy-containing ingredients are available, as well as a wide range of curing agents and catalysts. Resins with different viscosities, amounts of reactive groups, and structures are available. Additives that change the uncured resin viscosity, reduce brittleness, or impart some other property are available. Aromatic backbones and high functionality give a strong high-temperature, highly cross-linked matrix that is usually brittle. Aliphatic epoxies and low functionality usually result in matrices with higher elongation, lower temperature capability, and higher toughness. The primary resin for aerospace application is *N*,*N*,*N*′,*N*′-tetraglycidyl-4,4′-methylenebisbenzenamine. When reacted with the appropriate curative, it yields a hard resin with temperature capabilities of about 190 to 205 °C (375 to 400 °F).

Curatives. The epoxide group can react chemically with other molecules to form a three- dimensional network. This chemical reaction changes the liquid resin into a load-bearing solid. Curing agent scan include amines, anhydrides, acids, and many others. Two commonly used amine curatives for prepreg resins are 4,4′-diaminodiphenylsulfone and dicyandiamide. Other curatives are too reactive with the epoxies at low and room temperatures, resulting in an unacceptable reduction of storage and use life. Dicyandiamide appears to decompose at elevated temperatures of 145 to 154 °C (290 to 310 °F) to yield other nitrogen-containing species, which cause the curing reaction to occur. The curative 4,4′-diaminodiphenylsulfone may or may not completely dissolve in the epoxy resins. Insolubility contributes to its latent curing behavior. Curatives are usually mixed with epoxy content on a 1-to-1 chemical basis. In the calculation of amounts, each hydrogen of the amine group is considered to react with one epoxy group. The actual mix ratio may be varied to optimize desired properties.

Catalysts are used to accelerate the latent curatives in order to achieve a complete cure in a shorter time. Boron trifluoride (BF_3) can be rendered latent by complexing with nitrogen-containing compounds, such as monoethylamine. Other amines can be used to adjust latency.

The types of amines and epoxies used for prepregs react slowly at room temperature, and elevated temperatures are needed for complete cure and attainment of ultimate properties. However, as a general rule, the

temperature-use capability of the cured resin is slightly above the actual curing temperature. Therefore, a room-temperature system will operate at room temperature within a range; a formulation cured at 175 °C (350 °F) will perform at or somewhat above that temperature.

The actual mixture of epoxy resin or resins, curative, and catalyst that is formulated and blended is designed to meet end-use, prepregging, handling, and storage requirements. Low- viscosity resin components are used to reduce overall viscosity and aid in prepreg manufacture and flow during curing. Aromatic epoxies that differ in epoxy functionality are used to vary the cross-link density. Highly cross-linked aromatic resins used in aerospace prepregs make a very strong composite that is nonetheless brittle; flexibilizers or tougheners may be added to decrease brittleness. The amount of type of epoxy resins is varied to maximize desired composite properties as well as improve processing and handling characteristics.

Cure cycles for resin formulations are determined empirically. A given cure cycle may have several hold steps on the temperature rise to the maximum cure temperature. Hold steps at a given temperature allow resin flow to ensure a void-free part. They also prevent runaway temperature increases caused by rapid rates of reaction and cross-linking. The programmed heat- up cycle allows reactive groups to be consumed at a rate that permits removal of the heat of reaction. Subsequent heating to a higher temperature (and higher polymerization rate) is safe, because the amount of reactive material has been reduced. Conversely, hold steps can build viscosity through a reaction that reduces resin flow when the temperature is increased. Cure cycles recommended by the prepreg supplier are designed for specific composite thicknesses and resin formulations. Significant departures from customary lay-ups and cure schedules should be reviewed for safety as well as for achievement of ultimate properties.

Another epoxy application for prepregs is in circuit boards. Glass is used for this application because carbon fiber is electrically conductive. The combination of glass and epoxy resin yields good electrical properties, in addition to good temperature capabilities and ease of epoxy chemistry processing.

High-temperature epoxy resins have maximum continuous-use temperature of 205 to 230 °C (400 to 450 °F). Temperature spikes up to 290 °C (550 °F) can be tolerated by some formulations based on epoxy novolacs. The amine-cured epoxy resins are also affected by water. Because of the hydroxyl groups generated during cure, water is absorbed readily and acts like a plasticizer. Water exposure can reduce the operating temperature by 56 °C (100 °F). Although much effort has been spent to synthesize polymers that possess adequate thermal and water resistance, very few have proved to be economically feasible. However, two chemical approaches appear able to solve the problem: addition polyimides and condensation polyimides (Ref 8).

Addition polyimides are based on the reaction of bismaleimide molecules with aromatic amines or dienes. These systems possess temperature capabilities in excess of 260 °C (500 °F). Addition polyimides are similar to epoxies in that no volatiles are released by the polymerization reaction. In order to achieve the high-temperature properties, autoclave cures at 175 °C (350 °F) are followed by postcures at 315 to 340 °C (600 to 650 °F) in a free-standing oven. The primary drawback to addition polyimides is their extreme brittleness, which can be compensated for, somewhat, but usually at the loss of temperature capability or water resistance.

Condensation polyimides have temperature capabilities exceeding 315 °C (600 °F) and are not as brittle as the addition polyimides. A polyimide solution of in situ polymerization of monomer reactants consists of a mixture of monomers dissolved in solvent. The monomers are latent, as in the case of prepreg epoxy resins, but react at high temperatures. The presence of solvent, as well as the liberation of volatiles during polymerization, can create voids in the cured parts. The cure cycle and devolatilization are critical for producing high-quality parts.

Glass-phenolic and carbon-phenolic prepregs are used in specialty flame-resistant and ablative applications (Ref 9, 10), including aircraft interior panels and exit cones for rocket motors. Phenolic resins have excellent heat resistance, but their drawbacks include brittleness and the need for press curing at high pressures to suppress volatiles generated during the cross-linking reaction.

More detailed information is provided in the articles “Epoxy Resins,” “Bismaleimide Resins,” and “Phenolic Resins”in this Volume.

Prepreg Resins for Lower-Performance Applications

Sheet molding compounds (SMCs), used in applications where the high performance and high cost of carbon prepregs are not justified, consist of continuous or chopped fibers and a polyester or vinyl ester resin. The formulation includes inorganic filler, thixotrope, catalyst, release gent, and pigments. Processing conditions usually are 1 to 3 min in a press at 90 to 150 °C (200 to 300 °F).

Sheet molding compound is manufactured by calendaring a strip that contains the fiber and resin. Because of the latent nature of the catalyst, molding compounds can be stored and shipped at ambient temperature.

The two types of resin families that are used— polyester and vinyl ester—are similar in chemistry. A typical polyester resin is formed by the reaction of glycols and dibasic acids and anhydrides. Other unsaturated compounds, such as styrene, are added to cross-link and act as a diluent. Curing is accomplished by peroxide-initiated free-radial polymerization.

Vinyl ester resins are manufactured by reacting unsaturated carboxylic acids and epoxies.

As in the case of polyesters, styrene or vinyl toluene is used as a diluent for processing and chemical reactions. Vinyl esters are tougher, shrink less, and are more resistant to chemical attack than polyesters.

For both families, the composition of the resin affects the physical properties of a final part. The type of chemical backbone and diluent will allow weather resistance, chemical resistance, impact properties, and flow during processing to be tailored to fit the application. The curing time and storage life is altered by the amount and type of catalyst, accelerator, and inhibitors

Additional information about SMCs in provided in the article "Molding Compounds" in this Volume.

Woven Fabric Prepregs

Woven fabric prepregs are one of the most widely used fiber-reinforced resin forms. Fabrics typically offer flexibility in fabrication technique, but a higher cost than other prepreg forms. The designer must consider these and other factors before selecting a prepreg form for structural application. Information about fabric types and weave patterns is provided in the section "Unidirectional and Two-Directional Fabrics" in this article.

Fabrics can be prepregged using either a hot- melt or a solvent-coating process. The hot-melt process uses a machine similar to that used for fabricating unidirectional tape. Resin can be applied to the fabric either by using prefilmed substrate paper, a "knife over roll," or a similar coating mechanism. Solvent coating is typically accomplished by immersing the fabric into a bath containing 20 to 50% of a solvent and resin mixture and then drying the fabric in a one-pass or multipass former coater. The two techniques generate different characteristics in the prepreg:

Hot melt

- Less drape and lower tack, due to higher resin viscosity, which in turn is due to lack of residual solvent in the prepreg

- Better hot/wet mechanical properties, less flow, and longer gel time, due to the absence of volatiles
- Higher cost, due to slower process speed and higher resin scrappage

Solvent coating

- Better drape, due to lower resin viscosity and, usually, higher tack
- Residual solvent of 1 to 2%, which incurs longer gel time, higher flow, and lower hot/ wet mechanical properties
- Lower cost, due to increased process speed and reduced resin waste.

Fabrication Techniques. Woven fabric prepregs can be darted to conform to convoluted shapes of low-stressed items. Darting is the practice of slitting the prepregs at locations where folds would normally occur in a lay-up; the excess material at those locations is removed completely, and the remaining edges butted together. As an alternative, the prepreg can be slit where a crease would normally form, and the excess material can overlap, provided that it is wrinkle free. When the former method is used, an additional ply may be required to compensate for the weak butt joints in the lay-up. Darting is not recommended for highly stressed, lightweight construction; on those occasions, prepregs should be cut in predetermined patterns such that joints in successive plies do not coincide. Overlapping joints must be deliberately placed and joint widths must be controlled. Usually, patterns for precutting the prepregs allow for 13 mm (0.5 in.) overlaps on the lay-up.

When woven fabric reinforcements are laid up on convoluted shapes, weave patterns become distorted and the fiber directions change. Orientations of 0°, ±60° or 0°, ±45°, 90° are used to compensate for undetermined deficiencies. These plying sequences provide reinforcements for laminate plane quasi-isotropic properties. However, ply alignments of heavily draped lay- ups of fabric-reinforced prepregs are difficult to control. Colored tracer fibers, woven into the fabrics, simplify the lay-up and inspection of the composite.

Structural composites that are required to resist loads must be designed to obtain reproducible properties. Their shapes should permit the plies to be oriented in predetermined directions. Whether the lay-up is produced manually or is automated, the principles behind the lay-up techniques are similar. When the structural shapes permit, the most reproducible properties are developed by laying up plies that are cut to size and then applied to transfer films. These transfer films, or polyester film templates, are indexed to specified ply locations and orientations with respect to the mold. Plies that are laid up on templates are transferred to molds without additional distortion; after the plies are laid up and transferred, the templates are removed.

Anisotropies of a fabric-reinforced prepreg in one ply are corrected with equal but opposite anisotropy in adjacent plies. The symmetry achieved by making these corrections is important to avoid distortions in the cured laminates Other corrections are sometimes made by cross- plying compensating misalignments to attain orthotropy (Ref 11).

Unidirectional Tape Prepregs

Prepreg tapes of continuous-fiber reinforcement in uncured matrix resin are one of the most widely used forms of composite materials for structural applications. Tapes offer the designer advantages in the areas of economics and translation of fiber properties. Prepreg tape is a collimated series of fiber-reinforcing tows impregnated with a matrix resin. Before tape is manufactured from fiber, the fiber is usually found in a spooled form with widely varying tow size, weight per unit length (denier), and filament size, as shown in Table 4.

Table 4 Fiber bundle dimensions

Material	Yield/tow		Filament size	
	m/kg	**yd/lb**	**µm**	**µin.**
Graphite (1000 to 12,000 filaments per tow)	300–1200	150–600	5–10	200–390
Fiberglass (2450–12,240 filaments per tow)	490–2400	245–1200	4–13	160–510
Aramid (800–3200 filaments per tow)	2000–7850	980–3900	12	470

Tape Manufacture and Product Forms

The fiber is typically converted into a prepreg by bringing a number of spooled tows into a collimated form, as shown in Fig. 10. The prepregging operation consists of heating a matrix resin to obtain low viscosity and creating a well-dispersed fiber-resin mass. The amount of fiber is controlled by the number of tows brought into the prepreg line, and the resin can be cast onto the substrate paper either on the prepreg line or in a separate filming operation to obtain the desired fiber-resin ratio. The prepreg is calendered to obtain a uniform thickeness and to close fiber gaps before being wound on a core. Substrate paper is ordinarily left between layers of tape. The paper can be any releasing film, but is typically a calendered paper coated with a nontransferable, cured silicone coating. Figure 11 shows a typical spool of graphite-epoxy prepreg tape, which is available in a wide variety of widths, thicknesses, and package sizes.

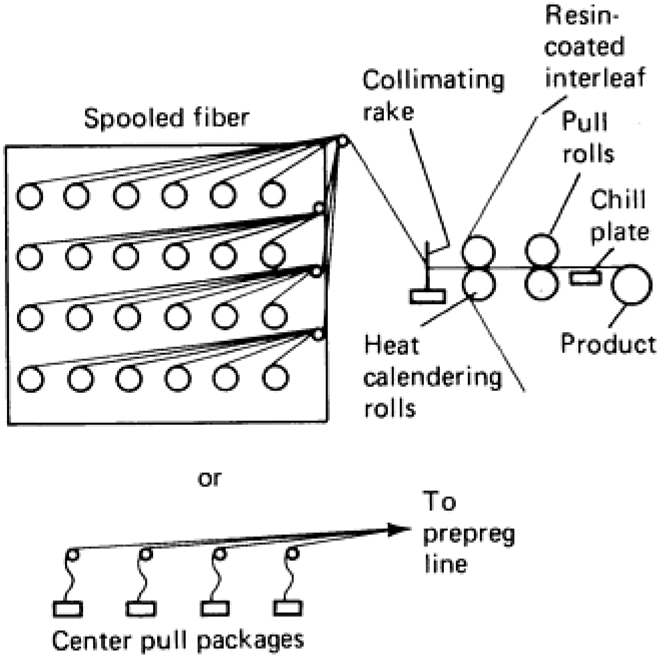

Fig. 10 Typical prepreg machine

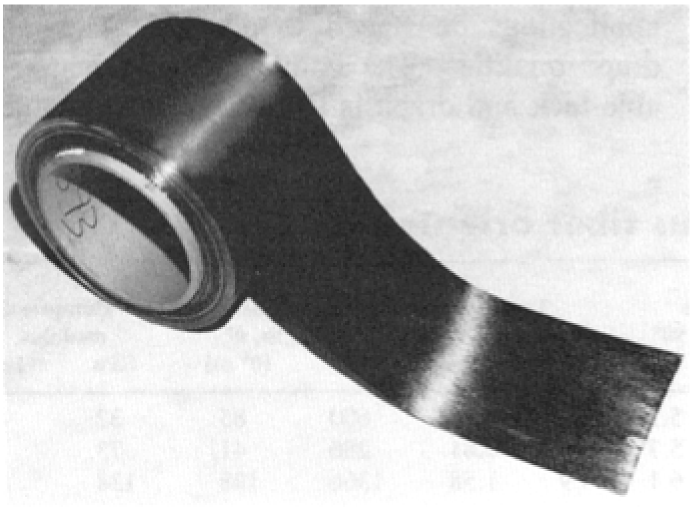

Fig. 11 Spool of graphite-epoxy tape

Using narrow (75 mm, or 3 in.) prepreg tape usually results in a minimal material loss of 7 to 10%. Narrow tape is ideally suited for a very expensive material, such as boron-epoxy. However, using narrow tape increases labor costs, which must be balanced against material costs.

Tape Properties

Reinforcement fibers by their nature are anisotropic (reinforcing primarily in one direction). Consequently, unidirectional tapes reinforce primarily in the 0° direction of the reinforcing fibers. Other structural properties also vary depending on fiber direction.

Tapes offer the best translation of fiber properties because the fibers are not crimped or distorted as in fabric prepregs. Significant differences exist between tape and fabric mechanical properties. Figures 12 and 13 show typical tensile property translation differences between tape and fabric prepregs.

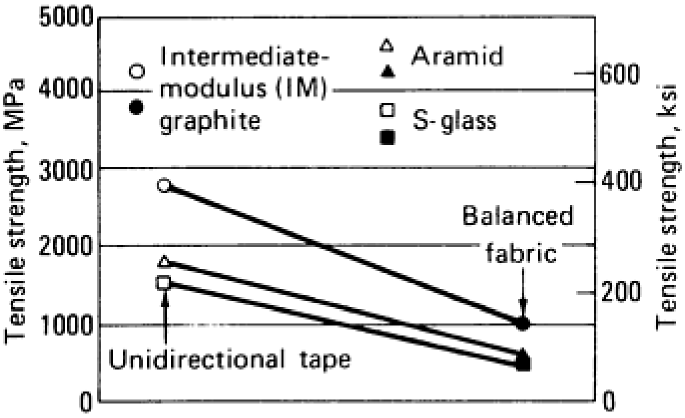

Fig. 12 Tensile strength comparison—fiber-epoxy tape versus fabric

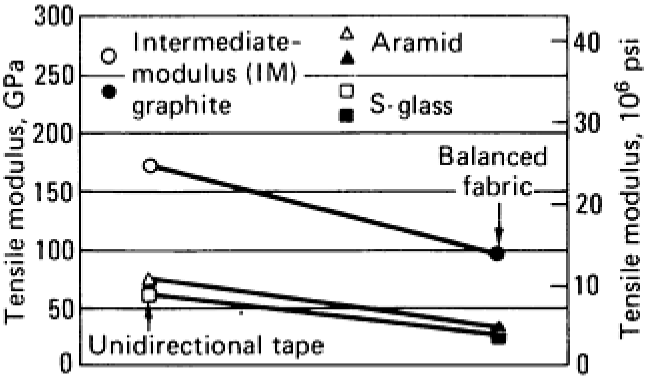

Fig. 13 Tensile modulus comparison—fiber-epoxy tape versus fabric

Properties such as tack, flow, gel time, and drape are critical to proper selection of material form.

Tack should be adequate to allow the prepreg to adhere to prepared molding surfaces or preceding plies for a lay-up, but light enough to part from the backing film without loss of resin. Tack qualities can be specified to require the prepreg to remain adhered to the backing until a predetermined force is applied to peel it off.

Prepregs with excessive tack generally are difficult to handle without disrupting resin distribution and fiber orientation or causing a roping (fiber bundling) of the reinforcements. Constituents are not reproducible because undetermined amounts of resin are removed when the release film or backing is separated from prepreg. In general, all the disadvantages of wet lay-up systems are inherent to overly tacky prepregs.

Prepregs with no tack are either excessively advanced, have exceeded their normal storage life, or are inherently low in tack. Such materials cannot attain adequate cured properties and should be discarded. Exceptions are silicones and some polyimides, which can only be prepared with no tack. Lay-ups with these materials are limited to those situations where lower mechanical properties can be tolerated in exchange for improved heat resistance or electrical properties. A lack of tack in thermoplastic prepregs does not interfere with their consolidation, provided that they can be heated to the melting point of the polymer during processing.

Flow is the measure of the amount of resin squeezed from specimen as it cures (under heat and pressure) between press platens. Flow measurement indicates the capability of the resin to fuse successive plies in a laminate and to bleed out volatiles and reaction gases. Flow can be an indicator of prepreg age or advancement. It is often desirable to optimize resin content and viscosity to attain adequate flows. In some cases, prepreg flow can be controlled by adding thickening or thixotropic additives to the resin.

Gel time, the measure of the time a specimen remains between heated platens until the resin gels or reaches a very high viscosity stage (Ref 11), can be an indicator of the degree of prepreg advancement. The useful life of prepregs is limited by the amount of staging or advancement. Most prepregs are formulated to attain a useful life of ten days or more at standard conditions. Life can be prolonged by cold storage, but each time the prepreg is brought to thermal equilibrium at lay-up room temperatures, useful life is shortened. Gel time measurements are used as quality control verifications (Ref 11).

Drape is the measure of the formability of a material around contours, which is critical to fabrication costs. Tape drapability is typically measured by the ability of a prepreg to be formed around a small-radius rod. The pass/fail criterion for drape is the ability to undergo this forming without incurring fiber damage. This measurement translates to the ability of fabrication personnel to form the prepreg to complex tools. Of the physical properties mentioned, drape is one property where tapes differ from other prepreg forms. Tapes are typically less drapable than fabric forms of prepreg, and this difference must be considered when specifying a prepreg form for manufacture.

It is essential that prepregs for structural applications be staged to desirable tack and drape qualities. The combination of manageable tack and drape is sometimes best attained from woven satin fabric-reinforced prepregs. Cross-plied or multiplied prepregs are sometimes used to provide transverse strengths for lay-ups of broad goods. The term “broad goods” refers to wide prepreg tape (>305 mm, or 12 in.) that consists of one or more plies of tape oriented at 0° or off- axis to each other.

Multidirectional Tape Prepregs

When a number of tape plies are laminated at several orientations, the strength of the composite increases in the transverse direction. As the number of oriented plies is increased, the isotropic strength is approached asymptotically.

Multidirectional tapes can be manufactured with multiple plies of unidirectional tape oriented to the designer's choice. These tapes are available in the same widths and package sizes as unidirectional tape, with varying thickness. Up to four or five plies of tape, with each ply typically being 0.125 mm (0.005 in.), can be plied together in various orientations to yield a multidirectionally reinforcing tape. Figure 14 depicts the difference between unidirectional and multidirectional tapes.

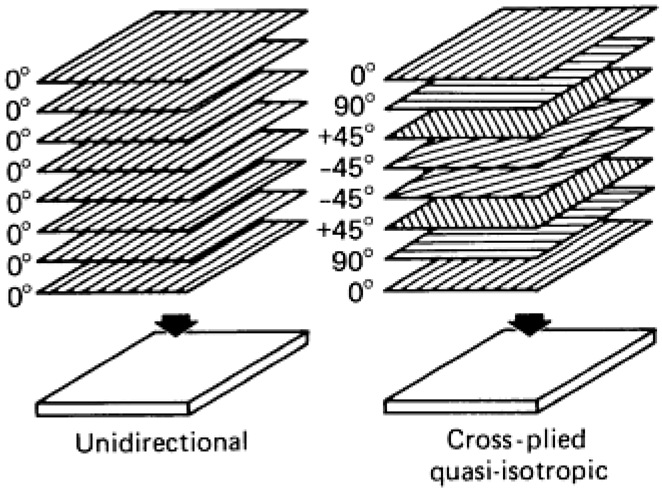

Fig. 14 Unidirectional versus quasi-isotropic lay-ups

By using a preplied quasi-isotropic prepreg, the fabricator can avoid a substantial lay-up cost. However, preplied prepregs are typically more costly than unidirectional prepregs because of the additional work necessary to ply the tape.

Multioriented prepreg performance can be accurately predicted from test data that have been generated on these configurations. Tables 5 and 6 show typical mechanical property data for these lay-ups compared with other structural materials.

(a) In epoxy-resin matrix

Cross-plied tapes offer controlled anisotropy, that is, properties can be varied and modified in selected directions, but these tapes are generally more expensive than unidirectional tapes because of the additional manufacturing steps. This disadvantage is often overcome, however, by the cost savings from using a preplied tape in part lay-up.

Properties are controlled by the number of plies of tape oriented in critical directions. Figures 15 and 16 show typical changes in tensile properties and when ply orientation is changed.

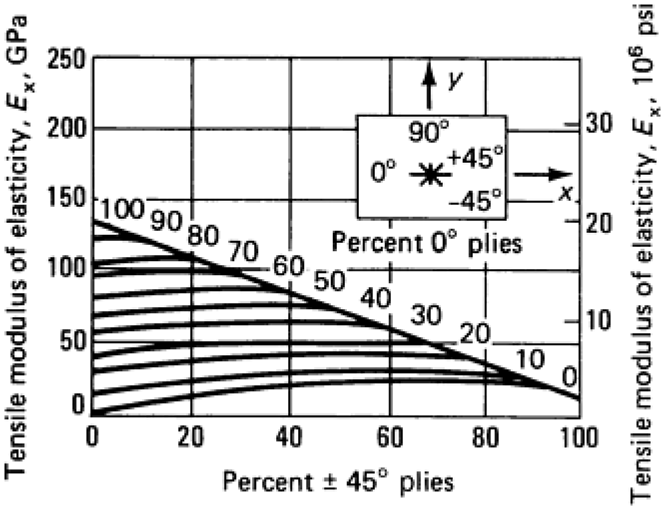

Fig. 15 Tensile modulus of elasticity of carbon-epoxy laminates at room temperature

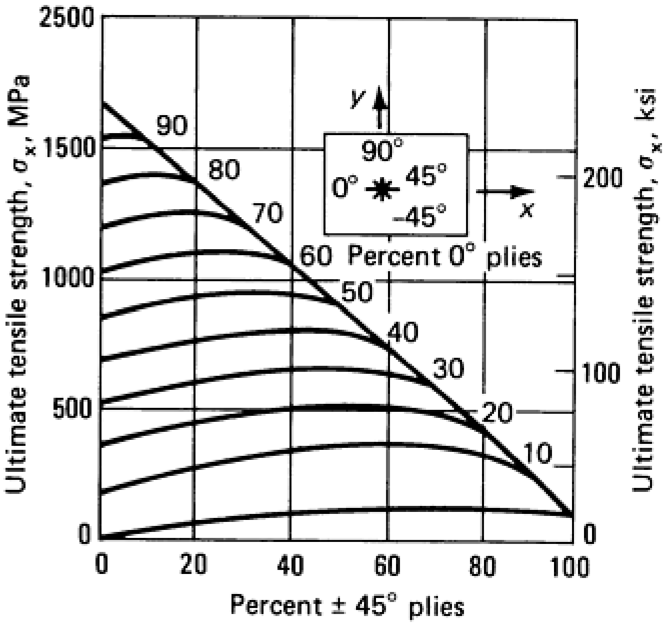

Fig. 16 Ultimate tensile strength of carbon-epoxy laminates at room temperature

Tape Manufacturing Processes

Tape manufacturing processes fall into three major categories: hand lay-up, machine-cut patterns that are laid up by hand, and automatic machine lay-up.

Hand Lay-Up. Historically, tapes have primarily been used in hand lay-up applications in which the operator cuts lengths of tape (usually 305 mm, or 12 in.) and places them on the tool surface in the desired ply orientation. Although this method uses one of the lower-cost forms of reinforcement and has a low facility investment, it results in a high material scrap rate, fabrication time/cost, and operator-to-operator part variability. The scrap factor on this type of operation can exceed 50%, depending on part complexity and size.

Auxiliary processing aids should be used extensively to expedite the lay-up operation and to use molds and tools more efficiently. It is customary to presize the laid-up ply before it is applied to the mold. Usually, an auxiliary backing is fixed in position on the lay-up tool, which is sometimes equipped with vacuum ports to anchor the backings. Plies are oriented to within ±1° using tape-laying heads, or manually, using straight edges, drafting machine dividing heads (Ref 4) or ruled lines on the table (Ref 4).

Indexes or polyester film templates also can be used to reduce the lay-up times on molds. The presized plies are first laid up and oriented on the templates. When the mold is available for the lay-up, the plies are positioned on them and transferred. Positioning is achieved by using the references used for indexing. Reference posts for the templates are sometimes located on the mold; corresponding holes in the templates fit exactly over the posts. In some cases, the templates are shaped so that they fit only one way in the mold. The plies are rubbed out from the templates onto the mold, the mold is removed, the bleeder systems are laid up, and the assemblies are bagged and cured.

Machine-Cut Patterns. More advanced technology uses machine-cut patterns that are then laid up by hand. This method of manufacture involves a higher facility cost but increases part fabrication output and reduces operator error in lay-up. The right-sized pattern can be automatically cut in one or more ply thicknesses using wider tapes of up to 1500 mm (60 in.), which are potentially more economical to fabricate.

The cut is normally done on a pattern-cutting table, where up to eight plies of material are laid up. Various templates are located on top of the lay-up, and the most economical arrangement is determined by matching templates. The patterns are then cut and stored until required. Cutting of plies can be done by laser, water jet, or

high- speed blades. The machine-cut method is often used in modern composites shops and is best suited for broad goods and wide tapes. A typical cutting machine is shown in Fig. 17.

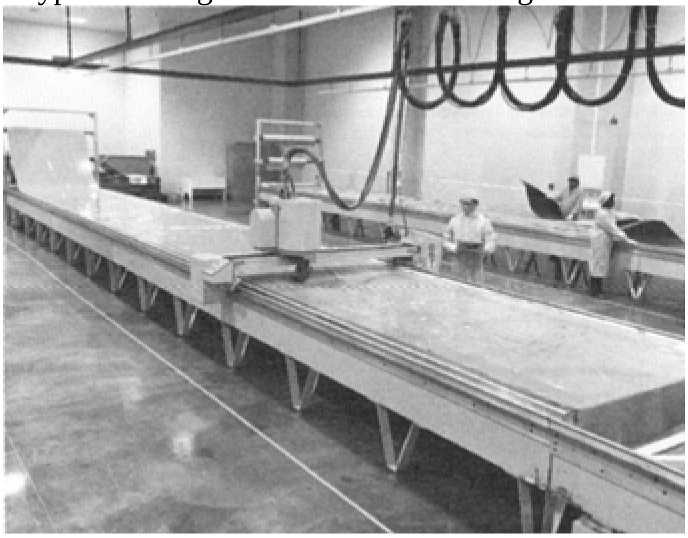

Fig. 17 Gerber cutting machine

Automatic Machine Lay-Up. Numerically controlled automatic tape-laying machines, especially in the aerospace industry, are now programmed to lay down plies of tape in the quasi- isotropic patterns required by most design applications. In addition to being able to lay down a part in a short time and with reduced scrappage, robotics also lend consistency to lay- down pressures and ply-to-ply separations. These advantages are rapidly causing the aerospace industry to switch from hand lay-up operations. Automatic tape layers are evolving from being able to handle only limited tape widths and simple tool contours to being able to fabricate large, heavily contoured parts. Additional information is provided in the article "Automated Tape Laying" in this Volume.

Prepreg Tow

Another form of prepreg is a towpreg, which is either a single tow or a strand of fiber that has been impregnated with matrix resin. The impregnated fiber is typically wound on a cardboard core before being packaged for shipment. Because a towpreg is potentially the lowest-cost form or prepreg, it is of significant interest to designers. It also lends itself to potentially low- cost manufacturing schemes, such as filament winding. Towpreg is being considered by filament winders as a way to combine the advantages of low-cost part manufacture and high-performance matrix resins. The fibers that are typically used are shown in Table 7.

Table 7 Fiber tow characteristics

Before impregnation

Material	Yield/tow		Filament size	
	m/kg	**yd/lb**	**µm**	**µin.**
Graphite (1000–12,000 filaments/tow)	300–1200	150–600	5–10	200–390
Fiberglass (2450–12,240 filaments/tow)	490–2400	245–1200	4–13	160–510
Aramid (800–3200 filaments/tow)	2000–7850	980–3900	12	470

Manufacture. Most towpregs are converted in a solvent-coating process (Fig. 18) in which base resin is first dissolved in a mix containing 20 to 50% solvent and resin. The dry fiber is then routed through the solvent-resin mix and dried in a tower consisting of one or more heated zones. Resin content is controlled either by using metering rolls after impregnation or by adjusting the solvent-resin ratio. This drying step reduces volatiles and advances the resin so that the towpreg will not adhere to itself during unspooling in part manufacture. Towpregs can also be manufactured in a hot-melt operation by filming resin on substrate paper, impregnating strands between two layers of filmed paper, and then advancing the resin to an intermediate point between freshly mixed and cured (B-staging) on a prepreg line. However, this tends to result in a higher-cost towpreg.

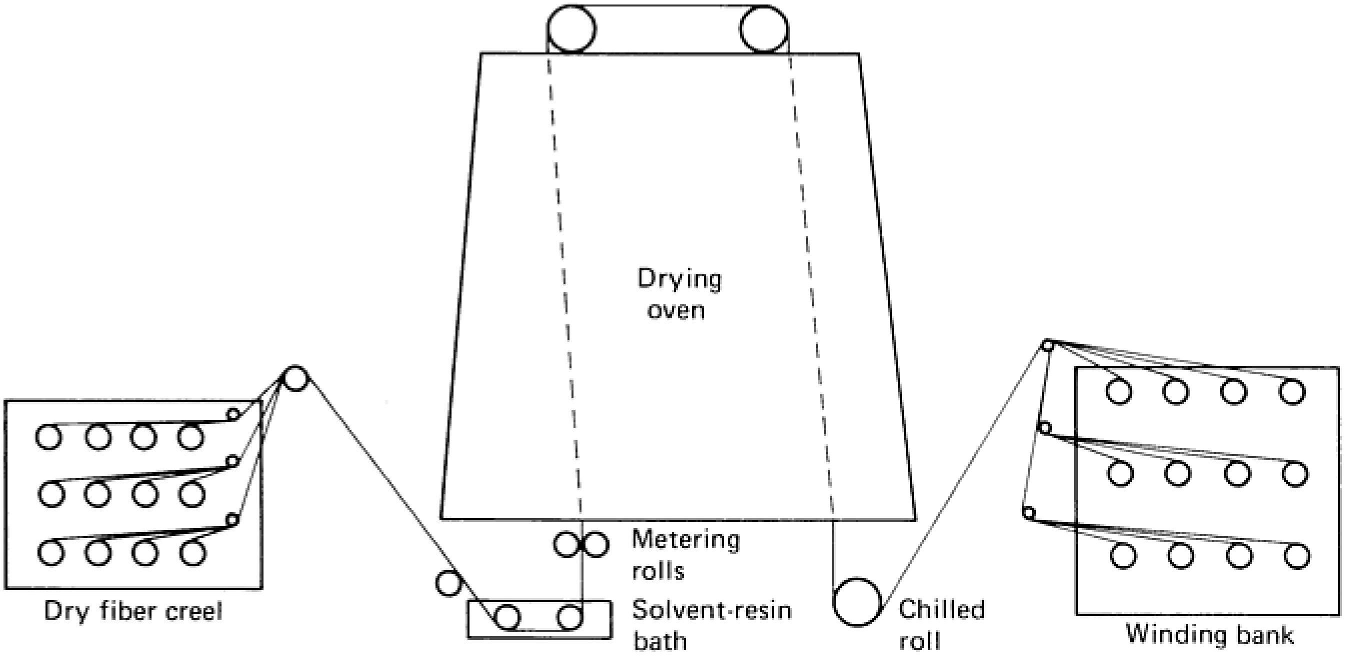

Fig. 18 Typical towpreg manufacturing process

Forms. Table 8 shows typical form parameters that a manufacturing shop might specify. A designer must evaluate the size and complexity of the part being designed before selecting material parameters. Resin content will determine part mechanical performance and thickness by determining fiber volume, assuming that little or no resin is lost in the curing process. Tow width, which is important in establishing ply thickness and gap coverage, can be modified during lay- down. Package size can be important to manufacturing personnel, especially when more than one spool is used in the manufacturing process. In such cases, manufacturing personnel often try to match the sizes of spools that are used in order to minimize spool doffs (changes) and splices in the manufactured part.

Table 8 Towpreg form parameters

Parameter	Typical range
Strand weight per length, g/m (lb/yd)	0.74–1.48 (0.00150–0.0030)
Resin content, %	28–45
Tow width, cm (in.)	0.16–0.64 (0.06–0.25)
Package size, kg (lb)	0.25–4.5 (0.5–10)

To determine the mechanical properties of a towpreg, it can be tested by a single-strand type of test or by winding tows on a drum to specified thicknesses and then laying up laminates from this wind. Mechanical properties of towpregs are comparable to those of tapes, if they are cured under autoclave conditions. Filament-sound structures that are not autoclave cured will typically have higher void contents than autoclave- cured parts.

Applications. The two basic uses for towpregs are as a filler in hard-to-form areas and in joints of structural components such as I-beams (Fig. 19) and as a replacement for low-performance filament-winding resins in filament-winding operations. Using a towpreg as a filler material in areas where tape or fabric prepregs will not lay down involves hand lay-up.

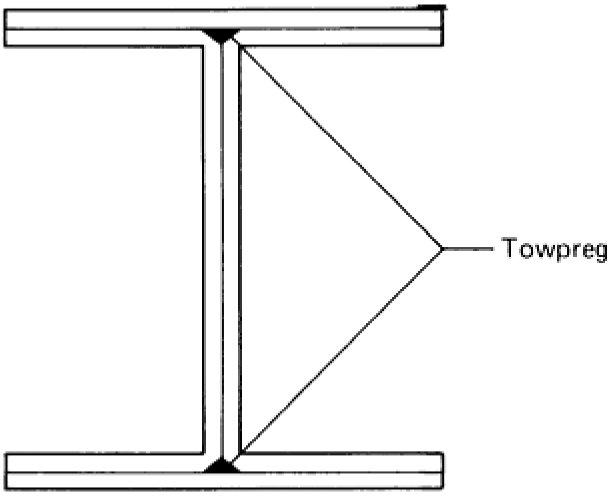

Fig. 19 Towpreg used a filler in an I-beam

Most of the development in towpreg technology has been in the area of winding, particularly using a graphite-epoxy towpreg. The six-axis winding machine (Fig. 20) unspools the towpreg bundles and collimates them into a band of prepregs before laying down a unified band. The band of prepreg can be laid into complex cylindrical or nongeodesic forms, as shown in Fig. 21. This technology has the potential of making significant inroads into complex low- cost aerospace-grade part manufacture and may revolutionize the amount of composites and types of techniques used in aircraft fuselage manufacture. Additional information on towpreg is provided in the article “Filament Winding” in this Volume.

Braiding

Frank K. Ko, Drexel University

Introduction

BRAIDING is a textile process that is known for its simplicity and versatility. Braided structures are unique in their high level of conformability, torsional stability, and damage resistance. Many intricate materials placement techniques can be transferred to and modified for composite prepreg fabrication processes. The extension of two-dimensional braiding to three-dimensional braiding has opened up new opportunities in the near-net shape manufacturing of damage-tolerant structural composites.

In the braiding process, two or more systems of yarns are intertwined in the bias direction to form an integrated structure. Braided material differs from woven and knitted fabrics in the method of yarn introduction into the fabric and in the manner by which the yarns are interlaced. Braided, woven, and knitted fabric are compared in Table 1 and Fig. 1.

Table 1 A comparison of fabric formation techniques

Parameter	Braiding	Weaving	Knitting
Basic direction of yarn introduction	One (machine direction)	Two (0°/90°) (warp and fill)	One (0° or 90°) (warp or fill)
Basic formation technique	Intertwining (position displacement)	Interlacing (by selective insertion of 90° yarns into 0° yarn system)	Interlooping (by drawing loops of yarns over previous loops)

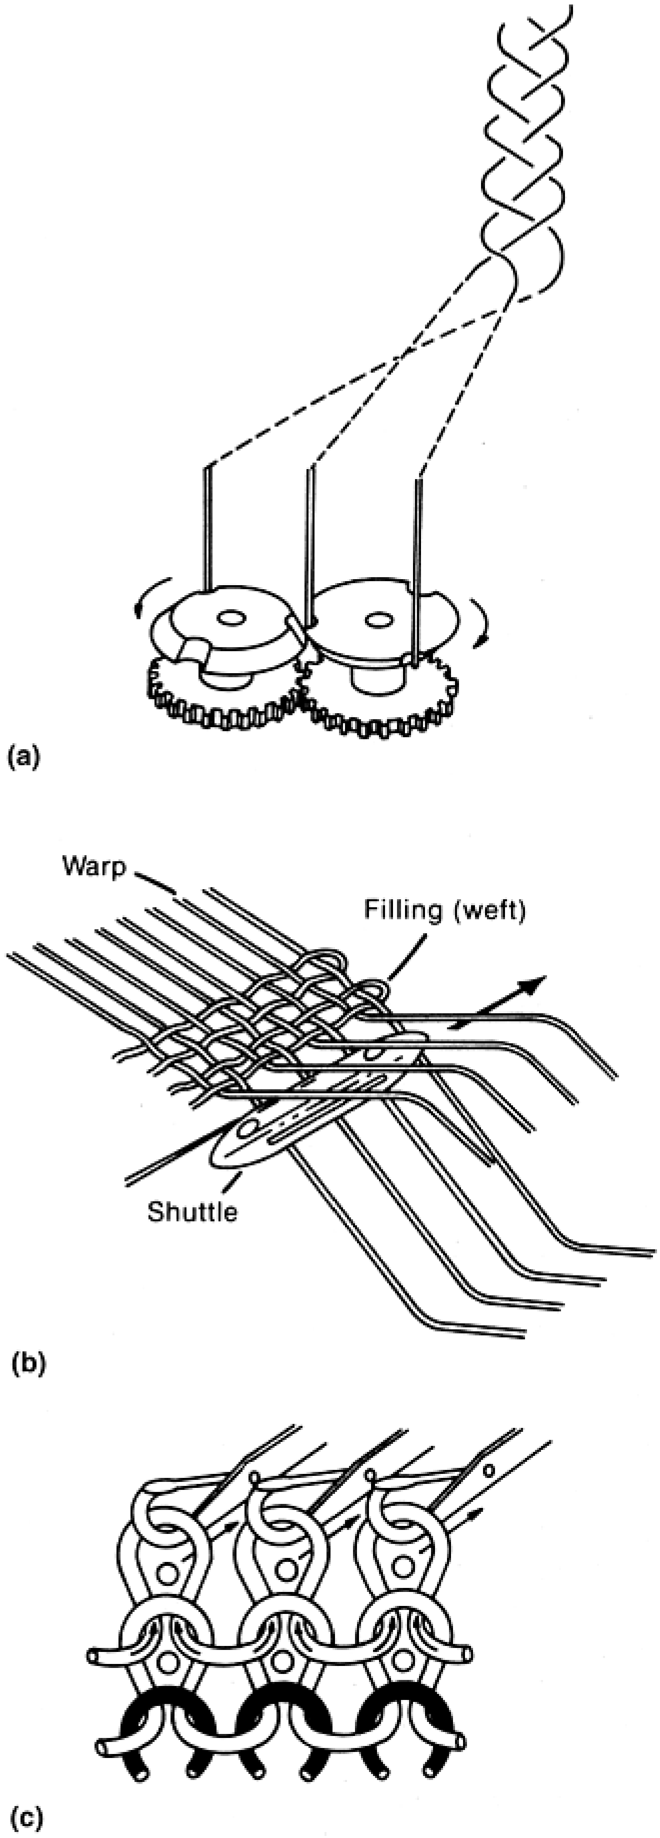

Fig. 1 Fabric techniques. (a) Braided. (b) Woven. (c) Knitted

Braiding has many similarities to filament winding (see the article "Filament Winding" in this Volume). Dry or prepreg yarns, tapes, or tow can be braided over a rotating and removable form or mandrel in a controlled manner to assume various shapes, fiber orientations, and fiber volume fractions. Although braiding cannot achieve as high a fiber volume fraction as filament winding, braids can assume more complex shapes (sharper curvatures) than filament-wound preforms. The interlaced nature of braids also provides a higher level of structural integrity, which is essential for ease of handling, joining, and damage resistance. While it is easier to provide hoop (90°) reinforcement by filament winding, longitudinal (0°) reinforcement can be introduced more readily in a triaxial braiding process. In a study performed by McDonnell Douglas Corporation, it was found in one instance that braided composites can be produced at 56% of the cost of filament-wound composites, because of the labor savings in assembly and the simplification of design (Ref 1). By using the three-dimensional braiding process, not only can the intralaminar failure of filament-wound or tape laid-up composites be prevented, but the low interlaminar properties of the laminated composites can also be prevented. A comprehensive treatment of braiding that does not directly relate to composites is provided in Ref 2.

Because of its knot-tying origins, braiding is perhaps one of the oldest textile technologies known to man. From the Kara-Kumi, an Oriental braid for ornamental purposes, to heavy- duty ropes, braids have long been used in many specialized applications. Their modern applications include sutures and high-pressure hose reinforcement. In short, braids have been used wherever a high level of torsional stability, flexibility, and abrasion resistance are required. On the other hand, because of their lack of width and relatively low productivity (due to machine capacity), braids have not gained as widespread use in the textile industry as have woven, knitted, and nonwoven fabrics.

As a result of the relatively low use of braids as a textile and clothing material, publications related to braiding are limited. Braids were considered a crafting art in the 1930s (Ref 3); one of the earliest treatments of braids as an engineering structure appeared in an article by W.J. Hamburger in the 1940s (Ref 4) in which the geometric factors related to the performance of braids were examined. The first comprehensive discussion of the formation, geometry, and tensile properties of tubular braids was given by D. Brunnschweiler (Ref 5, 6) in the 1950s. From the machinery and processing point of view, an informative book was written by W.A. Douglass (Ref 7) in the early 1960s. Relating processing parameters to the structure of braids, two articles (Ref 8, 9) reflect the sophistication of the development of braiding technology in Germany. A beautifully illustrated review on the historical development of braiding and its applications and manufacture was published by Ciba-Geigy Corporation (Ref 10). Serious consideration of braids as engineering materials did not occur until the later part of the 1970s, when researchers from McDonnell Douglas described the use of braids for composite preforms (Ref 11) to reduce the cost of producing structural shapes. About the same time, the first published article on the structural mechanics of tubular braids by S.L. Phoenix appeared (Ref 12), as well as an extended treatment by C.W. Evans of braids and braiding for a pressure hose, which is a flexible composite (Ref 13).

Since the 1980s, most of the published information on braids has been related to composites (Ref 1, 11, 14, and 15). A large concentration of articles on three-dimensional braiding has been appearing in the literature. Addressing the delamination problem in state-of-the-art composites and demonstrating the possibility of near-net shape manufacturing, the articles on three-dimensional braiding can be categorized into the areas of applications (Ref 16), processing science and structural geometry (Ref 17), structural analysis (Ref 18), and property characterization (Ref 19). As indicated in this brief review of the literature, braids have gained popularity in the composite industry because of the technological needs of structural composites for the inherent uniqueness of braided structures, as well as the recent progress in hardware and software development for braiding processes. At this point, two-dimensional and three-dimensional triaxial braids are more developed and widely applied than complex three-dimensional braids.

Coupled with the fully integrated nature and the unique capability for near-net shape manufacturing, the current trend in braiding technology is to expand to large-diameter braiding; develop more sophisticated techniques for braiding over complex-shaped mandrels, multidirectional braiding, or near-net shapes; and the extensive use of computer-aided design and manufacturing.

This article describes basic terminology, braiding classifications, and the formation, structure, and properties of the braided structures, with specific attention to composites.

Braiding Classifications

One of the most attractive features of braiding is its simplicity. A typical braiding machine (Fig. 2) essentially consists of a track plate, spool carrier, former, and a take-up device. In some cases, a reversing ring is used to ensure uniform tension on the braiding yarns. The resulting braid geometry is defined by the braiding angle, θ, which is half the angle of the interlacing between yarn systems, with respect to the braiding (or machine) direction. The tightness of the braided structure is reflected in the frequency of interlacings. The distance between interlacing points is known as pick spacing. The width, or diameter, of the braid (flat or tubular) is represented as *d*.

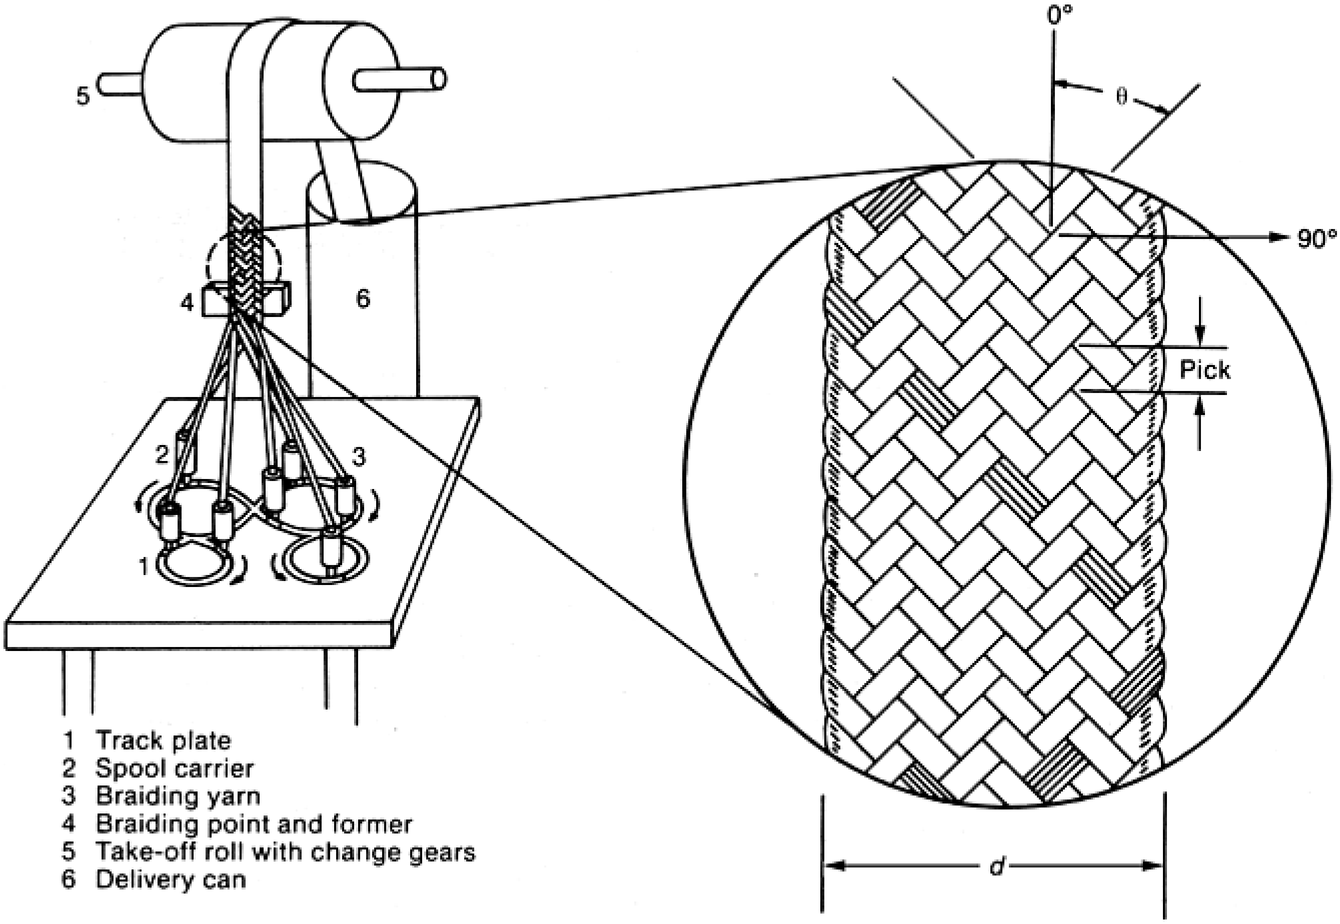

Fig. 2 Flat braider and braid

The track plate supports the carriers, which travel along the path of the tracks. The movement of the carriers can be provided by devices such as horn gears, which propel the carriers around in a maypole fashion. The carriers are devices that carry the yarn packages around the tracks and control the tension of the braiding yarns. At the point of braiding, a former is often used to control the dimension and shape of the braid. The braid is then delivered through the take-up roll at a predetermined rate. If the number of carriers and take-up speed are properly selected, the orientation of the yarn (braiding angle) and the diameter of the braid can be controlled. The direction of braiding is an area of flexibility, because it can be horizontal, vertical from bottom to top, or inverted.

When longitudinal reinforcement is required, a third system of yarns can be inserted between the braiding yarns to produce a triaxial braid with 0°±θ° fiber orientation. If there is a need for structures having a greater thickness than that produced as a single braid, additional layers (plies) of fabric can be braided over each other

to produce the required thickness. For a higher level of through-thickness reinforcement, multiple-track braiding, pin braiding, or three-dimensional braiding can be used to fabricate structures in an integrated manner. The movement of the carriers can follow a serpentine track pattern or orthogonal track pattern by means of a positive guiding mechanism and/or Jacquard- controlled mechanism (lace braiding). Jacquard braiding uses a mechanism that enables connected groups of yarns to braid different patterns simultaneously. Various criteria and braiding classifications are shown in Table 2. For simplicity, and to be consistent with the literature in the composite community, the dimensions of braided structures are used as the criteria for categorizing braiding. Specifically, a braided structure having two braiding-yarn systems with or without a third laid-in yarn is considered two- dimensional braiding. When three or more systems of braiding yarns are involved to form an integrally braided structure, it is known as three- dimensional braiding.

Table 2   Braiding classifications

Parameter	Biaxial	Triaxial	Multiaxial
Dimension of braid	Two-dimensional	Three-dimensional	Three-dimensional
Shaping	Formed shape	Formed shape	Net shape
Direction of braiding	Horizontal	Vertical	Inverted vertical
Construction of braid	1/1	2/2	3/3
Control mechanism for carrier motion	Positive	Positive	Jacquard
Braiding type	Circular	Flat	Jacquard, special

Braiding

Frank K. Ko, Drexel University

Two-Dimensional Braiding

The equipment for two-dimensional braiding is well established worldwide, but especially in West Germany. One of the oldest braiding machine manufacturers in the United States is Mossberg Industries (also known by its former name, New England Butt, and now called Wardwell Braiding Machine Company), which manufactures braiders ranging from three-carrier to 144-carrier models. There are a number of braid manufacturers actively producing braided preforms and/or developing braided composites. A sample list of these companies is given in Table 3. A wide range of applications has been reported by these companies, including medical, recreational, military, and aerospace uses, as defined in Table 4.

Figure 3 illustrates a 144-carrier horizontal braider that is capable of biaxial or triaxial braiding. The versatility of braiding for forming complex structural shapes is illustrated in Fig. 4, which shows a fiberglass preform for a composite coupling shaft being formed in the Fibrous Materials Research Laboratory at Drexel University, using a 144-carrier braiding machine. Using a similar braiding machine, a racing car chassis has also been fabricated (Fig. 5) by that laboratory.

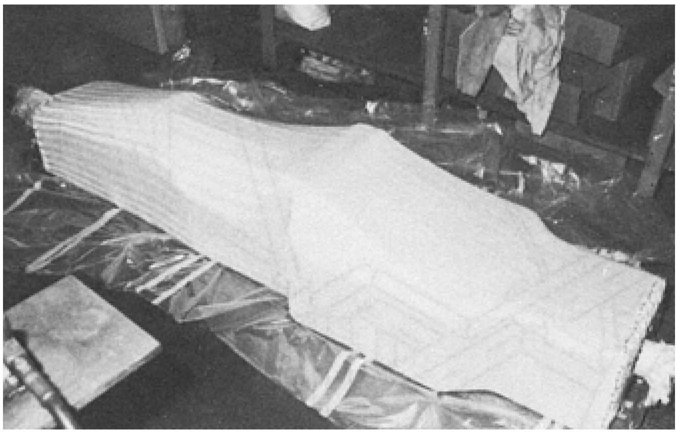

Fig. 5 Braided fiberglass car chassis

Governing Equations. The mechanical behavior of a composite depends upon fiber orientation, fiber properties, fiber volume fraction, and matrix properties. To conduct an intelligent design and selection process for using braids in composites, an understanding of fiber volume fraction and geometry as a function of processing parameters is necessary. The fiber volume fraction is related to the machine in terms of the number of yarns and the orientation of those yarns. The fiber geometry is related to the machine by orientation of the fibers and final shape.

Braided fabrics can be produced in flat or tubular form by intertwining three or more yarn systems together. The bias interlacing nature of the braided fabrics makes them highly conformable, shear resistant, and tolerant to impact damage. Triaxial braiding can be produced by introducing 0° yarns, as shown in Fig. 6, to enhance reinforcement in the 0° direction.

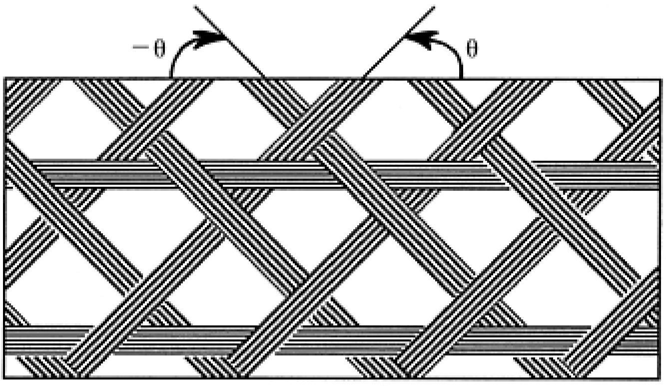

Fig. 6 Structure of triaxial braid

Multilayer fabrics can be formed by simply braiding back and forth or overbraiding in the same direction to build up the thickness of the structure. Each layer can be biaxial or triaxial. The fiber type and braid angle can be varied as needed.

Because of the highly conformable nature of braided structures, braiding has undergone a great deal of development in recent years (Ref 18). The formation of shape and fiber architecture is illustrated in Fig. 7, which depicts the process of braiding over an axisymmetric shape of revolution according to instructions generated through a process kinematic model. The governing equations for the model and the input parameters summarized in Tables 5 and 6 (Ref 20) form the basis for a computer-controlled braiding process.

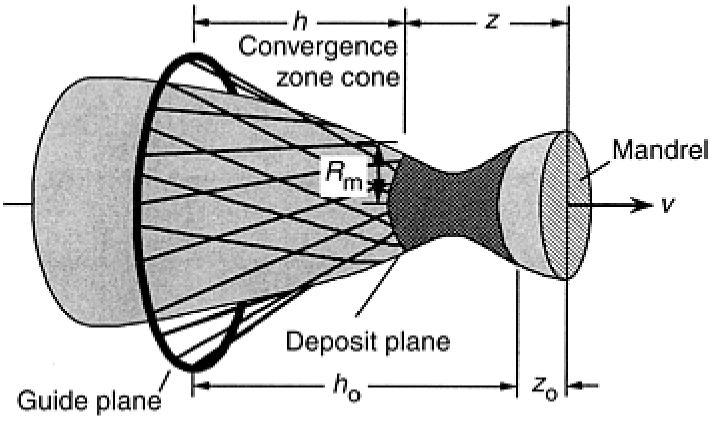

Fig. 7 Braid formation over mandrel. For definition of variables see Table 5.

Table 5 Key inputs and outputs for computer-controlled braiding

Inputs	
Constants	
Guide radius	R_g
Number of carriers	N_c
Yarn width	w_y
Mandrel shape	$R_{m(z)}$
Initial conditions	
Convergence zone length	h_o
Starting deposit location	z_o
Key inputs/outputs	
Local braid angle	$\theta(z)$
Local yarn volume fraction	$V_{y(z)}$
Machine speed profiles	$v(t)$, $\omega(t)$
Auxiliary outputs	
Convergence zone length	$h(t)$
Local cone half-angle	$\gamma(z)$
Velocity of braid formation	$\frac{dz(t)}{dt}$

Table 6 Governing equations for computer-controlled braiding

Convergence length	$$v(t) = \frac{dh(t)}{dt} + \frac{R_{m(z)} \supseteq \omega(t) \supseteq h(t)}{R_g\sqrt{1 - [\frac{R_{m(z)}}{R_g} + \frac{h(t)}{R_g} tan\gamma(z)]^2}}$$

Braid angle	$\theta(z) = tan^{-1}[\frac{R_g}{h(t)} cos\gamma(z)\sqrt{1-[\frac{R_{m(z)}}{R_g}+\frac{h(t)}{R_g}tan\gamma(z)]^2}]$
Fiber volume fraction	$V_{f(z)} = \frac{\kappa \supseteq w_y \supseteq sin\gamma(z)}{2 \supseteq R_{m(z)} \supseteq cos\theta(z) \supseteq sin[\frac{2 \supseteq \pi \supseteq sin\gamma(z)}{N_c}]}$
Yarn jamming criterion	$\theta_{max(z)} = cos^{-1}[\frac{w_y \supseteq sin\gamma(z)}{2 \supseteq R_m \supseteq sin[\frac{2 \supseteq \pi \supseteq sin\gamma(z)}{N_c}]}]$

Geometric parameters include distribution of braiding angles, yarn volume fraction, and fabric-covering factor along the mandrel length. Processing variables include profiles of the braiding and mandrel advance speeds versus processing time. The equations in Table 6 give the relationship between geometric parameters and processing variables, describe current machine status (braid length and convergence length), and provide process limits due to yarn jamming.

Braiding angle can range from 5° in almost parallel yarn braid to approximately 85° in a hoop yarn braid. However, because of geometric limitations of yarn jamming, the braiding angle that can be achieved for a particular braided fabric, as defined in Table 6, depends on the following parameters: number of carriers, N_c, braiding yarn width, w_y, mandrel radius, R_m, and half- cone angle, γ, of the mandrel.

When the mandrel has a cylindrical shape, that is, $\gamma = 0$, the fiber volume fraction (V_f) of the biaxial braid becomes:

$$V_f = \frac{\kappa \supseteq w_y \supseteq N_c}{4 \supseteq \pi \supseteq R_m \supseteq \cos\theta} \quad \text{(Eq 1)}$$

where κ is the fiber packing fraction, w_y is the yarn width, N_c is the number of braiding carriers, R_m is the radius of mandrel, and θ is the orientation angle of yarns. We define the braid tightness factor, η, as the ratio of the total width of either $+\theta$ or$-\theta$ yarns to the mandrel perimeter, namely:

$$\eta = \frac{w_y \supseteq N_c}{4 \supseteq \pi \supseteq R_m}(0 < \eta \leq 1) \quad \text{(Eq 2)}$$

which must be maintained within the range of 0 to 1 to avoid yarn jamming. Combining Eq 1 and 2, the fiber volume fraction is expressed as:

$$V_f = \kappa \frac{\eta}{\cos\theta} \quad \text{(Eq 3)}$$

Figure 8 shows the process window for the fiber volume fraction versus the braid angle at various levels of fabric tightness factor, based on Eq 3. The fiber packing fraction again is assumed to be 0.8. As can be seen, for a given fabric tightness factor, the fiber volume fraction increases with an increase in the braid angle, until the yarn jamming point is reached. In designing braided preforms, their fiber volume fraction and fiber orientation angles are usually determined from the composite properties desired. To achieve the requirement for the desired fiber volume fraction and orientation angle, it is only necessary to select a specific fabric tightness factor (either by changing the braiding carrier numbers, the width of braiding yarns, or a combination of the two) as defined by Eq 3.

Three-Dimensional Braiding

Three-dimensional braiding technology is an extension of two-dimensional braiding technology, in which the fabric is constructed by the intertwining or orthogonal interlacing of yarns to form an integral structure through position displacement.

A unique feature of three-dimensional braids is their ability to provide through-the-thickness reinforcement of composites as well as their ready adaptability to the fabrication of a wide range of complex shapes ranging from solid rods to I-beams to thick-walled rocket nozzles.

Three-dimensional braids have been produced on traditional maypole machines for ropes and packings in solid, circular, or square cross sections. The yarn carrier movement is activated in a restricted fashion by horn gears. A three-dimensional cylindrical braiding machine of this form was introduced by Albany International Corporation, with some modification that the yarn carriers do not move through all the layers (Ref 21). Three-dimensional braiding processes without using the horn gears, including track and column (Ref 22) and two-step (Ref 23), have been developed since the late 1960s in the search for multidirectional reinforced composites for aerospace applications. The track and column method is concentrated upon for analysis.

A generalized schematic of a three-dimensional braiding process is shown in Fig. 9. Axial yarns, if present in a particular braid, are fed directly into the structure from packages located below the track plate. Braiding yarns are fed from bobbins mounted on carriers that move on the track plate. The pattern produced by the motion of the braiders relative to each other and the axial yarns establishes the type of braid being formed, as well as the microstructure.

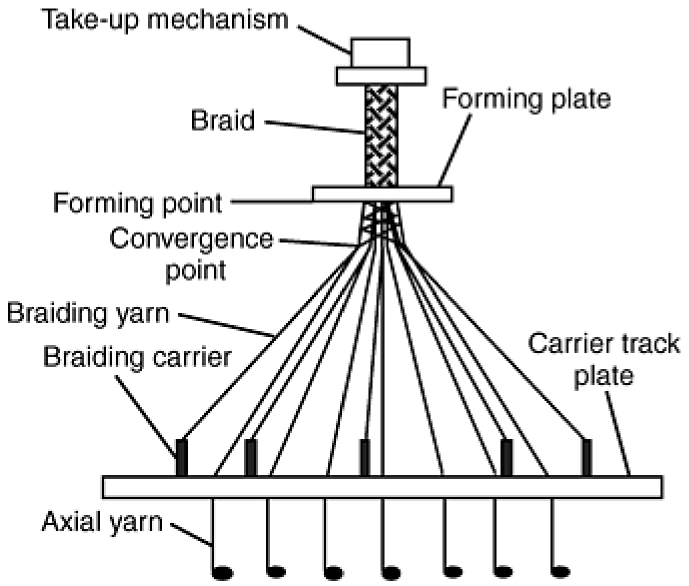

Fig. 9 Schematic of a generalized three-dimensional braider

Track and column braiding is the most popular process in manufacturing of three-dimensional braided preforms. The mechanism of these braiding methods differs from the traditional horn gear method only in the way the carriers are displaced to create the final braid geometry. Instead of moving in a continuous maypole fashion, as in the solid braider, these three-dimensional braiding methods invariably move the carriers in a sequential, discrete manner. Figure 10(a) shows a basic loom setup in a rectangular configuration. The carriers are arranged in tracks and columns to form the required shape, and additional carriers are added to the outside of the array in alternating locations. Four steps of motion are imposed to the tracks and columns during a complete braiding machine cycle, resulting in the alternate *X*- and *Y*-displacement of yarn carriers, as shown in Fig. 10 (b)–(e). Since the track and column both move one carrier displacement in each step, the braiding pattern is referred to as 1 × 1. Similar to the solid braid, the 0° axial reinforcements can also be added to the track and column braid as desired. The formation of shapes, such as T-beam and I-beam, is accomplished by the proper positioning of the carriers and the joining of various rectangular groups through selected carrier movements.

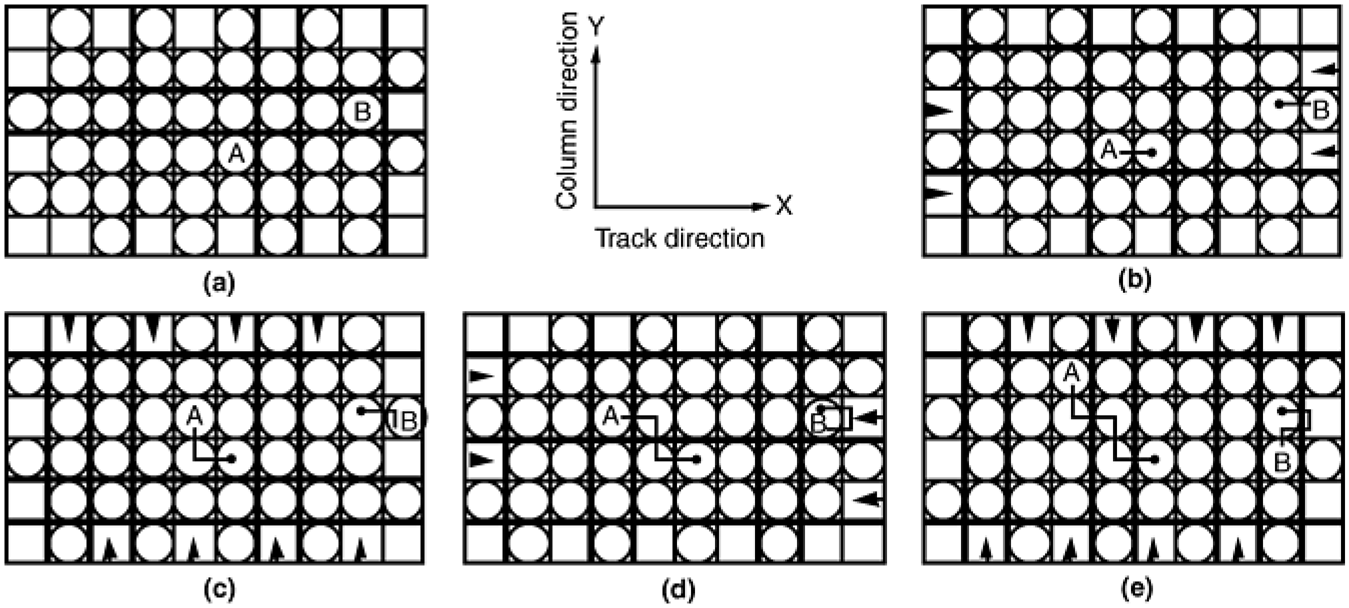

Fig. 10 Formation of a rectangular three-dimensional track and column braid, using 4 tracks, 8 columns, and 1 × 1 braiding pattern

The assumptions made in the geometric analysis of three-dimensional braids given by Du and Ko (Ref 24) are as follows: no axial yarns; rectangular loom with 1 × 1 braiding pattern; braider yarns have circular cross

sections, same linear density, and constant fiber packing fraction; yarn tensions are high enough to ensure a noncrimp yarn path; and the braid is mostly compacted so that each yarn is in contact with all its neighboring yarns. In other words, the braid is always under the jamming condition.

Figure 11(a) shows the unit cell identified from the analysis. The unit cell consists of four partial yarns being cut by six planes. Clearly, there does not exist such a unit cell that only consists of four complete yarns. The dimensions of the unit cell are $\frac{1}{2}h_{x'}$ in x'-direction, $\frac{1}{2}h_{y'}$ in y'-direction, and $\frac{1}{2}h_z$ in the z-direction (braid length), where $h_{x'}$ and $h_{y'}$ can be calculated from the yarn diameter, d, its orientation angle, α, and the fabric tightness factor, η. The dimension h_z is actually the pitch length of braid formed in a complete machine cycle (four steps). This length is one of the key parameters in controlling the fabric microstructures. The cross sections of the unit cell at $\frac{1}{2}h_z$, $\frac{3}{8}h_z$, $\frac{1}{4}h_z$, $\frac{1}{8}h_z$, and 0 are shown in Fig. 11(b)–(f), respectively. As can be seen, each unit cell cross section consists of four half-oval cross sections of yarn. The fiber volume fraction can then be derived based on this observation.

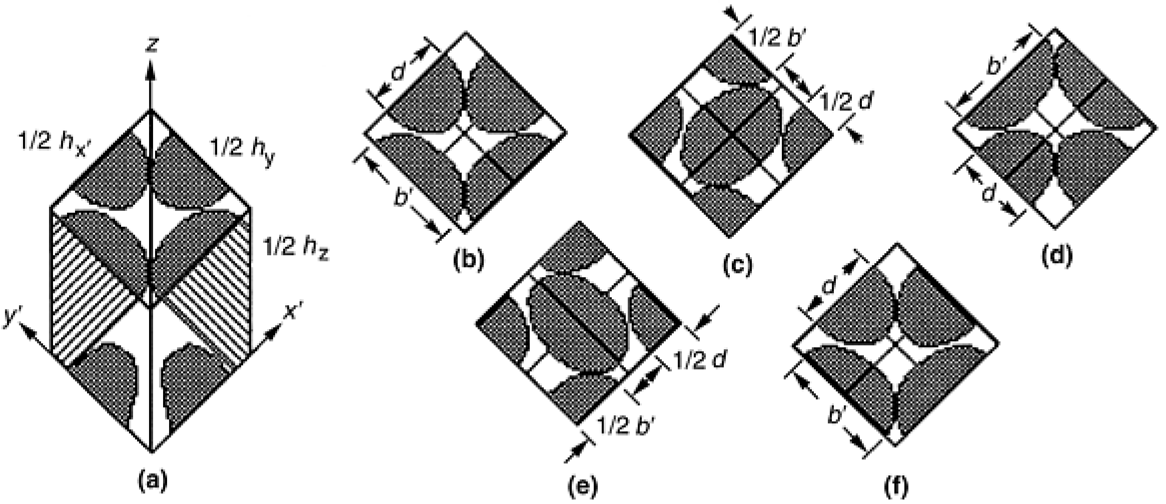

Fig. 11 Unit cell geometry of three-dimensional braid. (a) Unit cell. (b) Unit cell cross section at $z = \frac{1}{2}h_z$. (c) Unit cell cross section at $z = \frac{3}{8}h_z$. (d) Unit cell cross section at $z = \frac{1}{4}h_z$. (e) Unit cell cross section at $z = \frac{1}{8}h_z$. (f) Unit cell cross section at $z = 0$.

The braid has the tightest structure when each yarn is in contact with all its neighboring yarns, in other words, the yarns are jammed against each other. At the jamming condition, fiber volume fraction, V_f, can be derived from the geometric relationship:

$$V_f = \frac{\pi}{2}\kappa\frac{\cos\theta}{1+\cos^2\theta} \qquad \text{(Eq 4)}$$

where κ is the fiber packing fraction (fiber-to- yarn area ratio) and θ is the angle of braider yarn to braid axis (yarn orientation angle). Due to the bulky fiber and nonlinear crimp nature, it is difficult to fabricate the braid with tightest structure. In practice, the yarn orientation angle (braiding angle) is determined from the yarn diameter and braid pitch length. The fiber volume fraction is controlled by the braiding angle and the braid tightness factor. The governing equations are (Ref 25):

$$\theta = \sin^{-1}\sqrt{\frac{8}{(h_z/d)^2+4}} \quad (h_z \geq 2d) \qquad \text{(Eq 5)}$$

$$V_f = \frac{\kappa\eta}{\cos\theta} \leq \frac{\pi}{2}\kappa\frac{\cos\theta}{1+\cos^2\theta} \qquad \text{(Eq 6)}$$

where d is the yarn diameter, h_z is the pitch length of braid formed in a machine cycle (four braiding steps), and η is the fabric tightness factor. The tightness factor is within the range of 0 to π/4 and must be so selected that the required fiber volume fraction is achieved and also that the over-jamming condition is avoided.

Figure 12 shows the V_f-θ relationship prior to and at the jamming condition, based on the governing equations. The fiber packing fraction, κ, is assumed as 0.785. As can be seen, there are three regions of fiber volume

fraction. The upper region cannot be achieved due to the impossible fiber packing in a yarn bundle. Jamming occurs when the highest braiding angle is reached for a given fabric tightness factor, η. The nonshaded region is the working window for a variety of V_f-θ combinations. Clearly, for a given fabric tightness, the higher braiding angle gives higher fiber volume fraction, and for a fixed braiding angle, the fiber volume fraction is greater at higher tightness factors.

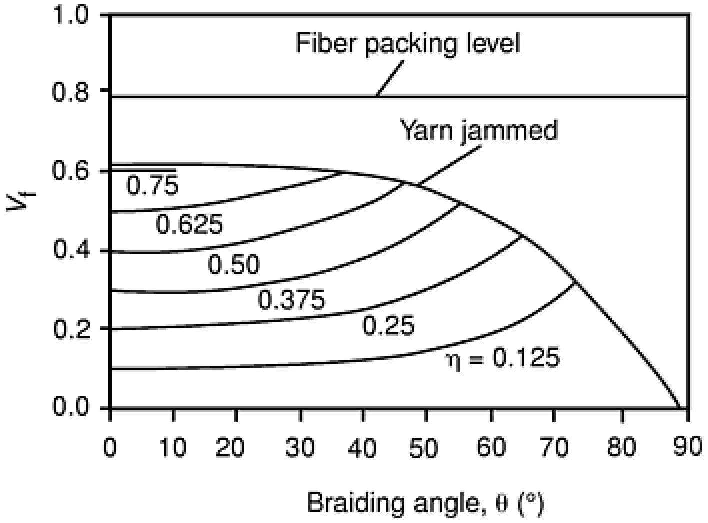

Fig. 12 Relationship of fiber volume fraction to braiding angle for various fiber tightness factors (η)

Properties of Braided Composites

The properties of braided composites are not as well characterized as those for unidirectional tape or woven ply laid-up laminated composites. For two-dimensional braided composites, most of the studies have been on tubular braids. For three-dimensional braid, a database is beginning to be accumulated in academia and

government laboratories. In addition to the near-net shape formability, the most outstanding properties noted for two-dimensional and three-dimensional braid composites are their damage tolerance and their ability to limit impact damage area.

Two-Dimensional Braid Composites. In a study by D.E. Flinchbaugh (Ref 26) on tubular braided S-2 fiberglass-epoxy composites, it was reported that the tensile strength of the braided composites is comparable to that of mild steel at a much lower density. Table 7 summarizes these results. The composite had a density of 1.66 g/ cm^3 and a fiber volume fraction of 75%.

The properties of triaxial braided graphite- epoxy composites was demonstrated by T. Tsiang et al. (Ref 27). As shown in Table 8, the hoop modulus was quite sensitive to the braiding angle. In the longitudinal direction, because of the 0° yarn introduced in the triaxial braiding process, the modulus was less sensitive to the braiding angle. It was also shown that the addition of longitudinal yarns can address the concern for the lack of compressive resistance in braids.

In another study by D. Brookstein and T. Tsiang (Ref 28), it was demonstrated, as shown in Fig. 13, that the capability for the formation of holes in the braiding process revealed the superiority of open hole and pin hole strength over that of machined holes.

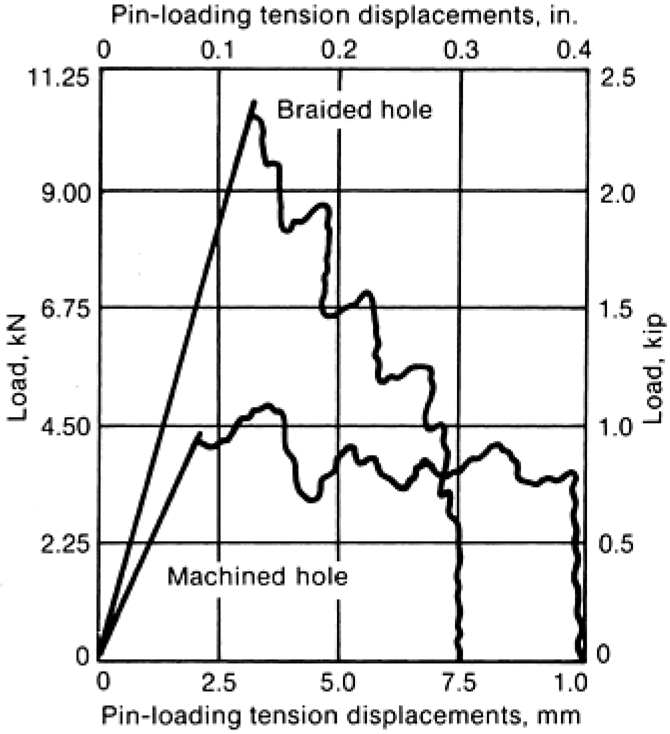

Fig. 13 Strengths of braided holes and machined holes

Three-Dimensional Braid Composites. Since 1983, an intensive effort has been devoted to studying three-dimensional braid composites. Mostly funded by the government, a rather extensive database is being generated in U.S. government laboratories (with the majority in the Naval labs) and in academia (Drexel University and the University of Delaware). The preforms used in these studies are primarily supplied by Drexel University and Atlantic Research Corporation. Although research work on three-dimensional braid composites has been carried out on polymer, metal, and ceramic-matrix composites as well as on carbon-carbon composites, the largest database by far is in polymeric-matrix composites. Therefore, for illustration purposes, only their properties are described subsequently.

General Mechanical Properties. The most comprehensive mechanical characterization of three-dimensional braid composite properties to date has been carried out by A.B. Macander et al. (Ref 29). In this study, the effect of cut-edge bundle size and braid construction were examined through tensile, compressive, flexural, and shear tests. It was found that the test specimens were sensitive to cut edges. As shown in Table 9, the tensile strength of a graphite-epoxy (T300/ 5208) composite was reduced by approximately 60%. When longitudinal yarns (0°) were added, the strength reduction was less than 50%. Accordingly, care should be exercised in the preparation of braided composites to ensure that the yarns on the surfaces are not destroyed. In the same table, one can also see the effect of braid construction and thus, the resulting surface fiber orientation. From a 1 × 1 construction to a 3 × 1 construction, the surface fiber orientation was reduced from 20° to 12°, which resulted in an increase in tensile strength from 665.6 MPa (96.5 ksi) to 970.5 MPa (140.8 ksi).

(b) T300 graphite y arn, 30,000 tow

In Table 10, the effect of yarn bundle size is illustrated. It was found that the tensile strength and modulus of the three-dimensional braid composites tend to increase as fiber bundle size increases. This is apparently related to the dependence of fiber orientation on yarn bundle size. A larger yarn bundle size produced lower crimp (fiber angles) and thus higher strength and modulus. From both Tables 9 and 10, one will notice that although the strength and modulus of the braided composites were significantly higher than those of the 0°/90° woven laminates, the Poisson's ratio (or specific Poisson's ratio) of the braided composites were exceedingly high, from 0.67 to 1.36. To address the instability characteristics in the transverse direction, it was found in the Drexel University laboratory that by adding 10 vol% transverse (90°) yarns, the Poisson's ratio of the braided composites can be reduced to 0.27 at a reduction of strength and modulus from 1250 MPa (180 ksi) and 100 GPa (15 × $l0^6$ psi) to 10 MPa (155 ksi) and 90 GPa (13 × 10^6 psi), respectively.

Table 10 Three-dimensional braided graphite-epoxy composite properties as a function of braid pattern

Uncut specimens, 25.4 mm (1 in.) wide including comparative data for a laminated fabric composite. Tensile specimens were tabbed with 1.6 mm ($\frac{1}{16}$ in.) thick, 25.4 mm (1 in.) × 63.5 mm (2 $\frac{1}{16}$in.) glass-reinforced plastic tapered tabs at grip ends. Celion 6K and 12K specimens had cut edges for the short-beam shear tests only.

Damage Tolerance. The first indication of the damage tolerance capability of the three-dimensional braid composites was observed by L.W. Gause and J. Alper (Ref 30). In the drill hole test performed on three-

dimensional braided Celion 12K/3501 (BASF Corporation), composites and quasi-isotropic composites, it was found that the braided composites were quite insensitive to the drill hole (retaining over 90% of the strength). In the case of the quasi-isotropic composites, a 50% reduction in strength was observed. In the same study, it was also found that although the braided composites did not increase the damage threshold, they did successfully limit the extent of impact damage of graphite-epoxy, compared to that of conventional laminated constructions. Similar observations were also made by F. Ko and D. Hartman on glass-epoxy composites (Ref 31) as well as on carbon-polyetheretherketone (PEEK) composites (Ref 32). The three-dimensional braid glass-epoxy required significantly higher levels of energy to initiate and propagate damage than did the laminated composites under drop weight impact test. In the study of three- dimensional braid commingled Celion 3K-PEEK thermoplastic composites, it was found, as shown in Fig. 14, that the compression-after- impact-strength of the three-dimensional composites was less sensitive than for the state- of-the-art, unidirectional tape laid-up graphite- PEEK composites. The most drastic difference, however, was the impact damage area of the three-dimensional braid composite, compared to that of the laminated composites. As shown in Fig. 15, an order of magnitude lower damage area was attained with the braided composites, compared to the laminated composites.

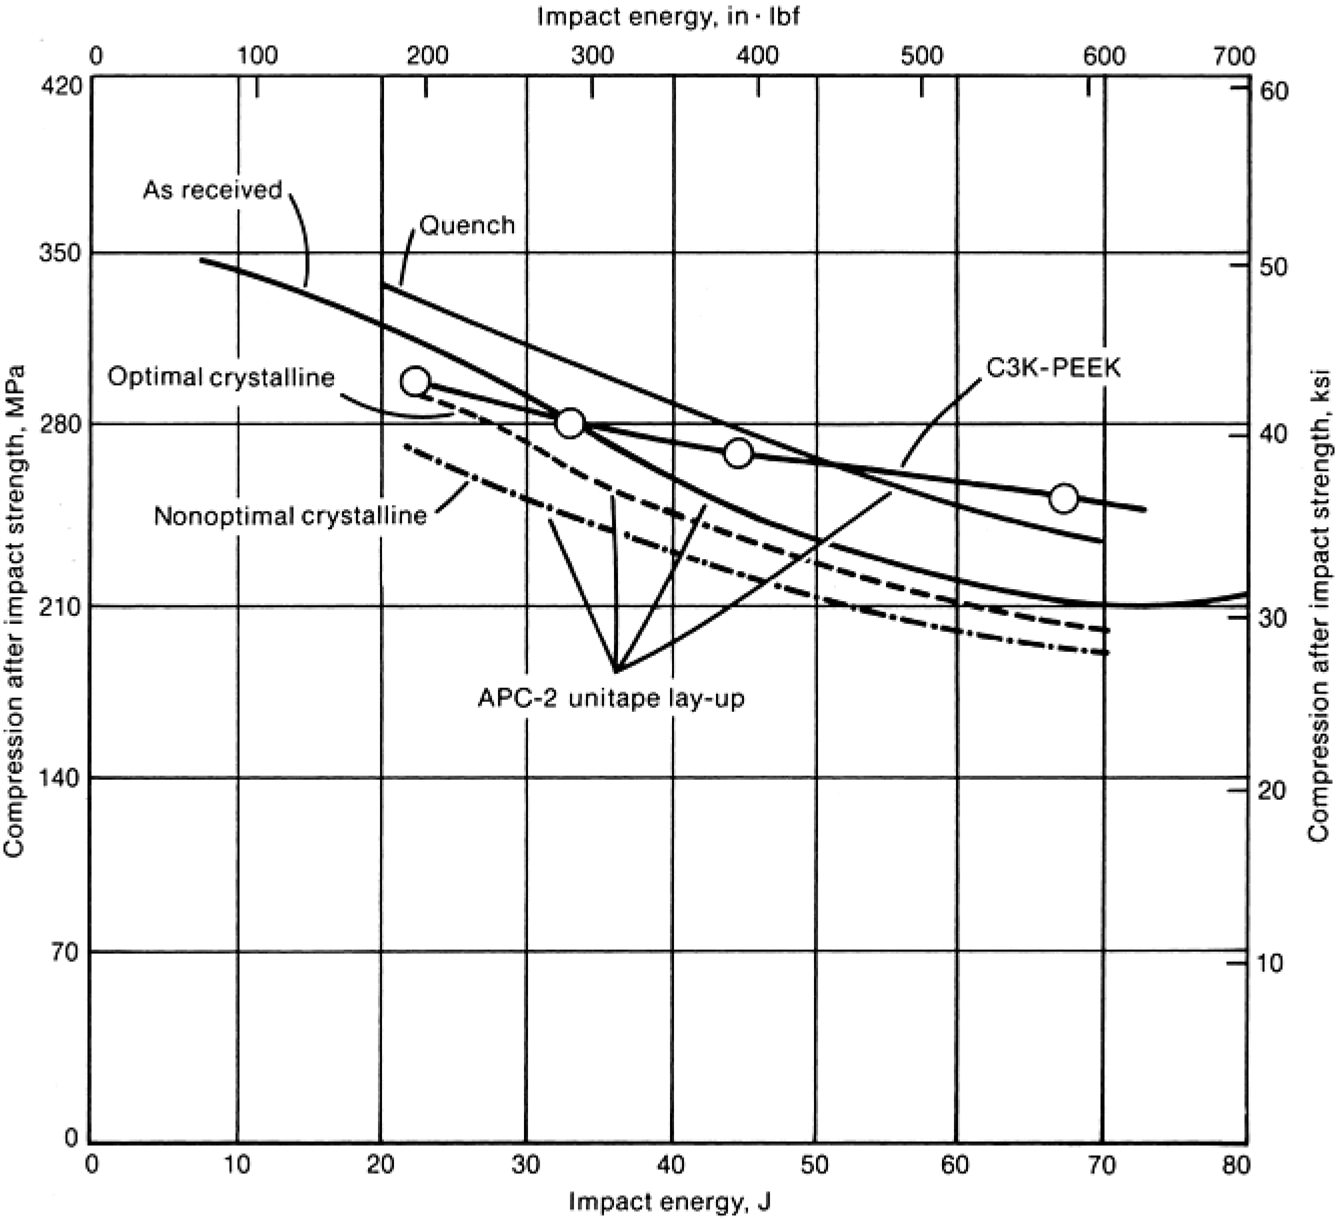

Fig. 14 Effect of impact energy level on compression after impact strength for three-dimensional braid comingled and laminated carbon-PEEK composites

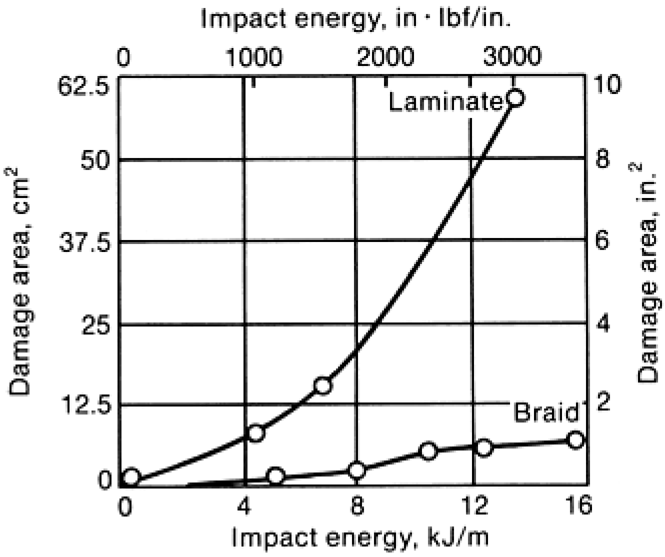

Fig. 15 Effect of impact energy on damage area of three-dimensional braid comingled and laminated carbon-PEEK composites

Properties of Three-Dimensional Braid Composite I-Beams. To illustrate the design flexibility and the structural properties of the three-dimensional braid net-shape composite, a study was carried out by S.S. Yau, T.W. Chu, and F.K. Ko on three-dimensional braided E-glass-polyester I-beams (Ref 33). It was demonstrated that mechanical properties of the net-shape composites can be tailored by the strategic placement of materials in the braiding process. For instance, in Table 11, it can be seen that the addition of longitudinal glass yarns in the flanges of the I- beam led to a more than 50% increase in tensile and compressive moduli. Instead of fiberglass, the addition of unidirectional carbon yarns in the flanges of the I-beam produced as much as a three-fold increase in compressive resistance. Furthermore, the delamination failure found in laminated composites was not observed in any of the I-beams as a result of the high degree of through-thickness strength in the three-dimensional braided composites.

Table 11 Properties of three-dimensional braid glass-polyester I-beams

	I-beam 1	I-beam 2	I-beam 3
Geometry	Braid	Braid/lay-in	Braid/lay-in

Epoxy Resins

Maureen A. Boyle, Cary J. Martin, and John D. Neuner, Hexcel Corporation

Introduction

THE FIRST PRODUCTION OF EPOXY RESINS occurred simultaneously in Europe and in the United States in the late 1930s and early 1940s. Credit is most often attributed to Pierre Castan of Switzerland and S.O. Greenlee of the United States who investigated the reaction of bisphenol-A with epichlorohydrin. The families of epoxy resins that they commercialized were first used as casting compounds and coatings. The same resins are now commodity materials that provide the basis for most epoxy formulations (Ref 1, 2, and 3).

Epoxy resins are a class of thermoset materials used extensively in structural and specialty composite applications because they offer a unique combination of properties that are unattainable with other thermoset resins. Available in a wide variety of physical forms from low-viscosity liquid to high-melting solids, they are amenable to a wide range of processes and applications. Epoxies offer high strength, low shrinkage, excellent adhesion to various substrates, effective electrical insulation, chemical and solvent resistance, low cost, and low toxicity. They are easily cured without evolution of volatiles or by-products by a broad range of chemical specie. Epoxy resins are also chemically compatible with most substrates and tend to wet surfaces easily, making them especially well suited to composites applications.

Epoxy resins are routinely used as adhesives, coatings, encapsulates, casting materials, potting compounds, and binders. Some of their most interesting applications are found in the aerospace and recreational industries where resins and fibers are combined to produce complex composite structures. Epoxy technologies satisfy a variety of nonmetallic composite designs in commercial and military aerospace applications, including flooring panels, ducting, vertical and horizontal stabilizers, wings, and even the fuselage. This same chemistry, developed for aerospace applications, is now being used to produce lightweight bicycle frames, golf clubs, snowboards, racing cars, and musical instruments.

To support these applications, epoxy resins are formulated to generate specific physical and mechanical properties. The designers of these systems must balance the limitations of the raw materials and the chemistry with the practical needs of the part fabricator. While the simplest formulations may combine a single epoxy resin with a curative, more-complex recipes will include multiple epoxy resins, modifiers for toughness or flexibility or flame/smoke suppression, inert fillers for flow control or coloration, and a curative package that drives specific reactions at specified times.

When selecting a thermoset resin, consideration is usually given to tensile strength, modulus and strain, compression strength and modulus, notch sensitivity, impact resistance, heat deflection temperature or glass transition temperature (T_g), flammability, durability in service, material availability, ease of processing, and price. Epoxy resins are of particular interest to structural engineers because they provide a unique balance of chemical and mechanical properties combined with extreme processing versatility. In all cases, thermoset resins may be tailored to some degree to satisfy particular requirements, so formulation and processing information are often maintained as trade secrets.

The three basic elements of an epoxy resin formulation that must be understood when selecting a thermoset system are the base resin, curatives, and the modifiers. When formulating an epoxy resin for a particular use, it is necessary to know what each of these components contributes to the physical and mechanical performance of the part during and after fabrication. The subsequent sections may be used as a practical introduction to formulary components and epoxy resin selection.

Epoxy Resins

Maureen A. Boyle, Cary J. Martin, and John D. Neuner, Hexcel Corporation

Base Resins

The term "epoxy resin" describes a broad class of thermosetting polymers in which the primary cross linking occurs through the reaction of an epoxide group. In general, an epoxy resin can be thought of as a molecule containing a three-membered ring, consisting of one oxygen atom and two carbon atoms (Fig. 1).

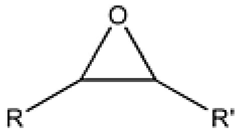

Fig. 1 Basic chemical structure of epoxy group

While the presence of this functional group defines a molecule as an epoxide, the molecular base to which it is attached can vary widely, yielding various classes of epoxy resins. The commercial success of epoxies is due in part to the diversity of molecular structures that can be produced using similar chemical processes. In combination with judicious selection of a curing agent and appropriate modifiers, epoxy resins can be specifically tailored to fit a broad range of applications.

It is important to understand basic production techniques in order to appreciate the available resins and how they differ from each other. Epoxy resins are produced from base molecules containing an unsaturated carbon-carbon bond. There are two processes that can be used to convert this double bond into an oxirane ring: dehydrohalogenation of a halohydrin intermediate and direct peracid epoxidation. While both processes are used to produce commercial epoxy resins, the halohydrin route is more common and is used to produce a wider variety of materials (Ref 4).

The most important raw material used in epoxy resin production is epichlorohydrin, which, with the exception of the cycloaliphatic resins, is used as a precursor for nearly every commercially available epoxy resin.

Catesonics and Defining Characteristics. Epoxy resins used in commercial composite applications can be loosely categorized as those suitable for structural or high-temperature applications, and those best suited to nonstructural or low-temperature applications. A primary indicator of service or use temperature of a polymeric composite is the glass transition temperature (T_g). The T_g is the temperature below which a polymer exists in the glassy state where only vibrational motion is present, whereas above this temperature, individual molecular segments are able to move relative to each other in what is termed the "rubbery state." The modulus of a material above its T_g is typically several orders of magnitude lower than its value below the T_g, so this becomes an important consideration when selecting an epoxy resin. The T_g is also strongly affected by the presence of absorbed moisture or solvents. Thus, exposure to moisture or solvents must also be taken into account when selecting or designing resins for particular applications.

The glass transition temperature of a cured epoxy resin is dependent upon the molecular structure that develops in the matrix during cure, which is driven by characteristics such as cross- link density, stiffness of the polymer backbone, and intermolecular interactions. It is generally agreed, however, that cured resin formulations suitable for elevated temperature applications are largely determined by cross-link density. The T_g is therefore closely related to cure temperature and will change as the cure temperature changes, so a resin system cured at a low temperature will have a lower T_g than the same system cured at a higher temperature. Every system, however, will have an ultimate T_g determined by its formulation that cannot be enhanced by an increase in cure temperature. In most cured epoxy resins, T_g will lag cure temperature by 10 to 20 °C (20 to 35 °F). It is

important to remember that the molecular structure and other characteristics of the cured product are equally dependent on the base resin, the curing agent, and modifiers employed in the formulation.

In addition to service temperature, there are many other physical and chemical differences between the commercially available epoxy resins that dictate both their ultimate use and how they are processed. Primary physical differences between uncured epoxy resins products within a family are material form and viscosity at room temperature, which can range from very thin liquids to solids. Application or processing guidelines often dictate what viscosity or form is required. For example, a solid or semisolid candidate is inappropriate in a wet lay-up application where low viscosity at room temperature is required. As processing capabilities are developed or modified, new material forms become available. The most commonly used resins can be purchased as powders, liquids, solutions produced from various solvents, and, in some cases, as aqueous emulsions.

Another key characteristic that determines resin suitability for use is the epoxy equivalent weight (EEW), which can be defined as the weight of the resin per epoxide group. The equivalent weight of a polymer is used to calculate the stoichiometric ratio between the epoxy and curing agent in order to optimize the cured properties. Dividing the molecular weight of a resin by the number of epoxide groups per molecule can approximate the equivalent weight of a resin. In practice, this estimate will be low as most available resins consist of distribution of molecular weights rather than the single idealized structure. Therefore, epoxy resin vendors routinely determine the EEW of each production lot experimentally as part of their quality control protocols.

Elevated-temperature base resins are those that cure to yield somewhat inflexible molecular structures. Rigidity can be built into the cured matrix in several ways: through the incorporation of aromatic groups, an increase in the number of reactive sites (epoxy groups) per molecule, or a reduction of the distance between reactive sites. The three primary classes of epoxies used in composite applications are phenolic glycidyl ethers, aromatic glycidyl amines, and cycloaliphatics.

Phenolic glycidyl ethers are formed by the condensation reaction between epichlorohydrin and a phenol group. Within this class, the structure of the phenol-containing molecule and the number of phenol groups per molecule distinguish different types of resins.

The first commercial epoxy resin in this class, the diglycidyl ether of bisphenol-A (DGEBA), remains the most widely used today. The structure of pure DGEBA is shown in Fig. 2. Various grades of material are available from multiple suppliers, some of which are summarized in Table 1. The primary distinction between these grades is their viscosity, which can range from 5 to 14 Pa · s (5,000 to 14,000 cP) at 25 °C (77 °F). As equivalent weight increases so does viscosity. Viscosity is ultimately dependent on the molecular weight distribution, with lower molecular weight or purer materials having a lower viscosity and a higher tendency to crystallize upon storage.

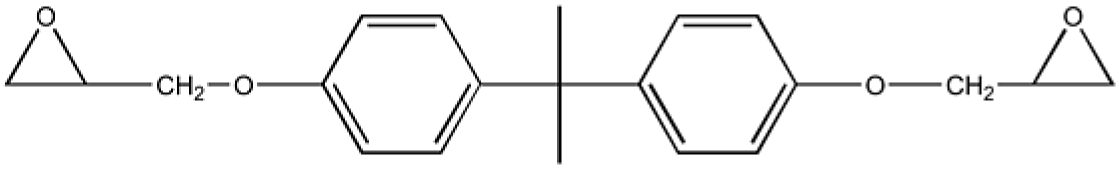

Fig. 2 Chemical structure of diglycidyl ether of bisphenol-A

Table 1 Epoxy resins

Chemical class	Form	Functionality (a)	Equivalent weight (b)	Viscosity at 25 °C (77 °F)		Trade name (supplier)

(a) Number of reactive sites per molecule.

(b) Weight of resin per unit epoxide.

Modifying the ratio of epichlorohydrin to bisphenol-A during production can generate high molecular weight resin variants. This growth in molecular weight increases the viscosity, resulting in resins that are solid at room temperature. Higher molecular weight analogs are used to adjust resin viscosity and tack at the expense of lower glass transition temperatures. Small increases in fracture toughness may also be observed as cross-link density decreases.

A variation on this theme is seen in the hydrogenated bisphenol-A epoxy resins. In this process, the epoxy resin is first formed from epichlorohydrin and bisphenol-A. Next, the aromatic benzene ring is converted to cyclohexane, producing a cycloaliphatic material. This results in a low-viscosity, moderately reactive resin with a structure analogous to the DGEBA-types.
An important variant is the epoxy resin produced from tetrabromo bisphenol-A. These brominated resins are used to impart flame retardancy into the final product and are commonly used in electrical applications. Multiple forms are available with various bromine contents and molecular weight ranges. This category of resins ranges from nearly pure diglycidyl ether of tetrabromo bisphenol-A to high molecular weight analogs similar to those available with the standard bisphenol-A resins.
Another type of phenolic epoxy resin is the diglycidyl ether of bisphenol-F. This material has a lower viscosity than most DGEBA resins and is commonly used to reduce mix viscosity while limiting reductions in glass transition temperature. Moderate improvements in chemical resistance are seen when bis-F resins are used in place of bis-A resins. Unlike the bisphenol-A- based resins, high molecular weight versions are not readily available (Ref 5).
Phenol and cresol novolacs are another two types of aromatic glycidyl ethers (Fig. 3). These resins are manufactured in a two-step process. Combining either phenol or cresol with formaldehyde produces a polyphenol that is subsequently reacted with epichlorohydrin to generate the epoxy. High epoxy resin functionality and high cured T_g characterize these resins and differentiate them from the difunctional bisphenol-A/F resins. The phenol novolacs are high-viscosity liquids while cresol novolacs are typically solids at room temperature. They are of general interest because excellent temperature performance can be achieved at a relatively modest cost.

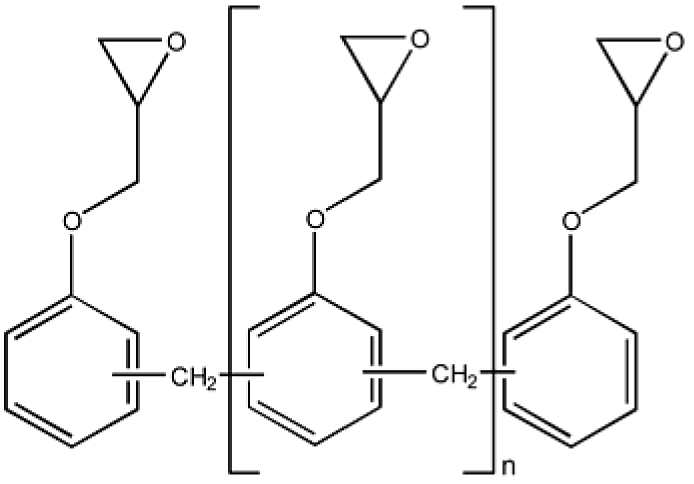

Fig. 3 Chemical structure of phenol novolac. A cresol novolac contains a methyl group on each benzene ring

Other important epoxy novolacs include bisphenol-A novolacs and novolacs containing dicyclopentadiene. Bisphenol-A novolacs achieve excellent high-temperature performance. Dicyclopentadiene novolacs impart increased moisture resistance to a resin (Ref 6).
Glycidyl amines are formed by reacting epichlorohydrin with an amine, with aromatic amines being preferred for high-temperature applications. The most important resin in this class, tetraglycidyl methylene dianiline (TGMDA), is shown in Fig. 4.

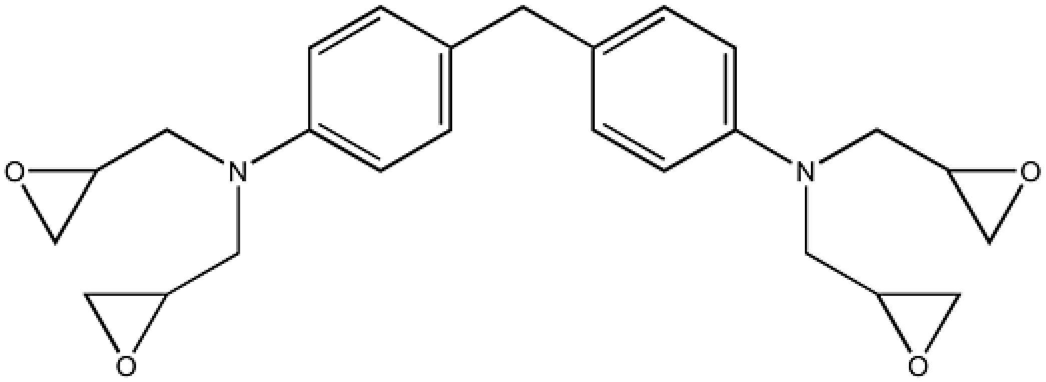

Fig. 4 Chemical structure of tetraglycidyl methylene dianiline (TGMDA)

This resin is used extensively in advanced composites for aerospace applications due to its excellent high-temperature properties. In general, these resins are more costly than either the difunctional bisphenols or the various novolacs. Advantages of TGMDA resins include excellent mechanical properties and high glass transition temperatures. Glycidyl amines are high-viscosity liquids or semisolids at room temperature. As with the DGEBA resins, a variety of grades are available, again dependent upon purity, molecular weight, and particle size.

Another glycidyl amine, triglycidyl p-aminophenol (TGPAP), consists of three epoxy groups attached to a single benzene ring. This resin exhibits exceptionally low viscosity at room temperature, from 0.5 to 5.0 Pa · s (500 to 5000 cP). The mechanical properties and glass transition temperatures approach those obtained with the tetrafunctional resins. Because of its low viscosity, TGPAP resins are commonly blended with other epoxies to modify the flow or tack of the formulated system without loss of T_g. The primary disadvantage is cost, which can be 6 to 8 times that of commodity bis-A resins.

Other commercial glycidyl amines include diglycidyl aniline and tetraglycidyl meta-xylene diamine. The primary advantage of these resins is their low room-temperature viscosity, which makes them useful for applications requiring very high resin flow, such as filament winding or liquid molding.

Cycloaliphatics are differentiated from other epoxies by containing an epoxy group that is internal to the ring structure rather than external or pendant (Fig. 5). Very low viscosity (0.25–0.45 Pa · s, or 250–450 cP, at 25 °C, or 77 °F) and relatively high thermal-mechanical performance (for an aliphatic resin) characterize this class of materials. The high T_gs possible with cycloaliphatics are primarily due to the difference in structure formed upon cross-linking. The cross- link formed upon curing is attached directly to the cyclic backbone structure. While this cyclic structure is aliphatic and therefore more flexible than the aromatic materials described previously, the distance between cross-links is reduced. While many materials have been described in the literature, as of 2000, only a few are available on the open market (Ref 7, 8). It may be important to note that unlike bis-A epoxies, cycloaliphatic epoxies react very slowly with some amines at room temperature.

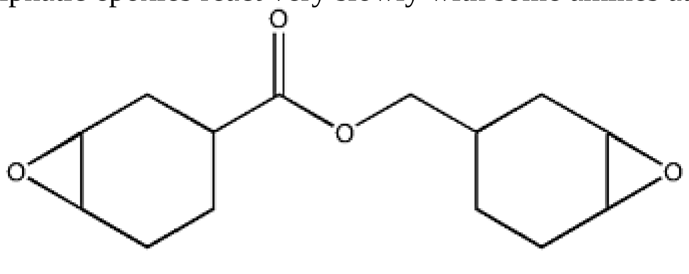

Fig. 5 Chemical structure of a typical cycloaliphatic epoxy resin

Other resins. A wide variety of other epoxy resins are available, including epoxidized oils and specialty, low-volume or experimental high- performance resins. These materials are conceptually similar to those discussed previously.

A list of commonly used epoxy resins and their suppliers may be found in Table 1.

Epoxy Resins

Maureen A. Boyle, Cary J. Martin, and John D. Neuner, Hexcel Corporation

Epoxy Resin Curatives

Epoxy resins will react with a large number of chemical species called curatives or hardeners. (Other terms often used, sometimes incorrectly, are catalysts and accelerators.) The most commonly used chemical classes of curatives are amines, amine derivatives, and anhydrides. Other classes of curing agents are mentioned briefly at the end of this section. Those seeking a more comprehensive guide to epoxy resin curatives should refer to one of several books on the subject (Ref 9, 10).

When selecting resin-curative combinations, the application or end use defines the resin characteristics that must be built into a particular system. Epoxy resins can be formulated in an infinite number of ways to manipulate characteristics such as system stability, cure kinetics, physical form, T_g, mechanical performance, and chemical resistance. Cure times can range from seconds to days, with some heat-activated systems being latent for months to years at room temperature. The uncured formulated resin can be solid, rubbery or liquid, tacky or dry, and can cure at temperatures from 5 to 260 °C (40–500 °F). The cured product can be soft and pliable or rigid and glassy, with glass transition temperatures ranging from below room temperature to 260 °C (500 °F) and tensile elongations from 1% to over 100%. The following sections are meant to give a quick overview of commercially available curatives as of 2001. The materials have been separated into the general categories of room-temperature cure, room- or elevated-temperature cure, elevated-temperature cure, and miscellaneous curatives. In some cases, a single curative or class of curatives may fit in more than one of these categories, however, no effort has been made to identify where classifications overlap.

Room temperature curing agents include aliphatic amines, polyamides, and amidoamines.

Aliphatic amines are the curatives most often paired with epoxy resins. When the functionality and cure mechanism of each component is understood, these materials are used in stoichiometric amounts, though mix ratios are more often determined experimentally and curative levels recommended in units of phr (parts curative per 100 parts bis-A epoxy). The reaction mechanisms of epoxy resin with primary, secondary and tertiary amines are illustrated in Fig. 6. Primary and secondary amines proceed as addition reactions where one nitrogen-hydrogen group reacts with one epoxy group. Reaction with tertiary amines results from the unshared electron pair on the nitrogen. Since there are no secondary hydroxyl groups generated, the resin may be said to homopolymerize. Numerous combinations are available since the various epoxy structures available may contain one, two, three, or more reactive sites and the amine can contain multiple nitrogen-hydrogen groups. Both the number and the distance between reactive groups affect material performance. The distance between reactive groups can vary, with few, widely spaced sites yielding soft and very flexible products while frequent, short separations yield hard and brittle products (Ref 12).

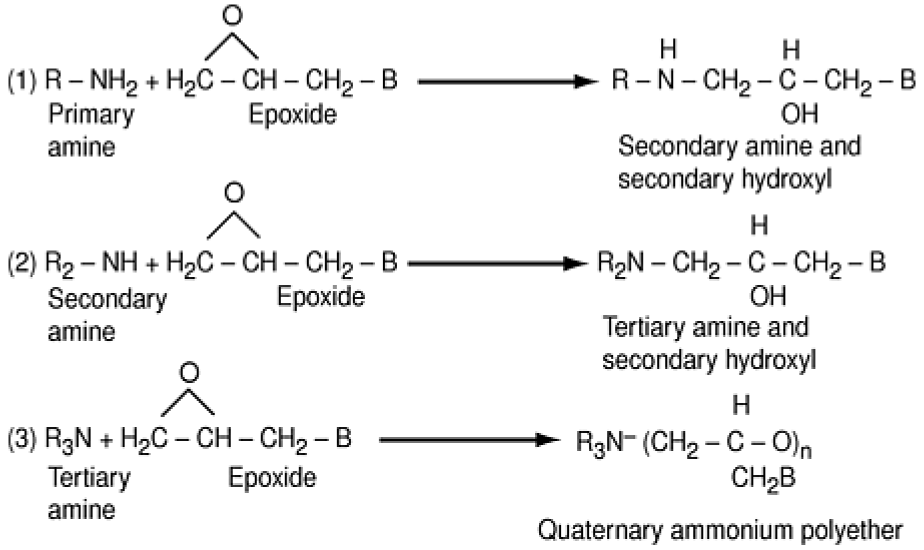

Fig. 6 Epoxy/amine reactions. (1) The primary amine group reacts with the epoxide group to provide secondary amine groups. (2) The secondary amine groups further react with the epoxide groups and generate tertiary amine groups. In both instances the hydroxyl groups are formed, which are believed to catalyze the amine-epoxide reaction. (3) The teriary amine group exerts a catalytic effect and causes the epoxide group to self-polymerize to form a polyether. Source: Ref 11

Commonly used primary amines are diethylene triamine (DETA), triethylene tetramine (TETA), tetraethlylenepentamine (TEPA), and N-aminoethyl-piperazine (N-AEP). Even though these amines will cure at room temperature, T_g and subsequent-use temperature are often improved by an elevated-temperature cure or postcure. The enhanced T_g of these baked materials however, will always be 10 to 20 °C (20 to 35 °F) below cure temperature.

The reactivity of some primary amines allows them to cure under adverse conditions where the substrate and surrounding environment may be cold and damp. Primary amines are highly exothermic and may be adducted with epoxy resins, ethylene, or propylene oxides to render curatives with higher viscosity, less reactivity, and less toxicity than the pure amines. Amine basicity must be carefully controlled in applications where workers come into contact with uncured materials.

Other aliphatic amines sometimes used as epoxy curatives are meta-xylenediamine (MXDA) and the polymeric form of MXDA, which are available as liquids. These curatives contain an aromatic ring but react as aliphatic amines, which gives them cured properties closer to that of the aromatic amines.

Polyetheramines, also known by the trade name Jeffamine (Texaco Inc.), are an interesting class of curative that are available as difunctional or trifunctional liquids with low viscosity and vapor pressure. These materials contain primary amines located on secondary carbons, which gives them relatively long pot lives due to the methyl groups adjacent to the nitrogen. They can be accelerated with nonyl phenol or proprietary compounds available from Huntsman Chemical. Low shrinkage, good clarity, and high toughness or flexibility characterize the cured products. When cured with a standard bis-A epoxy, tensile elongation can vary from 2 to over 100% with tensile strengths from 7 to 70 MPa (1 to 10 ksi) (Ref 13).

Tertiary amines (Lewis bases) react by catalytic anionic polymerization (Fig. 7) (Ref 14). The reactivity of tertiary amines varies widely as the electron density around the nitrogen changes. The composition and location of hydrocarbon groups on the amine will affect the electron density. Homopolymerization results in higher glass transition temperatures, better chemical resistance, and a more brittle product than a resin that has cured through an addition reaction. They may be used as sole curatives at a level of approximately 1 to 6 phr or as accelerators for other curing agents, such as polyamides, amidoamines or anhydrides. Examples of tertiary amines are pyridine, triethylamine, and 2,4,6-tris(dimethylaminomethyl)phenol (Ref 15).

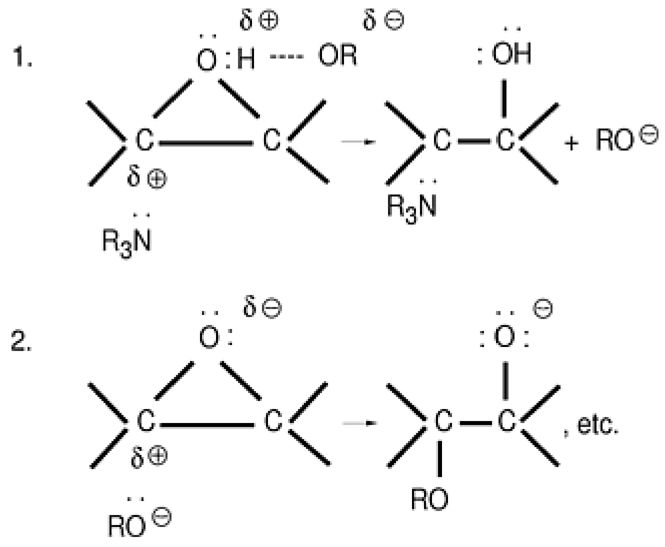

Fig. 7 Epoxy/tertiary amine (Lewis base) reaction mechanism

Cycloaliphatic amines are characterized by having at least one amino group attached directly to a saturated ring. Examples are isophoronediamine (IPDA) and methylene-di(cyclohexylamine) (PACM). In their unmodified state, they harden under ambient conditions but require heat to attain full cure. They can be modified to cure quickly under cold, damp conditions (at temperatures as low as 0–5 °C) and yield less blush, higher T_g, and toughness than aliphatic amines; therefore, these materials are often used in industrial applications, such as floor coatings, mortars, and grouts.

Polyamides, like polyamines, are classified as primary, secondary, or tertiary depending on the substituents on the amide group (Fig. 8). They are condensation products of polyamines and dimer acids or fatty acids. In general, polyamides are less reactive than most polyamines, therefore, they are often modified or adducted in order to increase ambient reactivity, decrease viscosity, and increase compatibility with epoxy resins. They offer excellent adhesion, low toxicity, and good toughness but tend to be somewhat dark in color, which may limit their application. Polyamides are often used for coatings, adhesives, and sealants.

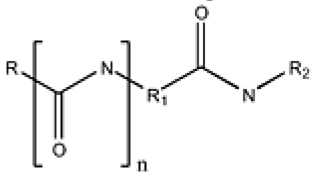

Fig. 8 Chemical structure of a polyamide

Amidoamines (which are sometimes classified as amides or amide/imidazolines by their vendors) contain both amide and amine groups (Fig. 9). They are reaction products of monobasic carboxylic acids (usually the acids derived from C_{16}–C_{19} fats and oils) and aliphatic polyamines. Those materials containing the imidazoline group (a five-membered ring structure) may exhibit more rigidity in the cured backbone resulting in a higher T_g. Amidoamines are low-viscosity amber liquids that have very long pot lives and afford good toughness, flexibility, and adhesion, particularly to concrete. They are used when low volatility and minimal skin irritation are desired. This class of curative also tends to yield better moisture resistance than aliphatic polyamines. Both polyamides and amidoamines may be only marginally compatible with epoxy resins, which means that they must be very thoroughly mixed before use. When stirred, the epoxy-curative may need to partially react before they become fully compatible with each other (Ref 16, 17).

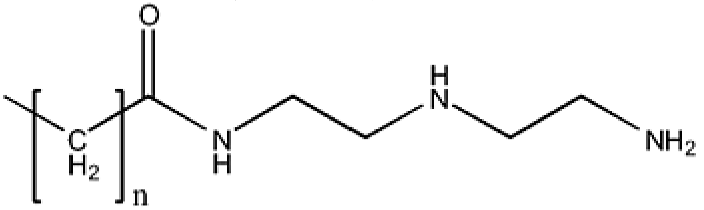

Fig. 9 Chemical structure of an amidoamine

Selection Factors. Cycloaliphatic amines, polyamides, and amidoamines can be used at a wide range of stoichiometric ratios to generate the desired handling or cured properties. Although both an amine value (functionality of the amine) and equivalent weight are available from the vendor, these curatives are generally compounded following recommended use levels given in units of phr. Glass transition temperatures vary between 5 and 55 °C (40 and 130 °F) after cure at room temperature and may be increased substantially with elevated temperature or postcure. Tensile strengths range between 21 and 59 MPa (3 and 8.5 ksi) and elongations between 3% and 8.5% (Ref 16).

Aliphatic amines, their adducts, and derivatives are available from a number of companies who offer a profusion of products (Table 2). The sheer number of options may seem confusing to the formulator, so it becomes important to note that a number of vendors have unique designations or trade names for what are basically the same product. Selection may hinge on purity, form, packaging, availability, or price. Many other products are proprietary adducts and mixtures that may contain accelerators and coreactants, such as free-aliphatic amines, benzyl alcohol, nonyl phenol, phenol, and salicylic acid. It is also important to understand that multiple formulations using different curing agents and different epoxies may yield the same cured properties but differ in the other parameters, such as mix viscosity, pot life, cure time, or appearance. Uses can range from electronics and encapsulation to thermosetting adhesives, flooring grouts, and trowel coatings. A general performance comparison of the major aliphatic amine types, which represent the bulk of room-temperature curatives, can be found in Fig. 10 (Ref 16).

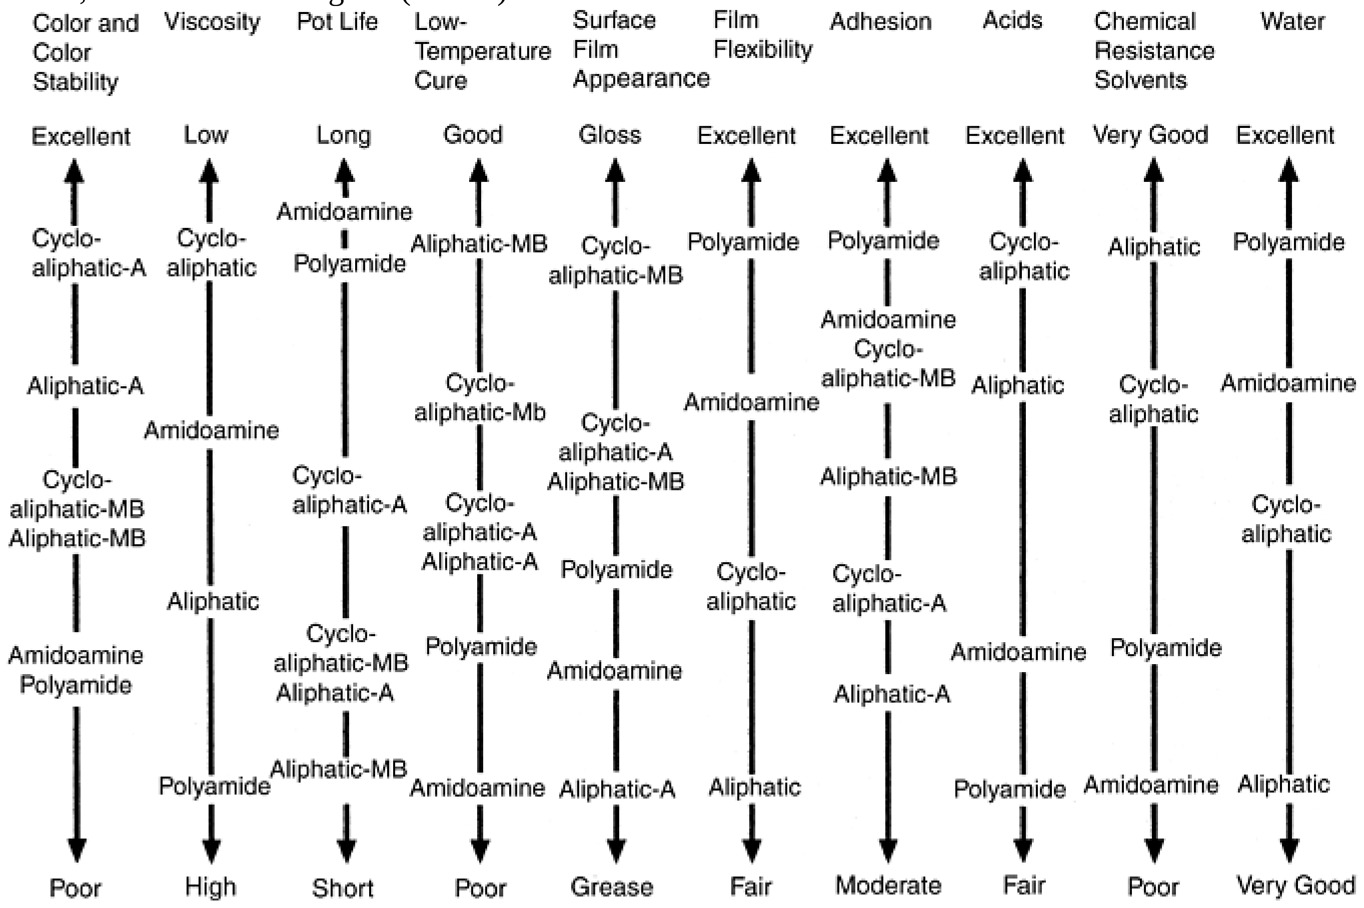

Fig. 10 Comparison of some amine curative classes. A, adduct-type curative; MB, Mannich base-type curative

Room or Elevated Temperature Curing Agents. Unlike the amines and amides discussed earlier, the following two classes of curatives, BF_3 complexes and imidazoles, contain variants that may be cured safely at room temperature and at elevated temperature. Instead of pot lives of minutes to hours, these compounds may be modified to remain latent at room temperature for periods ranging from hours to days. They are often used as accelerators in conjunction with other epoxy curatives.

Boron trifluoride-amine complexes (Lewis acids) cure epoxy resins by catalytic cationic polymerization. The mechanism is shown in Fig. 11 (Ref 18). Pure boron trifluoride (BF_3) reacts with standard bis-A epoxy in seconds, so room- temperature stability is built into the molecule by adducting BF_3 with various amines. These

curatives, most of which are proprietary, may be stabilized by the addition of excess amine, which also reduces the elevated-temperature reactivity. The complexes are available as liquids that vary in latency, activation temperature, and cured properties. Systems can be formulated to cure in hours at room temperature or they may be designed as stable at room temperature and require elevated-temperature cures. Boron trifluoride complexes are used to generate resin castings and coatings with T_gs of up to 200 °C (390 °F). As with amine cures, the product T_g will usually lag behind the cure temperature by approximately 20 °C (36 °F).

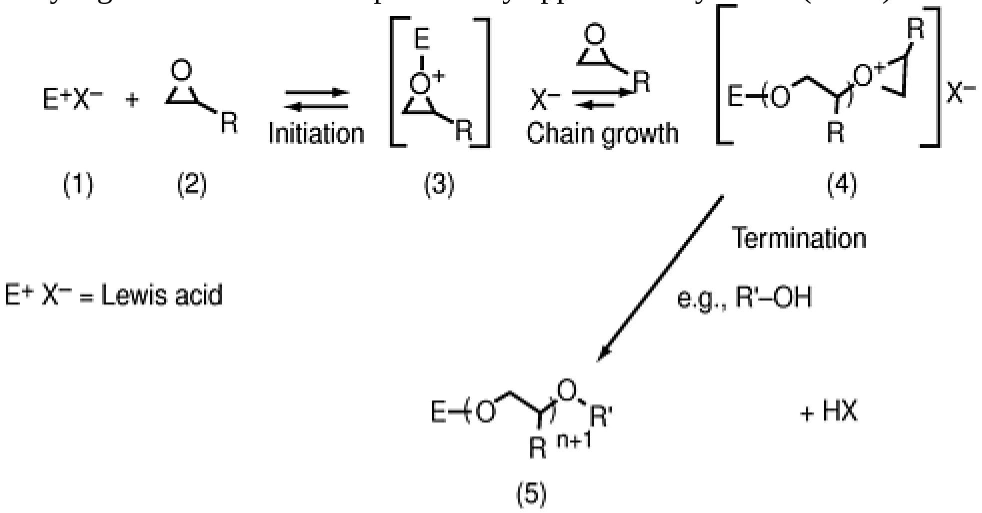

Fig. 11 Epoxy/Lewis acid reaction mechanism

With standard epoxy resins the cure reaction is rapidly triggered and highly dependent on temperature, so elevated-temperature cures can be long and often occur in a step-wise manner to prevent uncontrollable exotherms that can degrade physical properties, making a part unusable. One of the benefits of this class of curative is that they are used at relatively low levels (4–17 parts to 100 parts epoxy) (Ref 19).

Substituted imidazoles are a unique class of curatives that find applications in electronic, structural adhesive, automotive, and aerospace composites. They are generally employed as accelerators for the reaction between epoxies and other curatives but can also be highly effective as sole curing agents. They are one of the most efficient of the Lewis bases, initiating anionic homopolymerization of the epoxy resin at very low loadings (<8 phr). Imidazole curatives are tailored by substitution with organic groups on the ring, chemically blocking active amine hydrogen on the ring, and by salt formation with ring nitrogen. These modifications result in molecules that are rendered latent through steric hindrance or insolubility in room-temperature epoxy resin. Imidazole cures are characterized by high glass transition temperatures (which usually exceed the cure temperature), room-temperature latency that ranges from several hours to 6 months, and rapid cure beyond the activation temperature. Initial cures are generally 1.5 to 2 h at 80 to 100 °C (175 to 210 °F) while postcures range from 2 to 4 h at 150 to 200 °C (300 to 390 °F). The chemical resistance of the cured product is similar to that achieved with aromatic amines, and T_gs can exceed 200 °C (390 °F). Imidazoles are also used as accelerators in anhydride cures (Ref 20).

Elevated Temperature Curatives include aromatic amines and anhydrides.

Aromatic amines are generally fine-powder curatives that are blended or melted into epoxy resin. Some of the products mentioned subsequently will also be available as supercooled liquids or eutectic blends to facilitate mixing at room temperature. The aromatics tend to be more expensive than the aliphatic amines and fewer variants are available. An aromatic amine has the nitrogen of the nitrogen-hydrogen group directly bound to an aromatic ring. The aromatic amines are used in high-performance composites and generally require high-temperature cures to yield superior T_gs and greater chemical resistance than the same epoxy resins cured with aliphatic amines. The reaction of aromatic amines with epoxy resins follows the same mechanisms seen in Fig. 6. The reaction is slower due to lower nucleophilicity and steric factors, so formulated systems can show extended room-temperature out times. Although not as toxic as aliphatic amines, most aromatic amines are considered to be skin sensitizers or irritants and must be handled with the proper precautions.

One of the first aromatic amines used in industry, 4,4′-diaminodiphenyl methane (represented as DADM, MDA, or DDM in the literature), exhibits one of the best balances of properties available from a curative; however, it is currently used infrequently since it has been identified as a suspected carcinogen. The toxic nature of MDA has impeded the introduction of new aromatic amines with related structures because they too

would be suspected carcinogens. The alkyl-substituted versions of this molecule, such as methylene-bis(dimethylaniline) and methylene-bis(diisopropylaniline) (MPDA), are less toxic and are commercially available. The phenylenediamines follow the same pattern, with the alkyl-substituted derivatives such as diethyltoluenediamine being significantly less toxic than the base molecule. When the methylene group of MDA is replaced with a sulfone, the result is diaminodiphenylsulfone (DDS), which is well known and widely used in the aerospace industry. When cured with bis-A epoxy, DDS will yield higher T_g, tensile modulus, and elongation than either MDA or MPDA. In addition, DDS tends to be more latent at room temperature.

Anhydrides are another major class of epoxy curing agents (Fig. 12) (Ref 21), that are available in a variety of physical forms from various suppliers. Most of the products in use in epoxy- composite applications are low-viscosity liquids or moderate-viscosity eutectic blends; nonetheless, some solid anhydrides are also available. The reaction mechanism between an anhydride curing agent and epoxy resin is complex, because three competing reactions take place. The anhydride reacts with the epoxy hydroxyls to form half-esters. The half-ester containing the free carboxyl group is then available to react with an epoxide ring, which generates another hydroxyl. The newly formed hydroxyl can react with another anhydride or, in the presence of free acid, it can react with another epoxy to form an ether linkage.

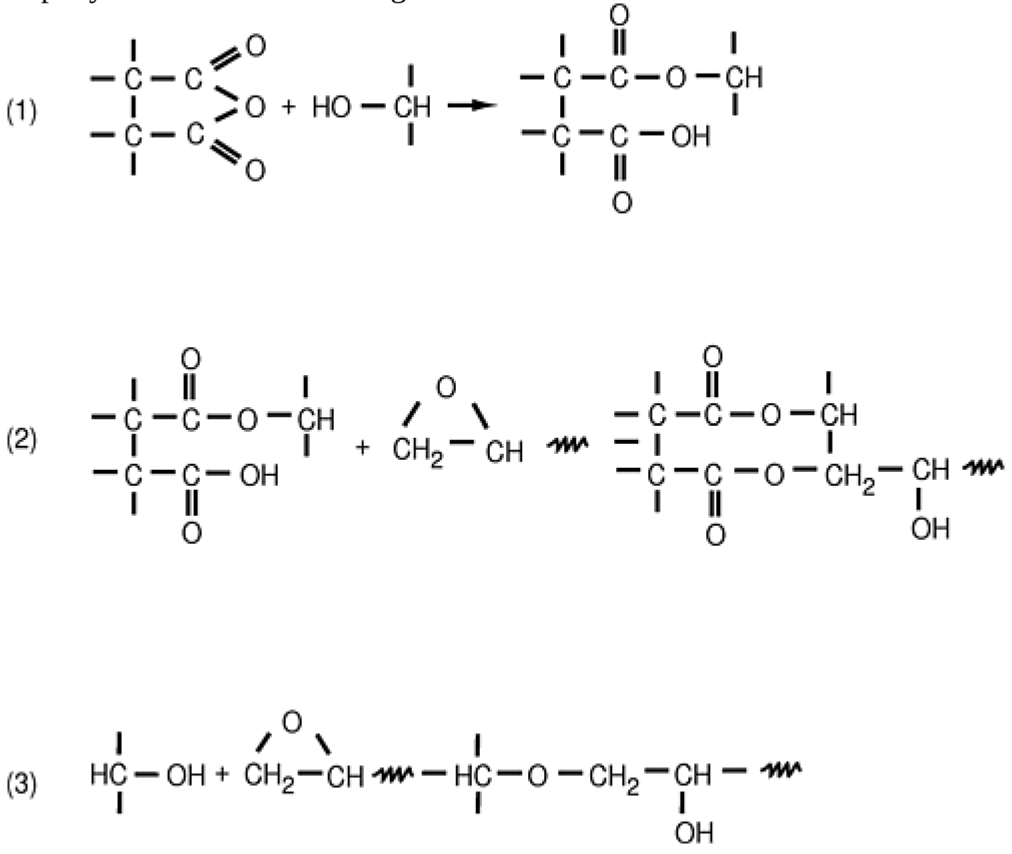

Fig. 12 Epoxy/anhydride reaction mechanism. (1) The opening of the anhydride ring with an alcoholic hydroxyl to form the monoester. (2) Subsequent to (1), the nascent carboxylic groups react with the epoxide to give an ester linkage. (3) The epoxide groups react with nascent or existing hydroxyl groups, catalyzed by the acid, producing an ether linkage.

Formulating with anhydrides requires some experimentation because the desired ratio of anhydride to epoxy can vary widely depending on materials selected, the concentration of hydroxyl groups in the formulation, and the presence of an accelerator. Anhydrides are usually used at between 0.4 to 1.1 equivalents to the epoxy. As with amine curatives, the equivalent weight is defined as the molecular weight divided by the number of functional sites (in this case, anhydride groups) on the molecule. In general, the reaction of epoxy resin with anhydride is more sluggish than with aliphatic amines or amides, with lengthy cure and postcure profiles being required to generate desired properties. Primary cure occurs between 80 to 150° C (175–300 °F) with postcures ranging to 200° C (3900 °F). Accelerators, usually tertiary amines or imidazoles, are used in the range of 0.5 to 3.0% to catalyze the epoxy anhydride reaction and speed up the cure. Representative anhydrides are methyl tetrahydro- phthalic anhydride, nadic methyl anhydride, and methyl hexahydro-phthalic anhydride. Some

commonly used accelerators are dimethylaminomethylphenol, benzyl-dimethylamine, phenylimidazole, and ethylmethylimidazole.

Anhydrides are selected as curatives when low viscosity, noncritical mix ratios, low potential for skin irritation, and long pot life are desired. As cured resins they can yield high T_gs, excellent electrical properties, low shrinkage, and retention of physical and electrical properties above the T_g. Polyanhydrides can offer excellent toughness and thermal shock resistance. Saturated liquid anhydrides offer excellent color, ultraviolet stability, and moisture resistance. Unsaturated anhydrides offer low cost and very low viscosity. The disadvantages of using an anhydride curative are moisture sensitivity (where the anhydride reacts with atmospheric moisture to hydrolyze into the corresponding diacids), brittleness (when unmodified), and only general formulation recommendations from vendors (experimentation is often required to achieve desired performance). Uses are casting, potting, encapsulation, and filament winding. It is noteworthy that cycloaliphatic epoxies are also cured with anhydrides in the presence of an accelerator (Ref 22).

Miscellaneous Curing Agents. Dicyandiamide (generally referred to as “dicy”) is widely used as an epoxy curative in composite applications where room-temperature stability is desired and rapid elevated- temperature cure is attractive. It may be employed as a sole curing agent but most often finds use paired with substituted ureas, substituted imidazoles, or as a cure accelerator for aromatic amines. Dicy is a fine white powder available in a variety of particle size distributions. Particle size distribution may significantly affect resin cost and reactivity as well as cured-product properties, so care should be taken in the selection of the appropriate grade. Dicy tends to be insoluble in epoxy at room temperature, and the reaction doesn't initiate until solubility is achieved (between 80 and 90 °C, or 175 and 195 °F, in most epoxy resins). During cure it decomposes, allowing all four nitrogen atoms to react; therefore, one molecule of dicy can react with six or seven epoxy groups (Ref 23). When used alone, full cure is attained in approximately two hours at temperatures between 145 and 175 °C (295 and 345 °F). When combined with substituted ureas (like monuron or diuron), cures take place at 120 to 175 °C (250–345 °F) over a period of minutes to hours, depending on curative concentrations. The combination of dicy with a substituted imidazole can cure epoxy at temperatures down to about 100 °C (210 °F) with cure time dependent on concentration and temperature selection. In most formulations, dicy is used at a level of 3–7 phr with an optional 2–4 parts of accelerator.

Polysulfides, thiols, or mercaptans (which are terminated with the S-H group) historically have not been used as sole epoxy curatives because these end groups are not acidic enough to thoroughly cure the resin. They have been used as reactive modifiers to increase the toughness or flexibility. Relatively new accelerated compounds are available that cure in seconds at temperatures as low as -40 °C (–40 °F). The cure mechanism is shown in Fig. 13. These curatives are used in adhesive applications where rapid cure is required and the sulfur odor of the curative doesn't prohibit use. Common applications are industrial road marker adhesives and commercial patch kits (Ref 24).

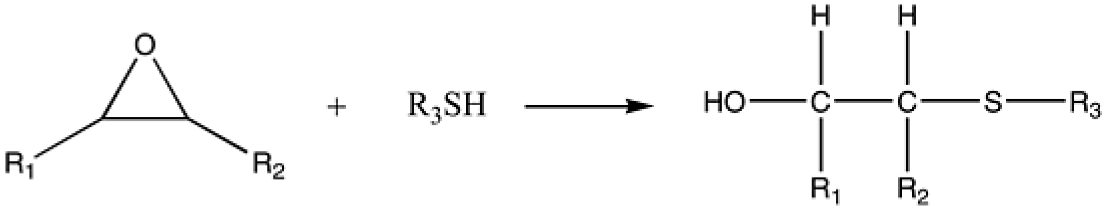

Fig. 13 Epoxy-thiol reaction

Alternate Cure Methods. One of the newer trends in the composites industry is to look at cutting production costs and decreasing cycle times by using radiation-curable resin systems (Ref 25, 26). Radiation sources are ultraviolet (UV), infrared (IR), or electron beam (EB). These methods of cure use radiation to physically or chemically change organic materials, forming cross-linked polymer networks. Historic applications are in the coatings, electronics, printing, and adhesives industries where only a thin film of resin is being cured or dried. Some benefits of radiation cures are energy efficiency, rapid cure times measured in seconds, dimensional stability, pollution abatement as solvent is eliminated from the process, low exotherm potential that permits the use of temperature-sensitive substrates, and no cure until source exposure. Disadvantages are large capital expense, difficulty in penetrating thick parts, and the sensitivity of the reaction mechanism to impurities. There are also limitations due to raw material availability and cost.

Epoxy acrylates can be cationically cured with aryl-sulfonium salt photoinitiators. Polyols are often added to the formulation for flexibilizing or cross-linking. Amines cannot be used in epoxy acrylate systems because they deactivate the sulfonium salts.

Standard cycloaliphatic and bis-A epoxies can be homopolymerized by exposure to radiation; however, cure times will be greater than those obtained with the epoxy acrylates, and the fundamental work to understand curing mechanisms has not been completed.

A higher-energy nonthermal curing method uses EB radiation. Initial equipment cost is very high because parts must be irradiated within a shielded room, but cures are very rapid and high volumes are realized with little overall energy. While there is some temperature increase in the part during cure, it is minor, so inexpensive tooling materials may be considered (including wood). Like UV curing systems, most nonamine-containing epoxies can be used and the initiators are similar. Cure shrinkage is lower than with traditional hardeners, so this is an attractive option for parts with tight dimensional tolerances. Although EB curing of composites is relatively new and work still needs to be done to commercialize the process, preliminary results suggest that the thermal and mechanical properties of these systems may eventually meet most requirements for high-performance applications.

A list of some commonly used curatives and their suppliers may be found in Table 2.

Table 2 Epoxy curatives

Curative class	Suppliers
DETA, TETA, TEPA, IPDA	Air Products, Dow Chemical
Aliphatic amine adducts	Air Products, Ajinomoto, Dow, Emerson & Cuming, Henkel, Hoechst-Celanese, Hüls America, Polychem, Reichold Chemical, Rhone-Poulenc, Shell, Vantico
Tertiary amines (Lewis bases)	Air Products, Henkel, Lindau, Lonza, Reichold Chemicals, Vantico
Cycloaliphatic amines	Air Products, Reichold Chemical, Rhone-Poulenc, Vantico
Polyamides	Air Products, Dow, Henkel, Reichold Chemical, Rhone-Poulenc, Shell, Vantico
Amidoamines	Air Products, Henkel, Hoechst-Celanese, Reichold Chemical, Rhone-Poulenc, Shell, Vantico
Aromatic amines	Air Products, BASF, Buffalo Color, CVC Specialty Chemicals, Dow Chemical, Rhone-Poulenc, Shell
Anhydrides	Dow, Humprey Chemical, Lindau Chemicals, Leepoxy Plastics, Lonza, Oxychem, Milliken Chemicals, Reichold Chemicals, Vantico
BF_3–amine complexes	Air Products, Leepoxy Plastics
Dicyandiamide	Air Products, CVC Specialty Chemicals, SKW, Vantico
Substituted ureas	Air Products, CVC Specialty Chemicals, SKW, Vantico
Thiols	Henkel
Ultraviolet cure initiators	Union Camp

Modifiers

The third major category of epoxy formulation constituents is modifiers. They are used to provide specific physical and mechanical performance in both the uncured and cured resin. General categories of modifiers include rubbers, thermoplastics, diluents, flame retardants, fillers, and pigments and dyes. In this discussion, examples are limited to a few types per category. It is important to note that while some materials offer multiple desirable characteristics, others demand trade-offs in processing or final product performance that must be carefully considered. Table 3 gives some examples of frequently used modifiers, with suppliers. Complete and updated lists may be found in a variety of publications including *Thomas Register* and *Modern Plastics Encyclopedia*.

Table 3 Epoxy resin modifiers

Class	Type	Form	Supplier
Rubbers	CTBN	Liquid-reactive	B.F. Goodrich, Zeon

		Solid-reactive	B.F. Goodrich, Zeon
		Particulate	Zeon
Thermoplastics	Phenoxy	Pellets and powders	Phenoxy Specialties
	Polyether block amide	Pellets and powders	Atochem America
	Polyvinyl butyral	Pellets and powders	DuPont, Solutia, Tomen
	Polyvinyl formal	Pellets and powders	Tomen
	Polysulfone	Pellets and powders	Amoco, BASF
	Polyether sulfone	Pellets and powders	Amoco, BASF, Sumitomo
	Polyimide	Pellets and powders	Ciba, DuPont, Mitsui
	Polyetherimide	Pellets and powders	GE Plastics
	Polyamide	Pellets and powders	Creanova, DuPont
Diluents	Monofunctional and difunctional	Liquid	CVC, Shell, Vantico
Flame retardants	Brominated reactive	Liquid, resin, solid	Akzo Nobel, Ameribrom, Great Lakes
	Aluminum trihydrate	Powders	Alcan, Amspec, Franklin Ind., Harwick
	MgOH	Powders	Harwick, Lonza, Morton
	Antimony oxide	Powders	Amspec, Great Lakes, Laurel Ind.
	Phosphates	Liquids and powders	Albright & Wilson, Clariant, Harwick, Solutia
Fillers	Carbon black	Powder	Cabot, DJ Enterprises, Degussa, Ashland
	Glass beads	…	Cataphote Inc., Ferro, Potters Industries
	Fumed silica	Flocculent	Cabot, Degussa
	Microballoons	Inorganic	3M, Dow Corning, Mitsubishi, PQ Corp.

CTBN, carboxyl-terminated butadiene acrylonitrile

Rubber Additives. Rubbers are used to increase flexibility, fatigue resistance, crack resistance, and energy absorption (toughness) in epoxy resins and can be separated into two categories, reactive or nonreactive. These polymers may be employed as liquid, solid, or particulate components in a formulation.

The concepts of resin and composite toughness are complex and may be somewhat ambiguous because definitions vary depending on audience and applications discussed. To simplify, toughness is defined as an increase in the stress or energy needed to reach an identified failure point. The definition of failure point is linked to the specific application and will vary as part design and materials selection changes.

Fracture mechanisms involved in toughening epoxy composites with rubbers have been widely investigated. Publications by Kinloch and Young (Ref 27), Yee and Pearson (Ref 28, 29), and Bascom and Huntsdon (Ref

30) discuss the subject in great detail. Toughening is principally due to plastic deformation of the matrix and rubber particle at the crack tip. In rubber- modified resin systems, this deformation is achieved through crazing, shear band formation, particle cavitation, bridging, and voiding for stress relaxation at a crack tip.

The liquid rubbers most often used in epoxy composites are carboxyl-terminated butadiene acrylonitrile copolymers, or CTBNs. CTBNs are miscible with most epoxy resins, so they can easily be added to formulations with only modest increases in room-temperature resin viscosity. These long-chain polymers have terminal carboxyl groups that may be reacted with epoxy to decrease cross-link density and increase tensile elongation. Once the rubber becomes an integral part of the matrix however, decreases in strength, modulus, and T_g are unavoidable. In order to moderate the negative impact of rubber addition in the cured part, the candidate rubber must be carefully selected and blended into the epoxy formulation (usually at levels below 30 phr) so that during cure it phases out of solution to form discrete domains within the epoxy matrix. This phenomenon is referred to as in situ particle formation. It is believed that cure kinetics and cure temperature play a critical role in determining final particle size and morphology, which in turn affects part performance (Ref 31).

Solid acrylonitrile-butadiene rubbers have higher molecular weights than the liquid rubbers. Loadings are generally low due to a rapid increase in resin viscosity as rubber content increases. They can be dissolved directly into the epoxy or addition can be facilitated with a solvent that is later removed. In all cases, the rubber must phase out of solution during cure in order to effectively toughen the resin without sacrificing modulus and thermal performance.

The acrylonitrile content of the rubber is an important consideration when choosing a rubber modifier. As the nitrile content of a rubber increases, solubility increases and eventual particle size in the cured matrix decreases. While a variety of rubbers are effective tougheners in DGEBA, rubbers with high-acrylonitrile content are generally used with the more polar novolac epoxies. Unreactive rubbers are not generally used in epoxy composite applications because they tend to have the drawbacks of both rubbers and thermoplastics.

Preformed rubber particles are occasionally used in composites when both the particle size distribution and the volume fraction of particles in the cured resin need to be closely controlled. If they are totally insoluble in the matrix, a formulation can contain high loadings without the rapid increase in viscosity present with high-molecular-weight soluble polymers. To be effective as tougheners, the surface of the particle needs to react with or adhere well to the matrix. The benefit of using preformed particles is that they generate a consistent matrix morphology that is independent of cure conditions. However, the particles may be expensive, difficult to disperse in the base resin, and their presence may make processing more challenging (Ref 32, 33).

Thermoplastic Additives. Thermoplastics (TPs) are used much like rubbers to increase the fracture toughness of epoxy resins. They may be dissolved into the formulation or added as a particulate. Only relatively low-molecular-weight TPs can be dissolved in epoxy resin, and not all TPs are compatible with epoxy, so options are limited when selecting a toughener of this type. Thermoplastics commonly used in epoxy composites are phenoxy, polyether block amides, polyvinyl butyral, polyvinyl formal, polysulfone, polyethersulfone, polyimide, polyetherimide, and nylon.

The ability to toughen epoxy resins with both rubbers and TPs is closely related to the cross- link density of the thermoset matrix. Thermoplastics differ from rubbers in that they are more effective tougheners in highly cross-linked matrices because phase separation will occur at lower concentrations as matrix rigidity increases (Ref 34). As with rubbers, the morphology of the cured resin will impact the effectiveness of the additive. Unlike rubbers, TPs do not tend to adversely affect T_g and modulus. If used in very small amounts the TP may remain dissolved in the epoxy matrix to form an interpenetrating network, however, when used in concentrations high enough to positively affect measures of toughness, the TP will phase out during cure to form discrete plastic domains (Ref 35). Most TPs have limited use as components in epoxy formulations because the viscosity of the resin increases dramatically with only moderate loadings of TP. The effectiveness of the TP-rich domains in the cured part may also be limited by the relatively poor interface between them and the matrix. Other potential drawbacks when using high loadings of TP are an increase in solvent sensitivity and decreases in resistance to creep and fatigue.

Epoxy Diluents. There are a number of resins that are used as diluents in epoxy composites. In most cases these are very low-viscosity reactive monofunctional epoxies, although there are a few difunctional resin diluents available. While monofunctional resins such as butyl glycidyl ether, phenyl glycidyl ether, and cresyl glycidyl ether are effective in reducing viscosity, their use will result in a reduction of thermal and mechanical properties. As a rule, the lower-molecular-weight compounds are most effective as diluents but they also tend to

be volatile and are often irritants, therefore, they must be used in controlled environments. The higher-molecular- weight materials are less toxic and impact other properties less, but they are generally used at higher loadings since they are not as effective at reducing viscosity. In order to address this trade- off, several epoxy manufacturers supply blends of high-volume resins preblended with diluent to alleviate the need for the user to handle them. As with other types of additives, the formulator selects a particular diluent to balance physical needs with thermal-mechanical performance.

Flame Retardants. Flame retardants (FRs) can be added to epoxy resins as a filler, or the matrix can be built to incorporate FR characteristics. Generally, the more carbon and hydrogen in a polymer system, the more flammable it is. The presence of halogens and char-forming aromatics in the epoxy-curative based resin decrease flammability. FR modifiers operate through the three mechanisms that govern the pyrolysis and combustion of polymers; the condensed phase, the vapor phase, and physical inhibition (Ref 36, 37). Fillers such as alumina trihydrate ($Al(OH)_3$) and magnesium hydroxide ($Mg(OH)_2$) are effective in inhibiting combus tion by undergoing endothermic decomposition and liberating water into the gaseous state during combustion. The oxides produced may also form an insulating barrier that prevents oxygen from reaching the unconsumed polymer. Unfortunately, they must be used at loadings of 30 to 40% by weight, which prohibits their use in many composite applications. Chlorinated or brominated epoxy resins and curing agents may be combined with antimony, phosphorous, or boron compounds to lower flammability of epoxy composites. These compounds work in the gas phase to liberate free radicals trapping ·H and ·OH, thereby blocking the chain reactions that contribute to decomposition. They also work in the condensed phase to catalyze reactions that form nonvolatile products and char. One standard approach to formulating a flame-retardant cured epoxy resin employs the use of brominated epoxy resin (approximately 10–15% Br content by weight) combined with antimony trioxide powder at levels of 5 to 10% by weight. The synergistic effects of combining halogens with metal-oxides have been researched extensively. Currently there is a trend to minimize the use of halogens because they have a negative environmental impact and they produce highly toxic and corrosive hydrogen-halide gases during combustion.

Unreactive Fillers. Fillers are used in epoxy resins as extenders, reinforcements, and to impart specific physical characteristics such as low density, low flow, shrinkage reduction, and thermal or electrical conductivity. The types of fillers used vary widely but can generally be categorized as minerals, metals, glass, fibers, carbon, and miscellaneous organics. Physically, they can be used in a variety of forms including powders, pulps, flakes, flocks, spheres, microballoons, short fibers, and whiskers. When compounding filled systems, variables to take into consideration are the volume fraction of the filler, particle characteristics (size, shape, surface area, and particle size distribution), filler aspect ratio, the strength and modulus of the filler, adhesion of the filler to the resin, the viscosity of the base resin, and the toughness of the base resin (Ref 38, 39). The specialty applications and extensive product lines of fillers used in epoxy composite materials prohibit detailed discussion in this article, however, the following generalities should be considered when selecting fillers.

The maximum loading possible in epoxy resin is generally about 50% by volume in low-viscosity resins and may be significantly less when working with complex systems of high-initial viscosity. Other factors to take into account during processing are aggregate formation and particle wetting. Particles may be treated with interfacial agents to aid wetting by the matrix, and care must be taken to make sure particle distribution is uniform and aggregates are dispersed. Final resin viscosity must be low enough to allow air or volatile removal from the resin before or during cure in order to minimize void formation. In general, increasing filler content increases the modulus and compressive strength of the resin. In most cases, the strength of the filler directly affects the strength of the composite. It is important to note that when weak or brittle fillers such as microballoons are used, the filler may increase the overall toughness of the resin by acting as an energy dissipating “defect” in the matrix (Ref 40). To a certain extent, particle size and shape are independent of modulus as long as the volume fraction remains constant. Shape and size become important during processing or when particle packing or particle orientation affects the isotropy of the part. Increasing filler- aspect ratio increases the resistance to crack propagation, but it also rapidly increases resin viscosity, decreasing the amount of filler that can be used (Ref 41).

Pigments and Dyes. Epoxy resins may be colored using a wide variety of pigments and dyes, both organic and inorganic. Pigments are insoluble particles dispersed in a resin, whereas dyes are soluble organic molecules. Dyes are generally not suitable for epoxy composite applications due to temperature limitations. If they are to be used, care should be taken to identify materials that are compatible with target systems and remain inert in them. The large number of colorant manufacturers and the wide range of color compounds make it possible to

color match epoxy products to customer specifications. A resin or prepreg vendor that offers color matching will maintain a large inventory of pigments that are blended to obtain target shades and hues.

It is important to evaluate the color of a particular resin-reinforcement combination only after it has gone all the way through final processing and cure steps. Most epoxy resins have color of their own that must be taken into account, and presence of a second phase will affect final part appearance. Changes in resin morphology or cure temperature will affect the color and clarity of the part. Other factors affecting part appearance are resin content, filler, fiber, and fabric type. Pigments compatible with epoxy resins are available as powders, slurries, or pastes. Predispersed pigments are desirable, as dispersion of powders can be difficult without the right equipment. Powders may be available in a number of grades that reflect ranges in particle size distribution (Ref 42).

Additional additives occasionally found in epoxy resins are flexibilizers, plasticizers, liquid and resinous extenders, antioxidants, light stabilizers, internal mold releases, and antifoams. It is important to note that there are a number of suppliers for each of these modifiers and that the vendors may be extremely helpful in selecting candidate materials for the less-experienced formulator.

Epoxy Resin Model Formulations

The following examples of epoxy resin formulations illustrate how raw materials are combined to tailor a formulation to a specific application. It should be noted that these examples are intended for illustrative purposes only. Raw materials vendors should be contacted to recommend mix ratios and safe handling practices. The potential hazards associated with mixing and curing these resin formulations are not addressed in this article. The formulator or manufacturer must make an independent assessment of process safety for each material before it is used.

These model systems are typical of epoxy resin formulations used in composite applications. In each case, an attempt has been made to identify practical considerations that must be addressed by the potential user. The examples include a room-temperature-curing wet lay-up system (Ref 43), a room-temperature-curing paste adhesive (Ref 44), a toughened elevated-temperature-curing film adhesive (Ref 45), and a high-performance elevated-temperature-cure aerospace prepreg resin (Ref 46).

Example 1: Room-Temperature-Curing Wet Lay-Up System. The key characteristics of a room-temperature-curing wet lay-up system (Table 4) are low viscosity, adequate pot life, and reactivity. Both the epoxy (part A) and the amine (part B) are liquids that may be blended easily at room temperature (mix viscosity 1560 cps). The part B is generally added to the part A as it is stirred. Additives may be premixed into either the A or the B or they may be included as part of the mixing procedure. Regardless of how the system is modified, the finished resin must have a low-enough final viscosity to thoroughly penetrate the target reinforcement or thoroughly wet the surface to be coated. In the example presented, the formulated resin can be applied to a fibrous reinforcement (usually glass fabric or mat) shortly after mixing and then placed on a mold and cured at room temperature. Care should be taken to introduce as little air as possible into the resin during mixing to minimize voids in the finished part.

Table 4 Composition of a room- temperature-cure wet lay-up system

Component	Content, wt%
Diglycidyl ether of bisphenol-A	62.3
Ancamine 2143	37.7

Source: Ref 43

Some room-temperature-curing systems will require 10 to 20 minutes of mixing to fully blend the curative with the resin. If mixing is not adequate, the part may cure with a tacky surface. Since these systems are highly reactive at room temperature, they should be mixed in small quantities and used as soon as possible to prevent premature gellation or destructive exotherm. Room-temperature-curing resins tend to be mass sensitive, so large quantities of compounded resin need to be moving at all times to facilitate heat transfer and prevent hot spots from developing. The introduction of fillers will also dissipate heat to reduce the chance of destructive exotherm and increase gel time (working life). To avoid the dangers inherent in mixing large masses, there are a number of chambered mixing devices available that will continually mix and dispense small quantities of resin.

A 150 g mass of this model system at 25 °C (77 °F) will gel in 42 minutes, yet has a thin-film set time of seven hours. If the ambient temperature is increased, the set time will decrease; conversely at 4 °C (40 °F), the thin-film set time increases to 21 hours. Properties obtained after a cure of seven days at 25 °C (77 °F) can be found in Table 5.

Table 5 Cured resin properties of wet lay- up model system

Property	Value
Glass transition temperature (T_g), °C (°F)	51 (123)
Heat distortion temperature, °C (°F)	49 (120)
Tensile strength, MPa (ksi)	51 (7.45)
Tensile modulus, MPa (ksi)	2979 (432)
Tensile elongation, %	2.8
Hardness, Shore D	81

Source: Ref 43

Example 2: Room-Temperature-Curing Paste Adhesive. The resin is produced (Table 6) by blending the Hycar 1300x16 (B.F. Goodrich) with Ancamide 400 (Air Products Polymers, LP) to create a viscous liquid (part B). This mixture is then added to the epoxy resin (part A) while stirring to form a high-viscosity adhesive. Note that if the viscosity of A differs significantly from that of B, the resin becomes difficult to mix, so it is not uncommon to find modifiers predissolved or predispersed in both the A and the B.

Table 6 Composition of an ambient-curing paste adhesive

Component	Content, wt%
Diglycidyl ether of bisphenol-A	56.6
Ancamide 400	26.4
Hycar 1300x16	17.0

Source: Ref 44

Like Example 1, this resin system is reactive at room-temperature, therefore it should be mixed in small quantities and used immediately. The inclusion of a Hycar liquid rubber in the formulation yields the high toughness required for an adhesive and increases the viscosity so that the adhesive will stay where it is put. Hycar 1300x16 is an amine-terminated acrylonitrile- butadiene copolymer that decreases tensile strength and modulus while greatly increasing the elongation to failure and toughness of the cured product. Ancamide 400 promotes room- temperature cure and reduces the resin viscosity. The properties obtained after curing 14 days at ambient temperature are found in Table 7. Like most room-temperature-cured systems, strength will increase with time or if the part is heated above room-temperature.

Table 7 Cured properties of a paste adhesive after 14 days at ambient temperature

Property	Value
Tensile strength, MPa (ksi)	33.3 (4.833)
Tensile modulus, MPa (ksi)	1220 (117)
Tensile elongation, %	12
Hardness, Shore D	77
Heat distortion temperature, °C (°F)	60 (140)
Izod notch impact strength, J/m (ft · lbf/in.)	56.5 (1.06)

Source: Ref 44

Example 3: Elevated-Temperature-Cure Film Adhesive. This system (Table 8) is intended for parts that can be bonded (cured) at elevated temperatures. Like the paste adhesive, the film adhesive achieves toughening through incorporation of a liquid rubber, Hycar 1300x9 (B.F. Goodrich), which is a carboxyl-terminated acrylonitrile-butadiene copolymer with acrylonitrile content of 18%. In addition to the rubber, toughness is obtained by the reaction of bisphenol-A with the epoxy to increase the molecular weight between reactive sites, thus decreasing cross-link density. Unlike the two previous resins, this example includes 11.5% MY9512

(Vantico Inc.), a tetra-functional epoxy which increases T_g, providing temperature resistance at the expense of toughness. Triphenylphosphine is used to catalyze both the reaction between the epoxy and carboxylic acid groups on the rubber and the epoxy-bisphenol-A reaction. The curative package is dicy/diuron; dicy is the curative and diuron the accelerator.

Table 8 Formulation of a high- temperature film adhesive

Component	Content, wt%
Epon 828	57.3
MY9512	11.5
Bisphenol-A	8.0
Hycar 1300x9	15.4
Dicyandiamide	5.3
Diuron	2.2
Triphenylphosphine	0.3

Source: Ref 45

The resin is made by first reacting the rubber and the phenol with the epoxies at elevated-temperature. The viscosity of the base resin will increase substantially as the reactions take place. The mix is then cooled and the curatives are dispersed into the resin. Although the curatives are stable at room-temperature, care must be taken to make sure that the resin is well below reaction initiation temperature when they are added to the other components, or uncontrollable exotherm may occur. It is important to remember that even latent systems may exotherm when heated, so the resin should always be stirred when at elevated temperatures and should be maintained at as low a temperature as possible until it is used. The use of a rubber decreases the T_g, whereas the addition of the multifunctional epoxy increases it, illustrating how the components of a formulation are balanced to yield desired properties. The system is cured at 180 °C (355 °F) for two hours to yield the properties found in Table 9.

Table 9 Cured properties of a high- temperature film adhesive cured two hours at 180 °C (355 °F)

Property	Value
Glass transition temperature (T_g), °C (°F)	157 (315)
Single lap shear strength at ambient temperature, MPa (ksi)	18.0 (2.61)
Interlaminar fracture toughness, J/m^2 (in. · lbf/in.^{2})	
G_{Ic}	800 (4.6)
G_{IIc}	2250 (12.9)

Source: Ref 45

Some critical considerations when developing or selecting a film adhesive are:

- *Room-temperature resin viscosity:* Film adhesives, depending on use, may need to be dry and tack-free or very tacky. The substitution of solid or liquid bis-A epoxy for the Epon 828 in this example will allow the tack to be tailored. In almost all instances, a film adhesive must be flexible enough at room temperature so that it does not crack or break when used. The application of a scrim cloth or other support will substantially increase the robustness of the adhesive.
- *Resin rheology:* At cure temperature, the adhesive must flow enough to wet the surface and develop a suitable bond line, but not so much that it runs out of the bond area.
- *Adhesive strength:* The type or the amount of toughener used in a formulation must be balanced against resin T_g because the incorporation of a toughener will tend to lower T_g.
- *Porosity:* The presence of gaseous or fugitive components in the adhesive film may result in significant void formation in the bond line, thereby decreasing the strength of the bond. Adhesives are often degassed before filming in order to eliminate residual gases and air bubbles from the product.

Example 4: A Typical High-Performance Aerospace Resin. This formulation (Table 10) is produced by dissolving the crystalline curative (DDS) into hot epoxy resin (MY9512) at 125 °C (255 °F). Care should be

taken to monitor the resin at all times while it is being heated. It should be noted that the system may exotherm with prolonged heating at this processing temperature. The resin is then usually applied to a fibrous reinforcement to make prepreg. Prepreg is the term used to describe the fiber-resin combination. While this resin is relatively brittle, excellent elevated-temperature performance is obtained by the combination of the tetrafunctional epoxy with DDS. This is evidenced by the mechanical properties shown in Table 11.

Table 10 Composition of a high- performance aerospace resin

Component	Content, wt%
MY720	69.4
4,4′-DDS	30.6

Heat distortion temperature, °C (°F)	238 (460)	…
Charpy impact strength, unnotched, J (ft · lbf)	7.7 (5.7)	…

Source: Ref 46

Some critical considerations when developing or selecting an aerospace grade resin are:

- *Room-temperature resin viscosity:* Aerospace-grade composite materials are often used to build large parts with complex contours so, once again, tack is a key product characteristic, with most tack-life requirements ranging from one to three weeks. How the part is fabricated (by hand or using special equipment) will dictate the specific tack needed. The substitution of higher- or lower- viscosity MY9512 variants in this example would allow the tack to be tailored. In almost all instances, both overall tack life and tack stability over that period of time are desired.
- *Resin rheology:* At cure temperature, the resin must flow enough to thoroughly wet the reinforcement, allow consolidation, and provide a pathway for trapped air and volatiles to escape. Insufficient flow can result in a cured part that is improperly consolidated, contains voids, and exhibits surface roughness. Too much flow can result in resin starvation, which also leads to parts with internal voids and external roughness.
- *Thermal-mechanical properties:* The final part application will dictate whether or not a basic epoxy resin system needs to be modified. This model system, as written, generates a strong, high-modulus part with a high T_g. It can easily be modified to provide a number of different characteristics. For examples, adhesive strength can be attained by incorporation of rubber, toughness by adding thermoplastics or rubbers, and hot/wet properties can be improved by the addition of a dicyclopentadiene novolac resin.

Safety

Epoxy resins and their associated products may be safely handled if care is taken to follow all recommendations made by materials suppliers. Product data sheets and technical service experts are usually available to aid in product selection. Vendors will always recommend processes for compounding, fabrication, and curing of composite parts. There are a number of publications that outline the environmental, safety, and health considerations related to the use of epoxy composite materials. It is important to understand that some epoxy resin systems and composite operations will require much more stringent controls than others, due to the specific chemicals and processes being used (Ref 47, 48).
General guidelines include but are not limited to:

- Read and understand all product literature and Material Safety Data Sheets (MSDSs) before exposing yourself or your workplace to any chemical. The MSDS will list all hazards associated with the product, including hazardous ingredients, exposure limits, exposure routes, health risks, effects of short and long term exposure, personal protection information, reactivity data, fire and explosion data, spill or leak procedures, special precautions, first aid procedures, and regulatory data. The MSDS will also include physical data about the material, including vapor pressure, vapor density, melting and boiling point, solubility in water, and specific gravity. Material Safety Data Sheets are required for all hazardous materials sold or transported in the United States and Europe.
- Work with uncured epoxy resins in areas with adequate ventilation. In some cases, this may require an enclosed area with a high rate of air exchange to minimize exposure through inhalation as well as irritation to the eyes, skin, and mucous membranes.
- Conventional personal protective equipment including barrier creams, gloves, respirators, and safety glasses should always be worn. Depending on work conditions, disposable or dedicated clothing should be provided in the workplace and washed routinely. Skin sensitization (contact dermatitis) and respiratory sensitization may occur when adequate industrial hygiene practices are not employed.
- Always follow manufacturer's directions carefully, especially with regard to mass of resin used, mixing procedure, and curing operations. Epoxy resins react exothermically and the heat generated may, if uncontrolled, cause fires or explosions.

Epoxy Resins

Maureen A. Boyle, Cary J. Martin, and John D. Neuner, Hexcel Corporation

Future Trends

Epoxy resins have been successfully used in composite applications since the 1960s. It is fair to say that this market has matured, as evidenced by the following facts. First, consumption of epoxy resins in composite applications has largely stagnated. From 1971 to 1984, use in the United States increased fourfold, from 21 to 86.8 million pounds, with most of this growth occurring in the late 1970s. Through the next decade, usage was essentially constant at approximately 83.7 million pounds in 1993. Second, of the three major U.S. producers of epoxy resins (Shell Chemical, Dow, and Ciba-Geigy), two (Shell and Ciba) have either sold or announced the sale of their epoxy resin businesses. The third, Dow, has concentrated away from the high-performance multifunctional resins and toward difunctional liquid resins, which compose the largest overall market segment. Finally, many of the specialty epoxy resins and curatives introduced since the 1980s have been withdrawn from the market and are no longer available. In the aerospace arena, industry consolidation has been reflected downstream by the intermediaries who manufacture formulated epoxy resin products as well as in the aerospace manufacturers themselves. This trend is driven by an overall industry emphasis on lower cost rather than improved performance. The introduction of epoxy composite materials into non-traditional markets continues but will not significantly affect the overall business until material and conversion costs can compete with those of commodity thermoplastics.

Given the maturity of the market and the technology, it's difficult to generalize with regard to future needs and research. It is clear, however, that the most serious barrier to the introduction of new chemistries is raw materials cost. Many of the specialty materials introduced since the mid-1980s (and later withdrawn from the market) were unsuccessful because the technological advantages they offered did not offset their high costs. Basic bisphenol-A epoxies are available on the order of $1–3/lb., with high-end multifunctionals ranging from $8–20/lb. To survive in this climate, new epoxy resin raw materials need to offer technical and/or handling advantages *and* be priced competitively. Without price competitiveness, it is unlikely that new raw materials, regardless of technical advantage, will be successfully employed in future composite programs. Additional factors that impede the introduction of new raw materials are decreases in the price of carbon fiber, which is now approaching the cost of the resins, improvements in strength and chemical resistance of glass fibers, and efficiencies in manufacturing methods.

A second barrier to the development of new epoxy resins and modifiers is the cost and time required in getting them approved for use. Before a new material can be sold commercially in a country, it must be registered by governmental agencies under regulations such as the Toxic Substances Control Act in the United States and the European Inventory of Existing Commercial Chemical Substances in the European Union. Registration requires a significant and expensive evaluation of the toxicological risks associated with a new substance. Unfortunately, the developers of new materials often find themselves in a no-win position. They cannot justify the expense of testing and registering a new material without a clearly identified market. Their customers, in turn, are reluctant to develop applications based on these new materials when long- term availability is not confirmed.

Beyond the requirement that any new developments be price competitive with existing technologies, several possibilities for future development exist. These include significant cost reduction for standard high-performance resin components, user-friendly materials, recyclable material forms, and processing operations that enable the displacement of conventional epoxy materials. Some general trends within the aerospace market are toward lower-cost materials forms and lower-cost processing methods. Nonaerospace applications are achieving cost- cutting targets by using large tow carbon fibers to reduce fiber cost, low-temperature-rapid cures to reduce processing cycles, and preformed reinforcements to reduce hand work. Both markets are evaluating materials that increase the design flexibility. These include a single resin available in multiple materials forms, thin tapes, alternate lay-up techniques such as tape and tow placement, and high-modulus carbon fibers.

Polyester Resins

Tim Pepper, Ashland Chemical Company

Introduction

UNSATURATED POLYESTER (UPE) RESIN is used for a wide variety of industrial and consumer applications. In fact, more than 0.8 billion kg (1.7 billion lb) was consumed in the United States in 1999. This consumption can be split into two major categories of applications: reinforced and nonreinforced. In reinforced applications, resin and reinforcement, such as fiberglass, are used together to produce a composite with improved physical properties. Typical reinforced applications are boats, cars, shower stalls, building panels, and corrosion- resistant tanks and pipes. Nonfiber reinforced applications generally have a mineral “filler” incorporated into the composite for property modification. Some typical nonfiber reinforced applications are sinks, bowling balls, and coatings. Polyester resin composites are cost effective because they require minimal setup costs and the physical properties can be tailored to specific applications. Another advantage of polyester resin composites is that they can be cured in a variety of ways without altering the physical properties of the finished part. Consequently, polyester resin composites compete favorably in custom markets.

Polyester Resin Chemistry

Polyesters are macromolecules that are prepared by the condensation polymerization of difunctional acids or anhydrides with difunctional alcohols or epoxy resins. Unsaturated polyester resins, commonly referred to as “polyester resins,” are the group of polyesters in which the acid component part of the ester is partially composed of fumaric acid, a 1,2-ethylenically unsaturated material. Maleic anhydride is the predominant source of this fumarate. Maleic anhydride is incorporated into the polyester backbone and then isomerized to provide fumarate esters (commonly referred to as unsaturated polyesters). In most cases, the polymer is dissolved in styrene to provide a solution that will typically have a viscosity in the range of 0.2 to 2 Pa · s (200–2000 cP). Other reactive vinyl monomers, such as vinyl toluene, diallyl phthalate, or methyl methacrylate may be used to obtain specific properties. The resin viscosity is tailored for specific fabrication processes in which the resin is ultimately “cured” via a free-radical process. A final formulation may include resin, inorganic filler, fiberglass reinforcement, and a free-radical initiator, such as an organic peroxide. This final formulation is formed against a mold prior to the cross-linking reaction between the unsaturated polymer and the unsaturated monomer. The “curing” is a cross-linking chain reaction, converting the low-viscosity solution into a three- dimensional thermoset plastic (Ref 1). This is referred to as the cure. Terminology has developed to distinguish between various types of UPEs.

General-purpose resins are a group of resins generally used because of their low cost. While processing parameters can affect this, the cost of the raw materials tends to limit the type of unsaturated polyesters selected. The resins used in this area are commonly referred to as PET, DCPD, and ortho resins. While PET (polyethylene terephthalic) resin and orthophthalic anhydride are sources of low-cost saturated acids, DCPD (dicyclopentadiene) is typically coupled with maleic anhydride during an initial step, prior to both the isomerization and the condensation polymerization. Dicyclopentadiene improves the solubility of the polyester resin in styrene. As one drives toward lower-cost resins, solubility in styrene is a serious concern. Dicyclopentadiene offers a low-cost solution. Due to government regulations aimed at minimizing styrene emissions in open molding, a subset of general-purpose resins, “low-styrene” resins, has been developed. These

resins tend to have a higher dependency on DCPD and are cooked to a lower molecular weight. This allows less styrene to be used to achieve the desired viscosity, and performance generally suffers.

Isophthalic resins are based on isophthalic acid and maleic anhydride. The incorporation of isophthalic acid creates a high-molecular-weight resin with good chemical and thermal resistance and good mechanical properties. The use of nonpolar glycols contributes to improved aqueous resistance, which is required to protect the fiberglass.

Bisphenol A (BPA) fumarate resins are prepared by the reaction of propoxylated BPA with fumaric acid. The result is a relatively nonpolar polyester with a reduced number of ester linkages. The reduced number of ester linkages contributes to excellent corrosion resistance. Bisphenol A fumarates were once the workhorse of the corrosion-resistant composite industry. In recent years, they have been replaced by isophthalic resins for mildly corrosive applications and bisphenol A epoxy based vinyl esters in more aggressive environments. Currently, BPA fumarates are used almost exclusively in applications requiring exceptional corrosion resistance to caustic environments.

Chlorendic resins are prepared using either chlorendic anhydride or chlorendic (HET) acid (Ref 2) reacted with maleic anhydride. Composites made from these resins have excellent chemical resistance and some fire retardancy because of the presence of chlorine. Chlorendic resins are used in applications requiring exceptional resistance to acidic or oxidizing environments. In many of these environments, metals are attacked quite aggressively, while chlorendic resin composites generally perform much better.

Vinyl ester resin is the common name for a series of unsaturated resins that are prepared by the reaction of a monofunctional unsaturated acid, typically methacrylic acid, with an epoxy resin. The epoxy resin is "end-capped" with an unsaturated ester to form the vinyl ester resin. The resulting polymer, which contains unsaturated sites only in the terminal positions, is mixed with an unsaturated monomer, generally styrene. At this point, the appearance, handling properties, and curing characteristics of vinyl ester resins are the same as conventional polyester resins. However, the corrosion resistance and mechanical properties of vinyl ester composites are much improved over standard polyester resin composites. These improved properties have enabled vinyl ester resins to become the workhorse of the polyester custom corrosion industry. However, the properties of vinyl ester resins are not as easily tailored to a specific application as are standard unsaturated polyester resins. This combined with the use of higher-cost raw materials has somewhat limited the ability of vinyl ester resins to penetrate the unsaturated polyester resin market.

Within each of these five resin classifications, specific polyesters can be formulated by varying the starting materials. Specific properties such as flexibility, thermal properties, fire retardancy, and hydrophobicity can be altered (Ref 3) by varying the type of dihydric alcohol/epoxy resin used or by varying the fumaric/saturated acid ratio.

Low-profile additives (LPAs) are a class of saturated resins that are used for dimensional stability. Although these materials are not UPEs, they play a very important role in the use of UPEs. One of the problems associated with the use of UPEs is that they shrink volumetrically about 6 to 8% upon curing. This creates challenges in fabricating a high-quality surface and/ or maintaining the dimensional stability of a part. Low-profile additives offer a unique solution to this problem when processing at elevated temperatures. Addition of an LPA to a UPE formulation reduces or eliminates shrinkage. Some formulations using LPAs can actually have expansion greater than the original mold or form size. Since the LPA does not chemically react with the UPE or styrene, care should be taken in determining the type and amount of LPA used.

Mechanical Properties

Mechanical properties are often the critical factor in selecting a polyester resin for a specific application. Table 1 lists the common test methods of the American Society for Testing and Materials (ASTM) that are used to characterize the mechanical properties of polyester resin composites.

Table 1 ASTM test methods for characterizing mechanical properties of polyester resins

Properties	ASTM Test Method
Tensile strength, modulus, and % elongation	D 638
Flexural strength and modulus	D 790
Compressive strength, modulus, and % compression on break	D695
Izod impact	D256
Heat distortion	D 648
Barcol hardness	D 2583

While the physical properties of polyester composites are predominately controlled by reinforcement, the physical properties of the polyester resin do affect the durability and thermal performance. Representative examples of clear- cast polyester resin data are shown in Table 2. It should be noted that within each class of resins, modifications are made to the polymer. These modifications effectively trade off thermal performance for increased toughness (Table 2). Table 2 highlights the differences among the classes of polyesters. Isophthalic resins tend to show higher tensile and flexural properties than orthophthalic resins. This may be because isophthalics usually form more linear, higher- molecular-weight polymers than orthophthalics. In contrast, the BPA fumarate and chlorendic resins are formulated for service in aggressive corrosive conditions and consequently are much more rigid. This results in clear castings that are brittle and have low tensile elongation and strength. The vinyl ester, because of its bisphenol diepoxide content, exhibits excellent tensile and flexural properties as well as high elongation.

In this article, it is impossible to discuss thoroughly the effects that dihydric alcohols, acids, levels of unsaturation, monomer types and amounts, and cure temperatures have on mechanical properties; however, Ref 4 provides an excellent review. In general, increasing the chain length of the dihydric alcohol increases the flexibility of the cross-linked resin. The same occurs with saturated acids. Aromatic groups, in either the dihydric alcohol or acid component, increase stiffness and hardness.

Using a reinforcing fiber to produce a polyester composite dramatically improves both the tensile and flexural properties. Table 3 lists the same five samples as Table 2; however, Table 3 shows the mechanical properties of the fiberglass reinforced polyester resin composites. In Tables 4 and 5, the properties obtained were dependent on the amount and type of glass fiber used. The last two entries in Table 5 show the influence of fiberglass orientation. Both contained 70 wt% glass fiber, but the unidirectional composite showed much higher tensile properties and flexural modulus when tested in the glass fiber direction. The properties of unidirectional composites are even more anisotropic than typical polyester laminates. Mechanical properties measured transverse to the glass direction will approach those observed for clear castings. The pultrusion or filament-winding process commercially produces polyester composites employing unidirectional reinforcements. They can be used in structural applications where strength or stiffness is required in only one direction. In Table 6, physical properties of fiberglass reinforced polyester resin composites are compared to those of various metals.

As mentioned earlier, different types of reinforcement affect mechanical properties. While E-glass is the most commonly used reinforcement in polyester resins, S-glass, aramid, and carbon fibers can also be used. Table 7 compares a variety of reinforcements in both orthophthalic polyester and vinyl ester resins. While the tensile strength of the orthophthalic polyester was much improved with aramid, no such improvement was seen with the vinyl ester.

Table 7 Effect of reinforcement on mechanical properties of polyester-matrix composites

Inorganic fillers are commonly used in polyester resin composites. While they do improve stiffness, as shown by an increase in modulus (see Table 8), they have little effect on other strength characteristics. They are used primarily to reduce cost.

As expected, mechanical properties at elevated temperatures vary significantly among the general classifications of polyester resins (Fig. 1). The extreme rigidity and high glass transition temperature (T_g), of BPA fumarate and chlorendic polyesters result in high flexural strength retention up to 120 °C (250 °F). Vinyl esters also show performance advantages over isophthalic polyesters in fatigue studies (Fig. 2, Ref 5). The advantage of vinyl ester was evident at elevated temperatures (Ref 6). At 105 °C (220 °F), vinyl ester and isophthalic polyester composites (60% glass) were cycled to a stress level of 60 to 70 MPa (9–10 ksi). After 200,000 cycles, the drop in flexural modulus was only 5% for the vinyl ester, compared to 12% for the isophthalic polyester. The thermal performance of vinyl esters, combined with their excellent mechanical properties and toughness, explains why they are often chosen for structural resin composites.

Thermal and Oxidative Stability

Polyester resins are commonly used in elevated-temperature applications, especially in the electrical and corrosion-resistance areas. At temperatures above 150 °C (302 °F), the polymer begins to slowly dissociate chemically. The temperature at which this decomposition occurs depends on the structure of the polyester used. Regardless of the polymer composition, at temperatures near 300 °C (570 °F), the cured polyester resin will undergo spontaneous decomposition. This is characteristic of vinyl polymers and is caused by their depolymerization to form monomeric species.

Among polyesters, high-molecular-weight UPEs and epoxy vinyl esters show better stability above 150 °C (302 °F) than low-molecular- weight UPEs. High-molecular-weight isophthalic, PET, DCPD, and BPA fumarate resins, when formulated properly, can perform very well in thermal applications (Fig. 3). In thermal stability, nonhalogenated resins outperform halogenated resins. While some chlorinated resins have respectable thermal stability, brominated resins universally have poor thermal stability with aromatic bromides performing somewhat better than aliphatic bromides. Low-styrene (general-purpose) resins also exhibit poor thermal stability. The same is true for orthophthalic resins, as they tend to be low-molecular-weight resins. In spite of their poor thermal stability, orthophthalic resins perform well in moderate- to low-temperature applications and are often preferred in such applications because of their low cost.

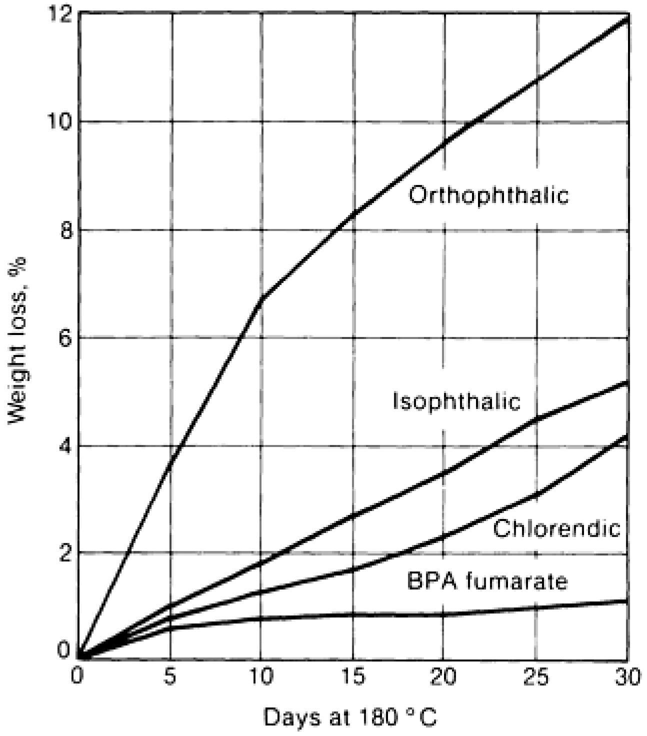

Fig. 3 Thermal stability of glass-polyester composites at 180 °C (355 °F)

Monomer type also plays an important role in the thermal stability of a polyester resin. For example, a polyester resin in vinyl toluene shows superior thermal stability when compared to the same resin in styrene. This is attributed to the strong copolymer bonds formed with the fumarate unsaturation. Even after aging at 200 °C (390 °F), an isophthalic resin in vinyl toluene has better flexural strength retention than an isophthalic resin in styrene (Fig. 4). While vinyl toluene versions of an isophthalic polyester and a BPA fumarate showed comparable performance at 200 °C (390 °F), the BPA fumarate had much better flexural strength retention at 220 °C (430 °F) (Fig. 5) and 240 °C (465 °F) (Fig. 6).

Polyester Resins

Tim Pepper, Ashland Chemical Company

Chemical Resistance

Polyester resins have been used for many years in applications requiring resistance to chemical attack. Parts made from UPEs have corrosion-resistant properties that complement most metals. As an environment increases in polarity, it becomes less aggressive toward parts made from UPEs. Numerous applications for corrosion-resistant tanks, pipes, ducts, and liners can be found in the chemical process and pulp and paper industries. Resin selection depends on the specific chemical environment to be contained. Table 9 shows how four different classes of polyester resin perform in several environments. Isophthalic resins perform well in both mild aqueous and mild organic environments. Generally, they are the most economic resin choice. Vinyl ester resins are typically used in more aggressive environments. A properly selected vinyl ester resin will perform well in many applications. When the environment becomes more aggressive, premium polyesters are preferred. Premium polyester resins offer improved corrosion resistance for specific applications. Chlorendic resins are chosen for strong acid and oxidizing environments, especially at elevated temperatures, while BPA fumarate resins are better in caustic environments. Using glass fiber does not improve the corrosion resistance of polyester resins and, in some cases, actually reduces performance. This is especially true in hydrofluoric acid or strong caustic environments where the chemicals actually attack and dissolve glass. In this and other special cases, reinforcing materials, such as carbon fibers, may be preferred (Ref 7).

Table 9 Corrosion resistance of glass fiber polyester resin composites

Resin	75% H_2SO_4 80 °C (175 °F)	15% NaOH 65 °C (150 °F)	5.25% NaOCl 65 °C (150 °F)	Xylene Ambient	Deionized water 100 °C (212 °F)	Seawater 80 °C (180 °F)

Polyester Resins

Tim Pepper, Ashland Chemical Company

Ultraviolet (UV) Resistance

Polyester resins are used in many outdoor applications. They can survive exposure to the elements for periods exceeding 30 years, although some discoloration and loss of strength will occur. The onset of surface degradation is marked by a yellow discoloration that becomes progressively darker as erosion and surface stress crazing occur. In translucent systems, this UV radiation causes yellowing of the composite as a whole, although the color is usually more intense on the surface. The negative effects of UV exposure can be effectively eliminated with the addition of UV stabilizers to the outermost resin layer. Monomer selection also affects UV stability. Styrene and other aromatic vinyl monomer derivatives are more susceptible to oxidative degradation and are usually supplemented with more resistant acrylate or methacrylate monomers. Of the acrylate monomers, methyl methacrylate (MMA) is the most common. When MMA is copolymerized with styrene, the cured polyesters have superior durability, color retention, and resistance to fiber erosion (Ref 8).

The improved UV resistance with MMA is evident in Table 10, which compares four polyester resins composed of identical polymers and four different monomer systems. These resins were used to prepare glass fiber reinforced panels that were exposed to outdoor weathering for five years. The gloss retention for styrene/MMA monomer blends was much greater than for either monomer alone. The refractive index of MMA is also lower than that of styrene, allowing the formulation of polyester resins with a refractive index matched to the glass fibers. This, combined with improved UV resistance, has resulted in the use of MMA polyesters to fabricate glass reinforced transparent building panels that can be used in greenhouses, skylights, and other applications. Using UV-absorbing chemical additives, such as the substituted benzophenones or benzotriazoles, can further reduce the effect of radiation.

Table 10 Effect of methyl methacrylate on the gloss retention of weathered polyester panels

Components	Panel number

Polyester Resins

Tim Pepper, Ashland Chemical Company

Electrical Properties

Most organic polymers have medium to excellent electrical properties. Wide ranges of thermoset and thermoplastic materials are used in the electrical and electronics industries. Applications in which polyester resins have been used include the insulation of motor windings, encapsulation of electrical components, fabrication of printed circuit boards, high-voltage standoff insulators, switch boxes, and miscellaneous equipment for high-voltage line work. Typical electrical properties of polyester resins are shown in Table 11. Tables 12 and 13 show specific data on an isophthalic polyester and a BPA fumarate as well as the influence of filler type.

Note: BPA fumarate polyester resin based on a vinyl toluene monomer

Because many electrical applications require performance at elevated temperatures, polyester resin composites must have good thermal stability. Thermal stability and electrical performance at elevated temperatures are directly related, as can be seen by comparing the retention of dielectric strength at 200 °C (390 °F), shown in Fig. 7, with the retention of flexural strength at 200 °C (390 °F), shown in Fig. 4. As with flexural strength, a vinyl-toluene-based polyester outperforms a styrene-based polyester. At temperatures above 200 °C (390 °F), vinyl-toluene- based BPA fumarates outperform vinyl-toluene- based isophthalic polyesters (Fig. 8, 9).

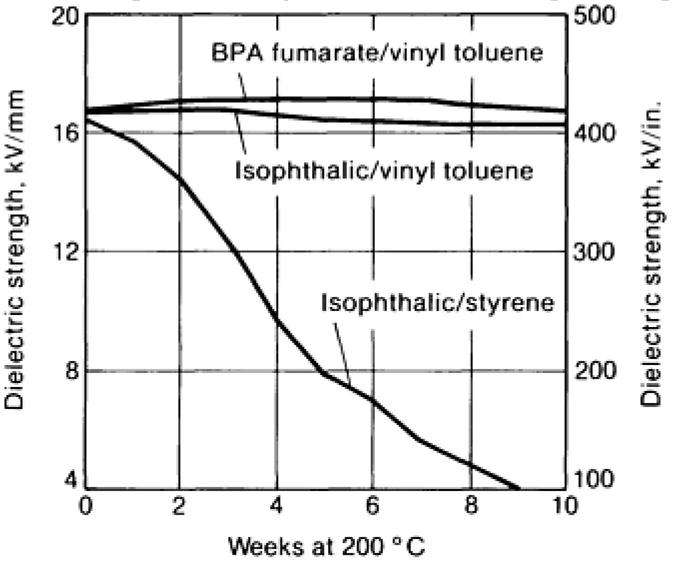

Fig. 7 Dielectric strength retention of glass-polyester composite when aged at 200 °C (390 °F), tested at room temperature

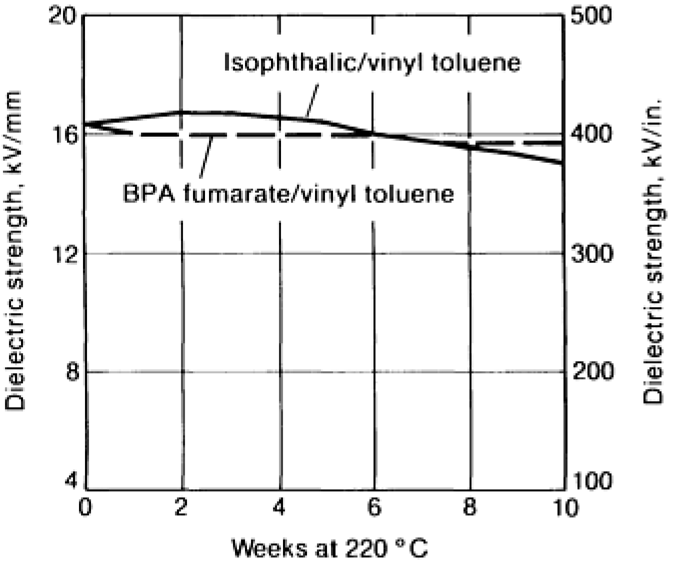

Fig. 8 Dielectric strength retention of glass-polyester composite when aged at 220 °C (430 °F), tested at room temperature

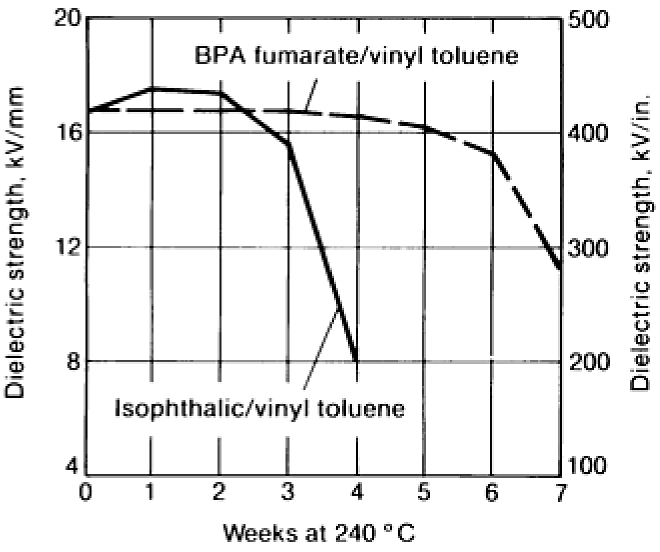

Fig. 9 Dielectric strength retention of glass-polyester composite when aged at 240 °C (465 °F), tested at room temperature

Large electrical equipment, such as high-voltage motors or generators, often operate at elevated temperatures. In such applications, the electrical property of greatest concern is the dissipation factor, especially the dissipation factor versus the temperature. Polyester resins can be formulated for a low dissipation factor at elevated temperatures (Fig. 10). They are used as electrical varnishes at continuous-use temperatures up to 180 °C (355 °F).

Tim Pepper, Ashland Chemical Company

Flame-Retardant Polyester Resins

All organic materials, including polyesters, will burn in the presence of a flame. In many applications, polyester resins are required to have some degree of resistance to burning. This can be accomplished by using either a filler or a specially formulated flame-retardant polyester resin, depending on the degree of resistance required. The addition of filler is the more economical route to achieving flame retardancy in parts made from UPEs. However, the addition of filler increases weight and compromises tensile properties.

Incorporating halogen into a polyester resin is an effective way of improving flame retardance. This can be accomplished using a halogenated dibasic acid, such as chlorendic anhydride or tetrabromophthalic anhydride, or a halogenated dihydric alcohol, such as dibromoneopentyl glycol or tetrabromobisphenol A. At equivalent concentrations, bromine is much more effective than chlorine. Additives such as antimony oxides and ferrous oxide act as synergists with halogenated polyesters and improve their flame-retardancy properties (Ref 9).

Burning rate and smoke generation are measured using the Steiner Tunnel Test (ASTM E 84). In this test, a gas burner is placed at one end of a 53 cm by 7.6 m (21 in. by 25 ft) section. The distance the flame travels and the amount of smoke generated are measured (by the obscuration of a photoelectric beam). These are compared to two standards: red oak board, which is given a rating of 100 for flame spread and smoke generation, and asbestos cement, which is given a rating of 0 for both flame spread and smoke generation. Smoke generation is also measured with an NBS smoke chamber, which uses a photoelectric cell to measure smoke buildup in a closed chamber. The sample is burned either with or without a direct flame. When NBS smoke chamber testing is used, it is often common to use ASTM E 162, Flame Spread Index, to measure this variable.

Table 14 compares the performance of several resins using the above-mentioned fire and smoke tests. In each of these tests, the halogenated resin clearly outperforms the orthophthalic resin. Ferrous oxide also reduces smoke generation in the NBS chamber when compared to antimony oxide.

Table 14 Performance of selected polyester composites in fire tests

Table 15 compares various filled and unfilled polyester resin composites. The improvement of an orthophthalic resin by the incorporation of alumina trihydrate (ATH) is dramatic, the flame spread is reduced from 350 to 64. However, halogenated resins reach this level of performance without the incorporation of any filler. Halogenated resins with a synergist show only a slight reduction in flame spread when ATH is added, but

smoke emission is greatly reduced. When comparing brominated and chlorinated resins, 26% Cl gave comparable flame and smoke results as 18% Br.

Bismaleimide Resins

Introduction

BISMALEIMIDE (BMI) RESINS are a relatively young class of thermosetting polymers that are gaining acceptance by industry because they combine a number of unique features including excellent physical property retention at elevated temperatures and in wet environments, almost constant electrical properties over a wide range of temperatures, and nonflammability properties. Bismaleimides have become a leading class of thermosetting polyimides. Their excellent processibility and balance of thermal, mechanical, and electrical properties have made them popular in advanced composites and electronics.

Composites of the BMI class are used on some of the most important and complex, high-performance applications ranging from military programs such as the U.S. Air Force's F-22 to Formula-1 race cars. The most important attribute of BMIs is the highest service temperature capability of an addition-cure matrix resin combined with epoxy-like autoclave processing. The BMI matrix composites provide the highest composite mechanical properties available through 177 °C (350 °F)/wet with damage tolerance equivalent to the best epoxies. Certain BMIs are capable of extended service at 230 to 290 °C (450 to 550 °F), approaching the performance of PMR-15 (see the article "Polyimide Resins" in this Volume). BMIs also are suitable for resin transfer molding (RTM) processing. This article first discusses BMI chemistry and then describes the use of BMI in composites. An analysis of the current applications illustrates how the advantages of BMIs have been exploited and perhaps suggests how these advantages might be extended to other applications.

BMI Resin Chemistry

Horst Stenzenberger, Technochemie GmbH, Germany

Bismaleimides are best defined as low molecular weight, at least difunctional monomers or prepolymers, or mixtures thereof, that carry maleimide terminations (Fig. 1). Such maleimide end groups can undergo homopolymerization and a wide range of copolymerizations to form a highly cross-linked network. These cure reactions can be effected by the application of heat and, if required, in the presence of a suitable catalyst.

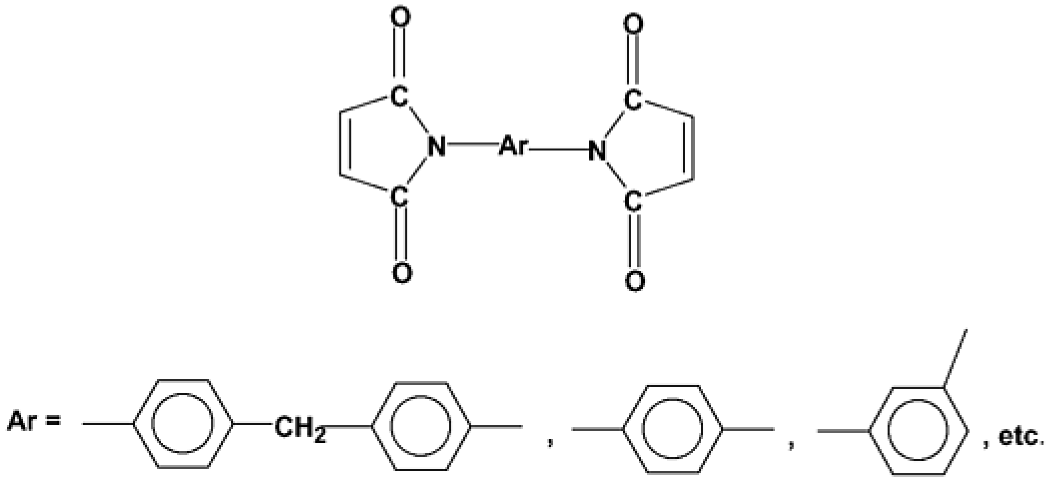

Fig. 1 General structure of bismaleimide resin

The first patent for cross-linked resins obtained through the homopolymerization or copolymerization of BMI was granted to Rhone Poulenc, France in 1968 (Ref 1), followed by a series of patents related to poly(amino BMIs) (Ref 2), which were synthesized from BMIs and aromatic diamine. Following the initial patent disclosures, numerous chemical modifications have been carried out and mixtures formulated to improve processibility and cured resin properties. Melt-processible BMI systems specifically designed for fiber reinforced applications are described in a patent granted to Technochemie in 1974 (Ref 3). The approach of blending selected BMI monomers and further formulating them with reactive diluents or comonomers provided formulated resins that are equivalent in processing to the conventional 177 °C (350 °F) service epoxy resins. The breakthrough with respect to application as tacky autoclavable prepreg was achieved through a divinylbenzene modified BMI system (Ref 4) that was used to build the delta wings of the General Dynamics F16XL demonstrator combat aircraft (Ref 5) and parts of the McDonnell Douglas AV8-B vertical takeoff aircraft (Ref 6).

The principal concern with BMI resins has been their inherent brittleness owing to their high cross-link density. Ciba Geigy, however, demonstrated that BMI and o,o′-diallylbisphenol A (DABA) copolymers are much tougher than high-temperature epoxies (Ref 7). The BMI/ DABA copolymers were patented in Switzerland in 1975, but the significance of the invention, that is, their toughness, was not recognized before toughness became an issue to the aerospace industry. Experience has taught that a useful BMI-resin comprises both a BMI part and a comonomer part.

Bismaleimide Building Blocks

A standard synthesis of N,N′-arylene BMI (Fig. 2) involves the chemical dehydration of N,N′-arylene bismaleamic acid with acetic anhydride in the presence of a catalyst (sodium acetate) at temperatures below 80 °C (175 °F) (Ref 8). The yield of the pure recrystallized BMI is usually 65 to 75%. Various byproducts, such as isoimides and acetanilides, are responsible for the relatively low yield of pure BMI. Almost every aromatic diamine can be converted to the corresponding BMI. However, the most widely used building block is 4,4′-bismaleimidodiphenylmethane, because the precursor diamine is readily available and inexpensive. Bismaleimides based on aromatic diamines are crystalline substances with high melting points. For reasons of processibility, BMIs with low melting points are the preferred building blocks for composite resins. The BMI-building blocks primarily used in commercial BMI resins are 4,4′-bismaleimidodiphenylmethane, 2,4-bismaleimidotoluene, 1,3-bismaleimidobenzene, and sometimes, aliphatic BMIs based on n- or iso-alkanes.

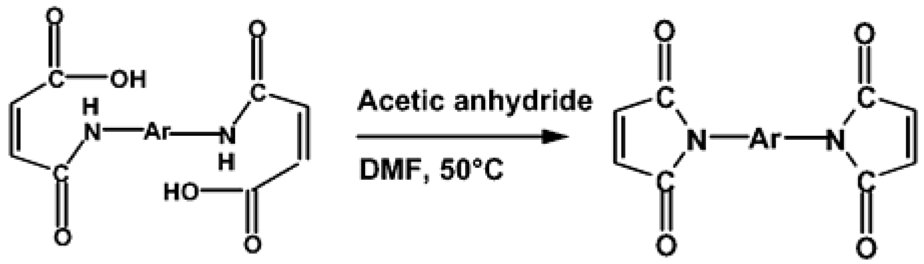

Fig. 2 The synthesis of bismaleimide from bismaleamic acid. DMF, dimethyl formamide

Because of the toxicity problems associated with methylene dianiline (MDA) (4,4′-diaminodiphenylmethane), the BMI precursor and other diamines with only one or two aromatic rings, polyaromatic diamines, and BMIs based on them are of increasing interest. In the past, it was almost impossible to introduce novel BMI building blocks with increased molecular weight because of the processing problems associated with the high melting points and high melt viscosities. With the new processing techniques, such as powder prepregging and blending with reactive diluents such as DABA, such limitations could be partly overcome. Examples of polyaromatic BMIs are provided in Fig. 3.

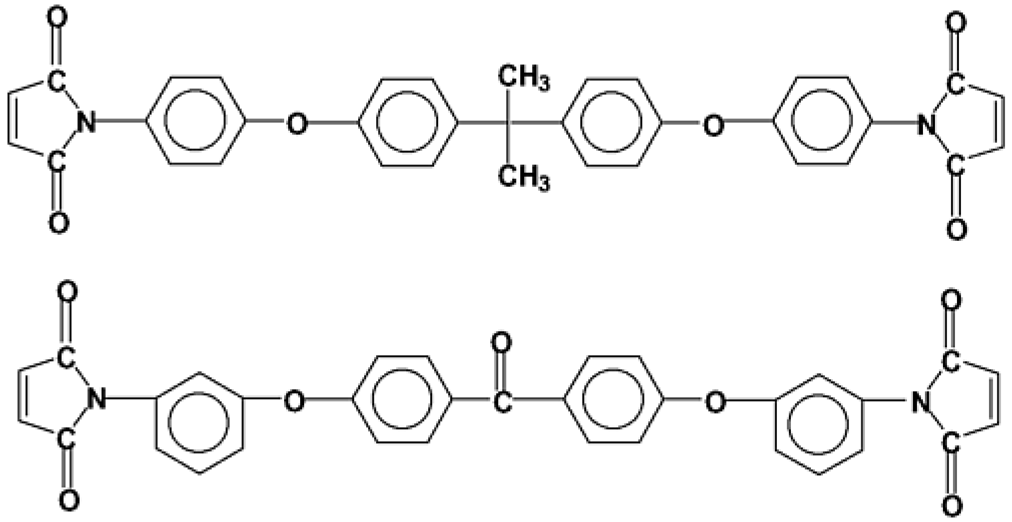

Fig. 3 Bismaleimide of polyaromatic diamines

The most important property of a BMI is its ability to undergo a temperature-induced polymerization. The maleimide double bond is highly activated owing to the adjacent carbonyl groups of the maleimide ring. Therefore, heating the BMI above its melting point effects polymerization. The cure exotherm peak temperature taken from a dynamic differential scanning calorimetry (DSC) scan is used to characterize the reactivity of individual BMIs. The reactivity is influenced by the chemical nature of the residue between the maleimide terminations and by the molar mass between the reactive maleimide groups. Normally, electron-donating groups such as alkyl groups reduce the BMI reactivity, provided they are present in the phenyl ring that carries the maleimide group. On the other hand, electron-attracting groups such as SO_2, carbonyl, and so on, have the opposite effect. Increasing the molecular weight between cross links (Mc) generally provides a more latent system owing to steric effects.

In their early days, the most important application for BMI resins was multilayer printed circuit boards. In this area, resins with low dielectric constants are required. Hitachi Research Laboratory, Japan recently reported the thermal and dielectric properties of fluorine-containing BMIs (Ref 9). The chemical structures of two fluorinated BMIs investigated are provided in Fig. 4.

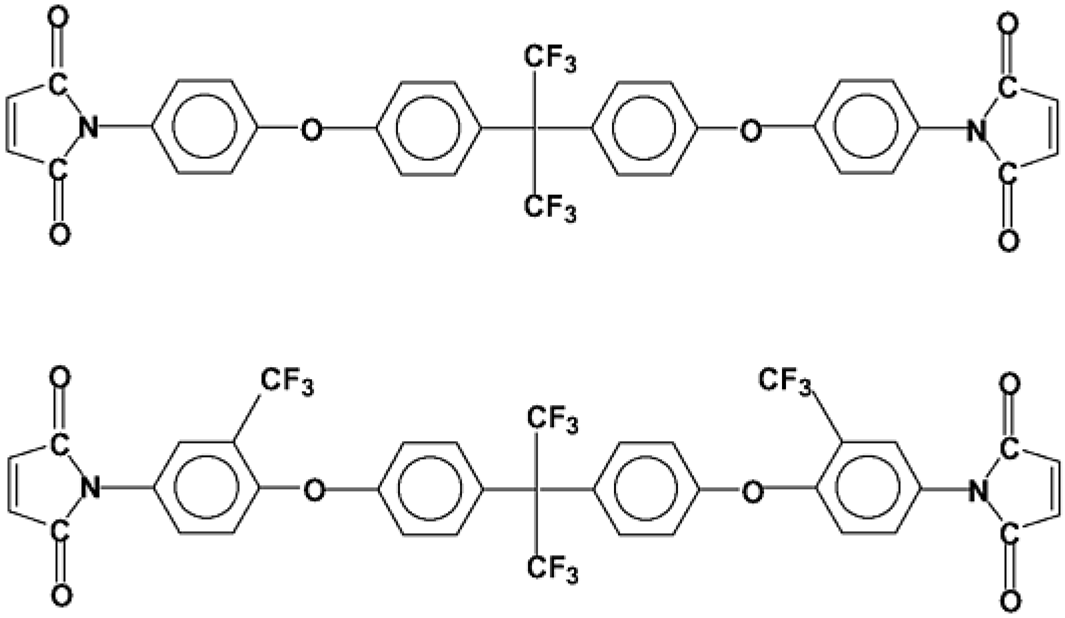

Fig. 4 Fluorine containing bismaleimides

Bismaleimides and maleimide-terminated prepolymers have been considered for systems with improved fire, smoke, and toxicity properties. For such applications, phosphorous-containing BMIs are of interest because they provide high limiting-oxygen index (LOI) values.
Besides the fact that synthesizing new BMI building blocks and investigating their application potential are still desired, the BMI building block is not the final resin product. Although building blocks usually make up 50 to 75 wt% of the resin, other ingredients—such as comonomers, reactive diluents, processing additives, elastomers, and catalysts—are combined with BMI to obtain a product suitable for the application considered. The application areas for BMI resins are reinforced composites for printed circuit boards (with glass fabric), structural laminates (with glass, carbon, and aramid fibers), and moldings (with short fibers and particulate fillers).

Bismaleimide Resin Systems

In order to fulfill the processing requirements, BMI building blocks have to be formulated into products that enable their use as highly concentrated solutions, powders, or hot melts. An early attempt in BMI modification with respect to achieving a meltable, noncrystalline resin was made by blending a complex mixture of BMIs and crystallization inhibitor (Ref 10). The resin (Compimide 353), although it is not a formulated product, shows a very low melting transition and a low viscosity at 110 °C (230 °F). This specific resin system can be further formulated with a wide range of vinyl and/or allyl compounds to provide prepreg resins that are tacky at room temperature and suitable for low-pressure autoclave molding.
The divinylbenzene approach to modify BMI into a hot-melt prepreg system was followed by U.S. Polymeric/British Petroleum (now Cytec Fiberite) (Ref 11). The resin system, known in the industry under the

trade name V378A, was the first BMI formulation used in primary aircraft application. Although the resin is relatively brittle in comparison with epoxy resin, it provides outstanding high-temperature mechanical properties in both dry and wet environments. V378A prepreg can be cured under standard low autoclave pressure of 700 kPa (7 bars) and temperatures similar to current 177 °C (350 °F) curing epoxy systems. However, postcure temperatures of 245 to 260 °C (475 to 500 °F) are required to maximize elevated-temperature strength retention.

Polyaminobismaleimides. The reaction of a BMI with a functional nucleophile (diamine, aminophenol, aminobenzhydrazide, etc.) via the Michael addition reaction converts a BMI building block into a polymer. The nonstoichiometric reaction of an aromatic diamine with a BMI converts the BMI into a polyaminobismaleimide as shown in Fig. 5.

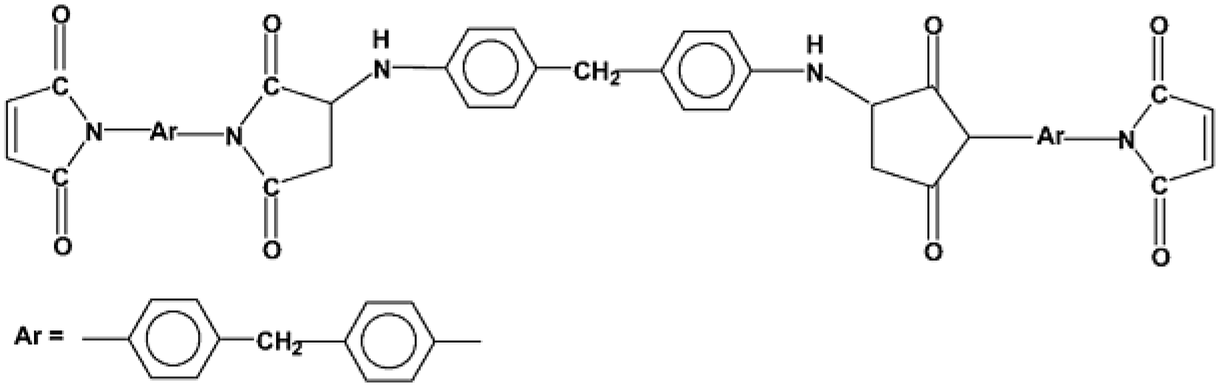

Fig. 5 Bismaleimide/MDA Michael addition product

The reaction product of 4,4′-bismaleimidodiphenylmethane and 4,4′-diaminodiphenylmethane, known as Kerimide 601, is prepolymerized to such an extent that the resulting prepolymer is soluble in aprotic solvents such as N-methylpyrrolidone, dimethylformamide, and the like, and therefore can be processed via solution techniques to prepreg. Kerimide 601 was mainly used in glass fabric laminates for electrical applications and became the industry standard for polyimide-based printed circuit boards. Recently the resin has been taken off the market because of the high free methylene dianiline (MDA) content in the product. The MDA is a suspected carcinogen.

Another approach to processible BMI resin via a Michael addition chain extension is the reaction of BMI, or a low-melting mixture of BMIs, with aminobenzoic hydrazide to provide a resin that is soluble in various solvents, such as acetone, methylene chloride, and dimethylformamide (DMF) (Ref 12). The idealized chemical structure for a 2:1 BMI-aminobenzhydrazide resin is provided in Fig. 6.

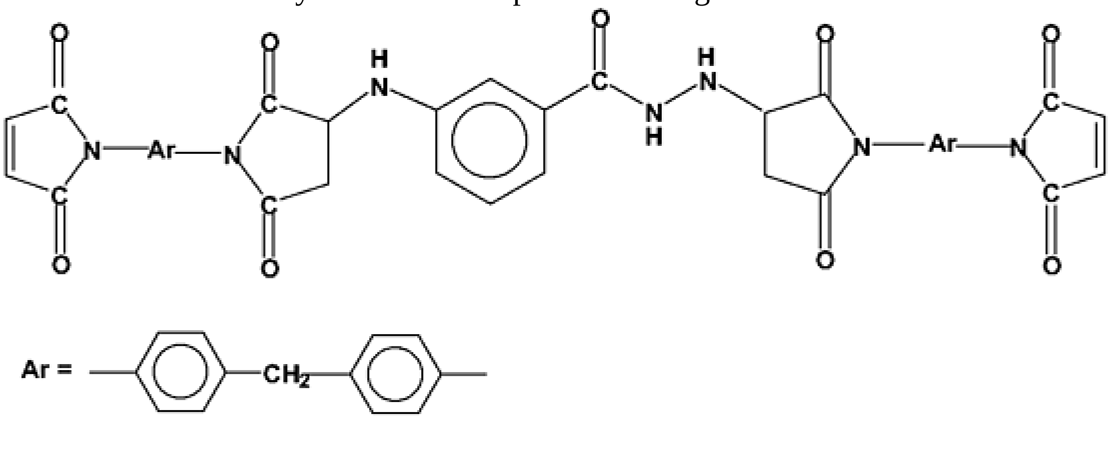

Fig. 6 Michael addition product of BMI-aminobenzhydrazide

Two resin systems based on this chemical concept are commercially available from Technochemie (now a subsidiary of Laporte PLC) under the name Compimide 183 (solid resin with no solvent) and Compimide 1206-R55 (resin solution in DMF) for use in printed circuit boards. Typical properties of Compimide 1206 printed circuit laminates are provided in Table 1.

Table 1 Properties of BMI (Compimide 1206) printed circuit laminates

Property	Value
Dielectric constant at 1 MHz	4.6–4.7
Dielectric loss constant at 1 MHz	0.01
Dielectric strength, V/μm	29.5
Volume resistivity, Ω· cm	10^{15}
Water absorption[(a)], %	<1
Heat stability at 287 °C (550 °F), s	>60
Thermal expansion coefficient, 10^{-6}/°C	
x, *y* directions	14–16
z direction	36–38
Flammability in comparison with UL 94	
3 mm (0.12 in.) laminate	V-0
1.5 mm (0.06 in.) laminate	V-1

Compimide 1206 is equivalent to Compimide 183. Properties measured using 1.0–1.5 mm (0.04–0.06 in.) glass fabric laminates.

(a) After postcure at 210 °C (410 °F)

The BMI/amine Michael adduct resins may be further modified and blended with other thermosets or reactive diluents to achieve either specific end-use properties or processibility. Epoxy resins are very suitable for the modification of BMI/primary amine adducts, because the secondary amine functionality in the aspartimide structure is a curative for the epoxy group.

A modified BMI-epoxy resin system has been developed and introduced by Shell Chemical Company. The system is a highly reactive blend of a BMI, Compimide 1206 R55, and Epon resin 1151, a polyfunctional epoxy resin (Ref 13). In this polyimide resin, no free MDA is present. This is an important feature because MDA has been identified as an animal carcinogen and a possible human carcinogen. The resin system has been fully evaluated for use in multilayer printed circuit boards (Ref 14). Catalysts such as methylimidazole or phenylimidazole are recommended for processing and for adjusting the processing window. The properties of two BMI-epoxy electrical laminates are provided in Table 2.

Table 2 Properties of BMI-epoxy electrical laminates

Property	Value for laminate composition (BMI/epoxy) of	
	70/30	**50/50**
Flexural strength at 23 °C (73 °F), MPa (ksi)	462 (67)	441 (64)

BMI resin is Compimide 1206. Epoxy is Epon 1151.

The Compimide 1206/Epon 1151 BMI/epoxy concept is particularly interesting because the ratios of BMI and epoxy resin may be varied widely to possibly tailor the thermal and electrical properties.

Bismaleimide/Bis(Allylphenol) Resins. The copolymerization of a BMI with DABA is a resin concept that has been widely accepted by the industry because BMI-DABA blends are tacky solids at room temperature and therefore provide all the desired properties in prepregs, such as drape and tack, similar to epoxies. Crystalline

BMI can easily be blended with DABA, which is a high-viscosity fluid at room temperature. On heating, BMI-DABA blends copolymerize via complex ENE and Diels-Alder reactions as outlined in Fig. 7.

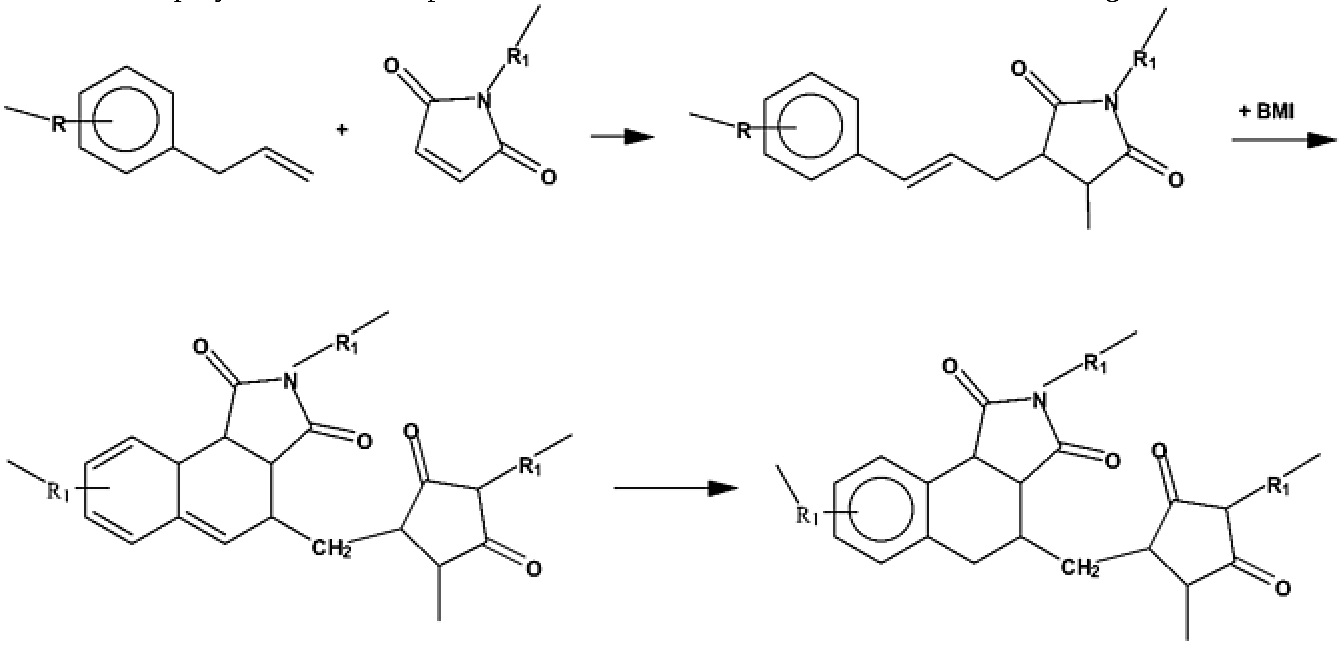

Fig. 7 Copolymerization of BMI with DABA

Reportedly, DABA is an attractive comonomer for BMIs because the corresponding copolymer is tough and temperature resistant (Ref 15). Toughness, however, is a function of the BMI-DABA ratio employed in the resin mix. In one study, optimized toughness properties were achieved when BMI and DABA were employed at a close to 2:1 molar ratio (Ref 16), as can be seen from Table 3.

Table 3 Properties of BMI/DABA copolymers

Property	BMI/DABA molar ratio			
	1.2/1	**1.5/1**	**2/1**	**3/1**
Flexural strength, MPa (ksi)	186 (27.0)	188 (27.3)	174 (25.2)	131 (19.0)
Flexural modulus, GPa (10^6 psi)	4.02 (0.58)	3.94 (0.57)	4.05 (0.59)	4.14 (0.60)
Deflection at breaking, %	7.78	7.30	5.53	3.50
Fracture toughness				
Plane-strain (K_{Ic}), MPa $\sqrt{m}$(ksi $\sqrt{in.}$)	0.97 (0.88)	0.86 (0.78)	0.80 (0.73)	0.64 (0.58)
Interlaminar (G_{Ic}), J/m^2 (in. · lbf/in.^{2})	197 (1.10)	158 (0.88)	133 (0.74)	83 (0.46)
Glass transition temperatures (T_g), °C (°F)	279 (534)	282 (540)	288 (550)	288 (550)

BMI resin is compimide 353A; curing conditions: 175 °C (350 °F)/3 h + 230 °C (445 °F)/4 h

Diallylbisphenol is commercially available under the trade name Matrimide 5292 from Ciba Geigy. Other comonomers of the o-allylphenol type have been synthesized and copolymerized with BMI (Ref 17). Bis(3allyl-4-hydroxyphenyl)-p-diisopropylbenzene, in particular, provided even better toughness properties than the BMI-DABA system.

Bismaleimide Resins via Diels-Alder Reaction. The Diels-Alder reaction can also be employed to obtain thermosetting polyimides. If BMI (the bisdienophile) and the bisdiene react nonstoichiometrically, with BMI in excess, a prepolymer carrying maleimide terminations is formed as an intermediate, which can then be cross-linked to yield a temperature-resistant network.

A new Diels-Alder comonomer for BMI is bis(o-propenylphenoxy) benzophenone. This comonomer is commercially available from Technochemie under the trade name Compimide TM123. It is of particular interest because the BMI/bis(o-propenylphenoxy)benzophenone copolymers are very temperature resistant. The synthesis involves a straightforward nucleophilic halogen displacement reaction. The o-allylphenol reacts with 4,4′-difluorobenzophenone at 160 °C (320 °F) in N-methylpyrrolidone as a solvent in the presence of potassium

carbonate as a catalyst. The alkaline reaction conditions are responsible for the o-allyl → o-propenyl isomerization (Ref 18).

The bis(o-propenylphenoxy)benzophenone, Compimide TM123, is commercially available from Technochemie, Germany. It is a low-melting, low-viscosity material that can easily be melt blended with BMI and then cured at temperatures of 170 to 230 °C (340 to 445 °F). The BMI/Compimide TM123 copolymer resin is attractive because of its extremely high temperature stability. It shows a better thermal oxidative stability than all other commercially available BMI systems. The copolymerization chemistry of BMI/propenylphenyl resins is provided in Fig. 8.

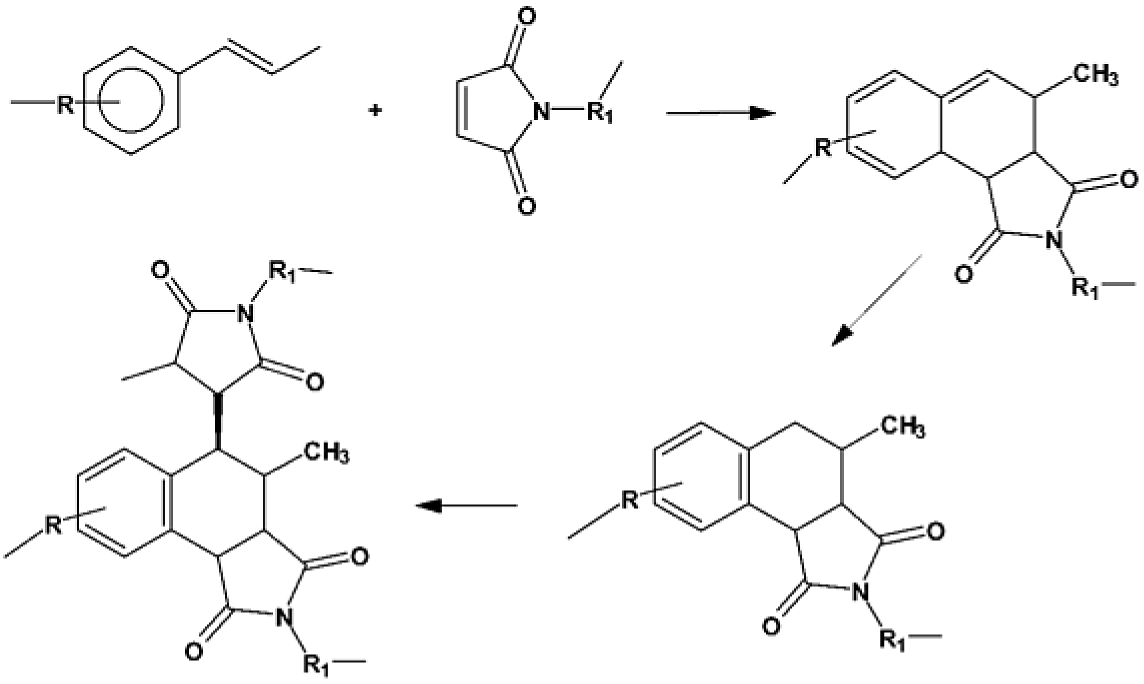

Fig. 8 Copolymerization chemistry of BMI-propenylphenyl resins

Continuing Development of BMI Resin Systems. The target in BMI resin technology for composite applications is to improve properties such as toughness and thermal stability and at the same time reduce moisture absorption. BMI comonomers influence such properties significantly. The DABA concept is favored when high toughness properties are desired. Compimide TM123 [bis(o-propenylphenoxy) benzophenone] on the other hand provides systems with excellent thermal oxidative stability. Figure 9 shows the weight retention versus aging time at 275 °C (525 °F) for up to 1000 h of a BMI- DABA system versus two BMI-Compimide TM123 resins. It is obvious that the Compimide TM123 neat resin is by far superior to the BMI- DABA resin.

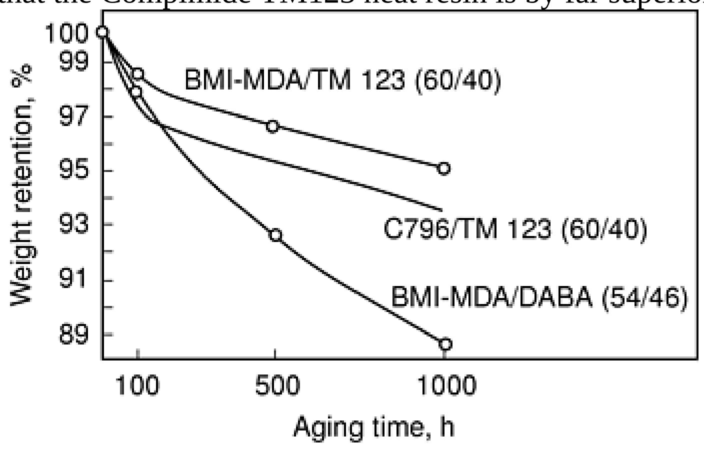

Fig. 9 Thermo-oxidative stability of BMI-comonomer systems (DABA versus Compimide TM123). Aging temperature, 275 °C (525 °F)

Another important property of BMI-comonomer blends is processibility. Processibility includes working viscosity and cure kinetics or reactivity. A comparative study of the relative reactivity of alkenyl-functionalized

modifiers for BMI was recently published (Ref 19). Differential scanning calorimetry measurements suggest that propenyl-functionalized aromatic comonomers do react more readily than the allylic analogues. For a series of recently synthesized bis[3-(2-propenylphenoxy) phthalimides], it could be demonstrated that these are by far more reactive than their allylphenoxy analogs (Ref 20). Therefore allylphenoxy comonomers are to be favored when processibility is desired. However, the thermal oxidative stability is superior for the propenylphenoxy reactive diluents and comonomers.

The key to improved BMI systems is the properties of the comonomer employed for the BMI resin. The BMI itself is limited to a very few chemical structures; 4,4′-bismaleimidodiphenylmethane represents the most important one because it is readily available and relatively inexpensive.

Research in the area of improved BMI resin systems is still ongoing. Technochemie has synthesized propenyl-group-functionalized poly(arylen ether ketone) high polymers and could demonstrate that these are excellent tougheners for BMIs; however, these systems suffer from high glass-transition temperatures and poor processibility (Ref 21). Many other chemical concepts to modified BMI systems have been published (Ref 22), but only a few combine all the desired properties for advanced fiber composites.

BMI Composites

Jack Boyd, Cytec Fiberite Inc.

Most advanced composite parts in the aerospace industry use epoxy resins. Epoxies have earned wide acceptance because of their excellent mechanical properties, extended service temperature range, and ease of part manufacture. However, many applications require service temperatures higher than the capability of epoxies. Some BMI composites are being selected for those applications, because they are capable of higher temperature use than epoxies, yet possess epoxy-like processing. Through this avenue, BMI composites are gaining important applications and acceptance.

The first BMI composites, developed in the early 1980s, possessed excellent mechanical properties in the 150 to 230 °C (300 to 450 °F) temperature range, but exhibited low damage tolerance. Research to improve BMI damage tolerance resulted in the development of a resin (Cycom 5250-4, Cytec Fiberite Inc.) with improved damage tolerance and excellent mechanical properties. The 5250-4 is being used as a matrix resin for composites that serve as the primary construction material for the F-22 Raptor, which is the first large-scale production use of BMI composites.

Mechanical Properties

Compression Strength. Fiber-dominated properties such as tensile strength are similar for most composites. Properties such as damage tolerance and compression at elevated temperatures differentiate matrix resins. The industry has not as yet established a standard measurement of composite service temperature. However, service temperature is often defined as the temperature when the open-hole compression (OHC) strength of moisture-saturated, quasi-isotropic specimens is equal to 205 MPa (30 ksi). The 5250-4 composite OHC strength is 240 MPa (35 ksi) at 177 °C (350 °F)/wet, indicating a service temperature capability of at least 177 °C (350 °F) (Table 4).

Table 4 Typical mechanical properties of 5250-4 and leading epoxies

Property	5250-4/IM-7 BMI[(a)]	977-3/G40-800 MTE[(b)]	5276-1/G40-800 HTE[(c)]

80 °C (180 °F)/wet	283 (41)	283 (41)	248 (36)
120 °C (250 °F)/wet	262 (38)	262 (38)	193 (28)
175 °C (350 °F)/wet	241 (35)	…	…

Compression after impact strength (6.7 J/mm, or 1500 in. · lb/in.), MPa (ksi)	185–200 (27–29)	180–200 (26–29)	303–324 (44–47)
Glass transition temperature (T_g)(d), °C (°F)			
Dry	280 (540)	210 (410)	180 (360)
Wet	210 (410)	165 (325)	145 (290)

BMI, bismaleimide; MTE, medium-toughness epoxy; HTE, high-toughness epoxy. IM-7 and G40-800 carbon fibers provide nearly identical mechanical properties (tensile strength, 5516 MPa, or 800 ksi; modulus of elasticity, 290 GPa, or 42 × 10^6 psi). Fiber areal weight, 145 g/m^2; resin content, 34%.

(a) Cure cycle for 5250-4: 175 °C (350 °F)/6 h cure plus 225 °C (440 °F)/6 h postcure.

(b) Cure cycle for 977-3: 180 °C (355 °F)/6 h.

(c) Cure cycle for 5276: 175 °C (350 °F)/2 h.

(d) Dynamic mechanical analysis (DMA) storage modulus using tangent intercept method

The aerospace industry is using a number of medium-toughness epoxies (MTEs) as the baseline for new applications. For example, the MTE, Cycom 977-3/IM-7, was selected for the F-18E/F program. The MTEs possess a good balance of high mechanical properties, good damage tolerance, and the highest OHC strengths for epoxy based composites. The OHC strength of 5250-4 composites equals or exceeds the values of Cycom 977-3.

Damage Tolerance. The aerospace industry has determined through experience that high compression properties are more important than damage tolerance in many applications. However, most designs still have damage tolerance requirements. For designs that do not require the highest level of damage tolerance, the medium- toughness epoxies are being selected. The compression after impact (CAI) strength of a leading MTE, 977-3/G40-800, is 180 to 200 MPa (26 to 29 ksi) after impact of 6.7 J/mm (1500 in. · lbf/ in.). The 5250-4 matrix provides a similar level of damage tolerance, 185 to 200 MPa (27 to 29 ksi) (Table 4, Fig. 10). Some designs require the highest level of damage tolerance. Table 4 and Fig. 10 also compare a high-toughness epoxy (HTE), Cycom 5276-1/G40-800, with 5250-4 and 977-3 composites. While the 5276-1 composite has the highest CAI strength (at >305 MPa, or 44 ksi), it also has the lowest OHC strength (248 MPa, or 36 ksi) at 80 °C (180 °F)/ wet.

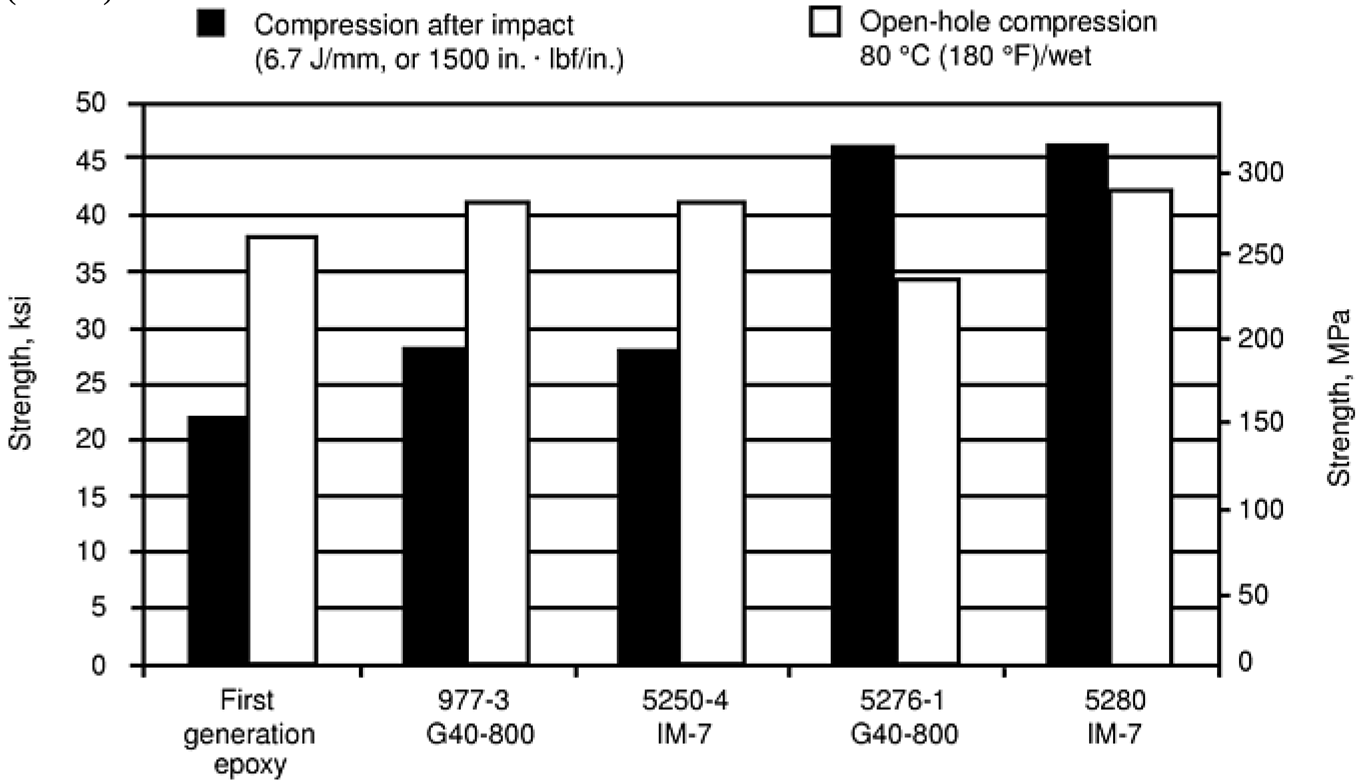

Fig. 10 Mechanical property comparison of BMI and epoxy composites

Bismaleimide composites are not limited to the medium toughness level. They can be formulated to provide the highest levels of toughness. Cycom 5280 provides CAI values >305 MPa (44 ksi) while maintaining the same high service temperature of the 5250-4 system (Fig. 10). This CAI value equals that of the high- toughness,

5276-1 epoxy composite. As a historical comparison, a first-generation epoxy is also shown in Fig. 10 with the CAI and OHC lower than the MTE or BMI. The improvements exhibited by the BMIs and epoxies are the result of the research conducted over the last 15 years to provide composites to the aerospace industry with superior capability.

Composite Applications

Recent applications show that BMI composites offer:

- Mechanical properties higher than those of epoxies at elevated temperature resulting in either lower weight or increased safety margins
- Epoxy-like processing using standard autoclave cure processes
- Installed cost similar to epoxy parts

F-22 Raptor Fighter Jet. The F-22 will be the frontline fighter for the U.S. Air Force in the twenty-first century. This program was the most sought-after composite application in the 1980s, and the high strength and high service temperature of the 5250-4 BMI system led designers to use it on half of the composite parts. The F-22 airframe is 24% composite, 39% Ti, 16% Al, 6% steel, and 15% other materials. Cycom 5250-4/ IM-7, BMI, accounts for about 50% of the composite weight with the balance epoxy. The epoxy prepreg is the medium-toughness Cycom 977-3/ IM-7. Product forms are unidirectional tape and fabric and fiberglass fabric. The BMI adhesive is FM 2550, which is used to fabricate complex sandwich structures.

The BMI wings, which give the F-22 a modified delta shape, are particularly noteworthy. The wings are designed for extended supersonic cruising at Mach 1.5 and for withstanding extremely “high G” maneuvers. The wings are large, flat structures and are, therefore, where composites can be most efficiently exploited to save weight. The wing materials are 35% composite, 42% Ti, and 23% Al and other materials. Each triangular-shaped wing measures 4.9 m (16 ft) (side of body) by 5.5 m (18 ft) (leading edge) and weighs about 900 kg (2000 lb). Each wing contains about 320 kg (700 lb) of composites, the majority of which is 5250-4/IM-7 BMI composite. The understructure is composed of titanium and composite spars. Each wing contains approximately 7000 holes to attach the composite skins to the titanium and composite understructure. This is the reason why high open-hole compression strength is vital.

C-17 Aft Flap Hinge Fairing Structure. The C-17 is the U.S. Air Force heavy-lift aircraft. The 5250-4 composites are used to build the aft flap hinge fairing structure that is attached to the trailing edges, four per wing, of the C-17 wings. Each measures about 1.5 m (5 ft) long, 0.6 m (2 ft) high, and 0.3 m (1 ft) wide. They are constructed by Aerostructures Hamble at its Southampton, United Kingdom facility. Figure 11 shows the four fairings installed on the wings.

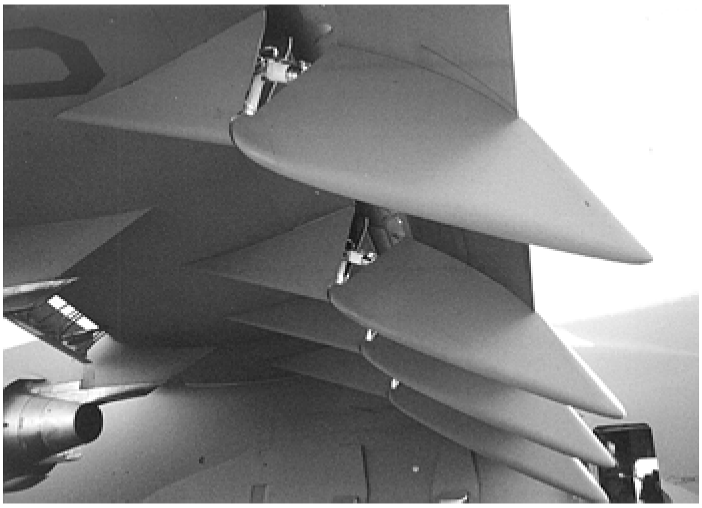

Fig. 11 C-17 aft flap fairings

The original fairing design was epoxy composite. A detailed analysis, however, indicated that the fairing would experience engine exhaust during routine operation, calling for an actual service requirement of 200 °C (390 °F). Therefore, the part design was switched to BMI because that is the only matrix resin with the required use temperature and with epoxy-like processing. A schematic of the fairing is shown in Fig. 12. All of the structure is built with BMI except for the forward bulkheads and lower access cover, which are built with epoxy composite. A 5250-4/T650-35 fabric is used for the BMI structures. All of the panels are monolithic, about 9 plies (365 g/m^2 fiber areal weight), with the exception of the side covers and lower tray, which are constructed with 2 to 3 plies of BMI fabric over glass phenolic honeycomb core. The skin is bonded to the core using FM 2550 BMI adhesive.

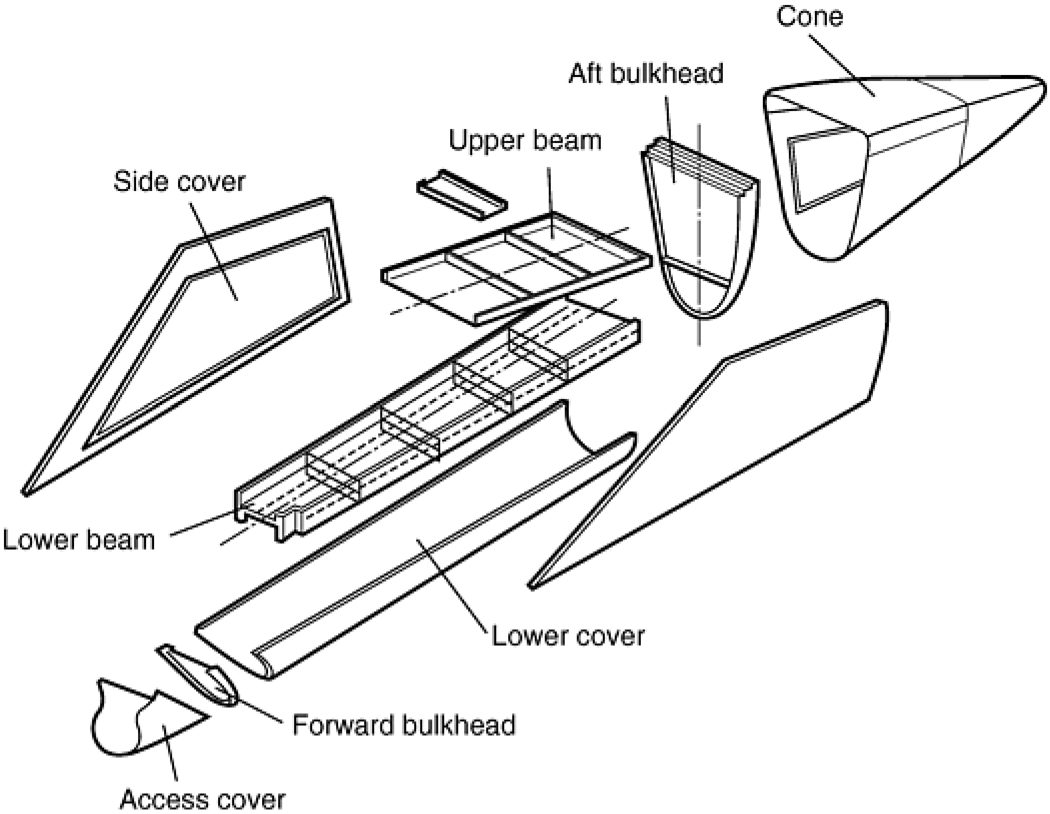

Fig. 12 Schematic of aft flap hinge fairing structure

The hinge-fairing program shows that BMI composites have reached the maturity of epoxy composites in terms of availability, producibility, and ease of design, thus providing the capability of rapid scale-up. The C-17 was the first application to use BMI to accommodate engine exhaust impingement. Exhaust can heat a part beyond the capability of epoxies. In such situations, BMI composite is an alternate candidate to metal.

Thrust Reverser Structures (Ref 23). Engine components are an application where the elevated temperature capability of BMI composites can be fully exploited. The 5250-4 composites and 2550 adhesive are used in two major thrust reverser applications. One of these is the inner fixed cowl structure for the Pratt & Whitney 4168 engine built by Middle River Aircraft Systems for use on the Airbus Model A330. The inner cowl of the thrust reverser is stationary and surrounds the hot engine core. It provides the primary attachments of the thrust reverser to the engine, access to engine components, and inlets for airflow for various engine or aircraft systems. Figure 13 shows a schematic of the 5250-4/ T650-35, one-piece inner core cowl. The structure is approximately 2.7 m (9 ft) long and 3.0 m (10 ft) in cross section. The composite part integrates many of the individual components of a metal part. It saves about 16 kg (35 lb) weight compared to a metal structure.

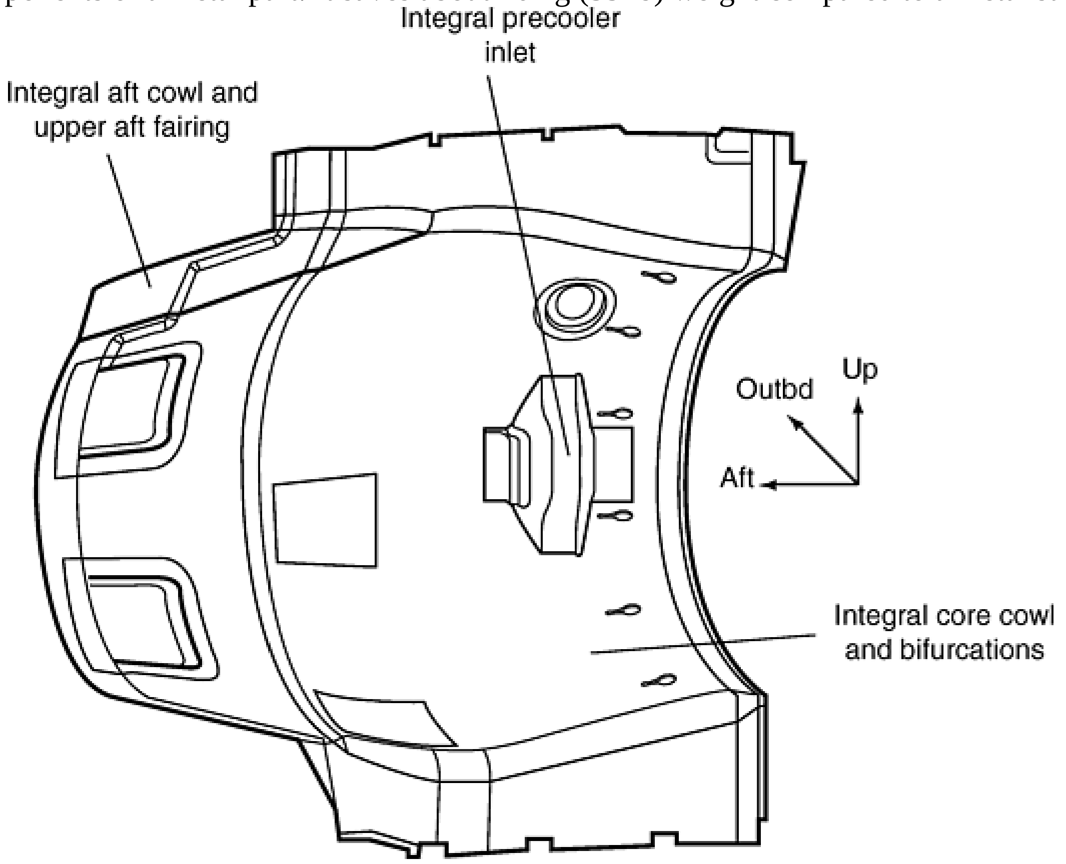

Fig. 13 One-piece inner cowl for Pratt & Whitney 4168 made from BMI composite (Cycom 5250-4)

The inner core cowl consists of a precured outer skin, local precured reinforcing doublers, aluminum honeycomb core, and a precured inner skin. Because the forward section of the inner cowl is part of the sound-suppression system for the engine, this portion has perforated BMI outer skin with the aft portion having a solid BMI outer skin. Now in service, this structure provides excellent performance with no unanticipated in-service problems.

Helicopter Tail Boom (Ref 24). Bell Helicopter Textron (BHT) has developed a BMI composite tail boom for its Model 412/212 helicopters to replace the existing metal tail boom. The tail boom will be exposed to hot engine exhaust during routine use, as well as a corrosive and fatigue environment. 5250-4 composite and 2550 adhesive were selected for this application based on their high-temperature performance, outstanding mechanical properties, and extensive use history.

The tail boom features and requirements are monocoque boom section, integral vertical fin, support of the tail rotor, drive system, and support of the synchronized elevator. Typically, composite parts cost more to manufacture than metal. Bell Helicopter Textron was able to overcome this potential difficulty by designing the tail boom for low-cost manufacture. The primary objective in designing for producibility is to achieve low recurring costs, which translates into minimizing the number of parts, reducing the lay-up cycle and assembly process times. The 6.4 m (21 ft) long tail boom is a bonded assembly comprising a four-piece skin construction extending the full length, with internal substructure composing only 17 components and no mechanical fasteners (Fig. 14).

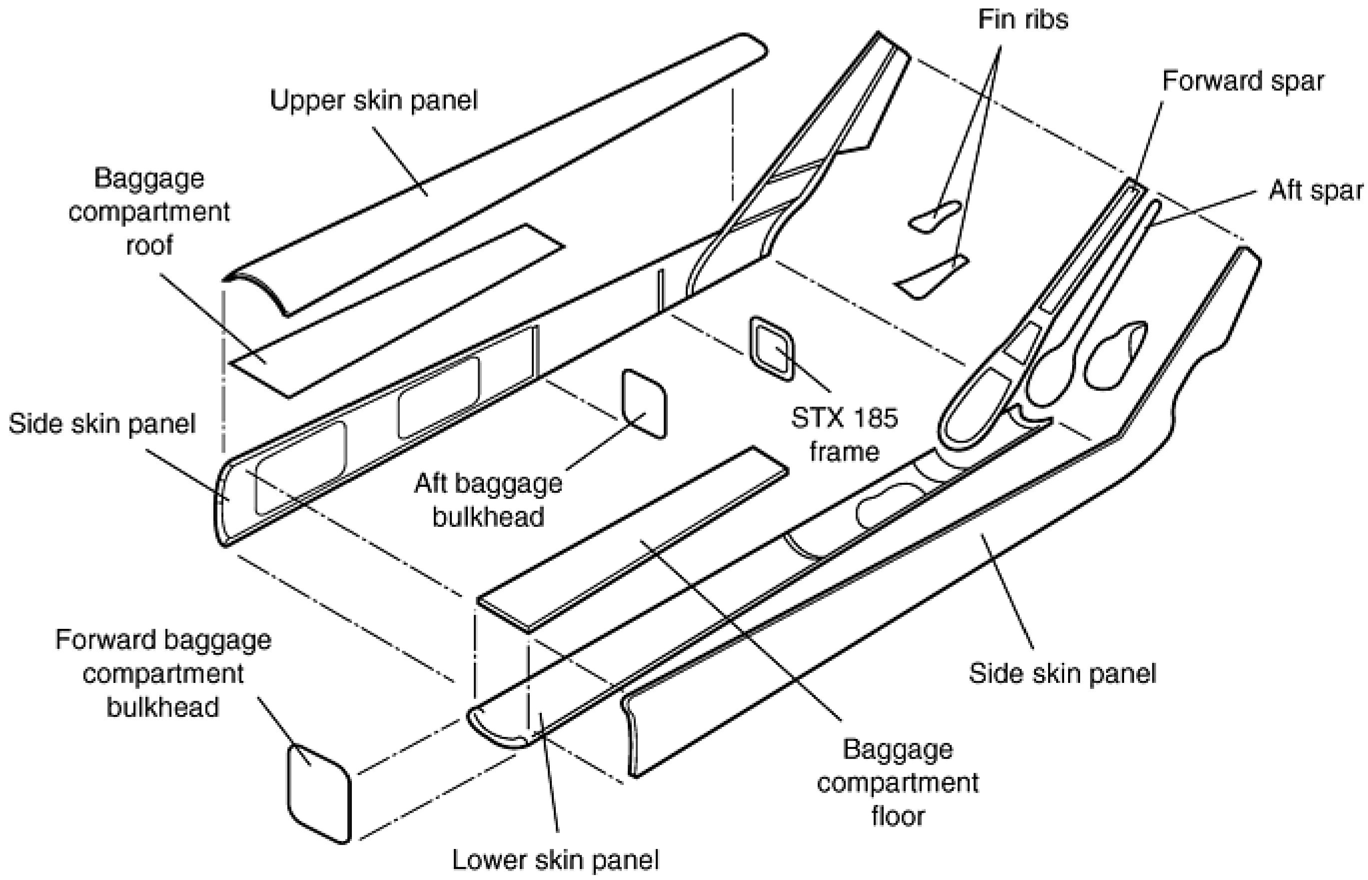

Fig. 14 Bell Helicopter Model 412 tail boom made from BMI composite (Cycom 5250-4)

The BMI tail boom will also save money in service compared to the metal tail boom. Its lower weight will reduce fuel costs and increase range, while the inherent composite corrosion and fatigue resistance will minimize maintenance. This application shows that BMI composites, if designed for producibility, can be cost competitive with metal structures.

Formula 1 Race Cars. Formula 1 racing is highly competitive. Designers will use any material that provides improved performance over metal parts. Composites of BMI have found extensive and increasing use on race cars. They are applied to structures in hot areas of engines and transmissions and in and around exhaust systems and areas where exhaust impinges a structure.

Resin Transfer Molding

Resin transfer molding (RTM) is finding increasing use because it can reduce composite manufacturing cost. Final assembly is one of the most costly aspects of composite part manufacture. Composites molded with a vacuum bag, single-mold surface typically have dimensional variation part to part. During assembly, shims and reinforcement parts are used to accommodate that variation. The technology of RTM is capable of making parts

with tight dimensional tolerances because all dimensions are defined by the mold. Processing by RTM can be efficient to make complex parts where many different shapes and contours are brought together, requiring tight tolerances.

The 5250-4 prepreg resin provides composites with excellent properties and the capability of operating in high-temperature environments. A derivative, Cycom 5250-4RTM (Ref 25), makes an outstanding RTM resin. This resin has been selected for a wide variety of RTM applications. The largest use is on the F-22, which is one of the first production aircraft taking advantage of RTM. A further advantage of 5250-4RTM is that the 5250-4 composite database is transferable. 5250-4RTM is one component and homogenous. The resin is used by heating and injecting into the mold. The RTM process requires low viscosity for several hours. 5250-4RTM has less than 10 P viscosity for over 4 h (Fig. 15), which meets the requirements of any process.

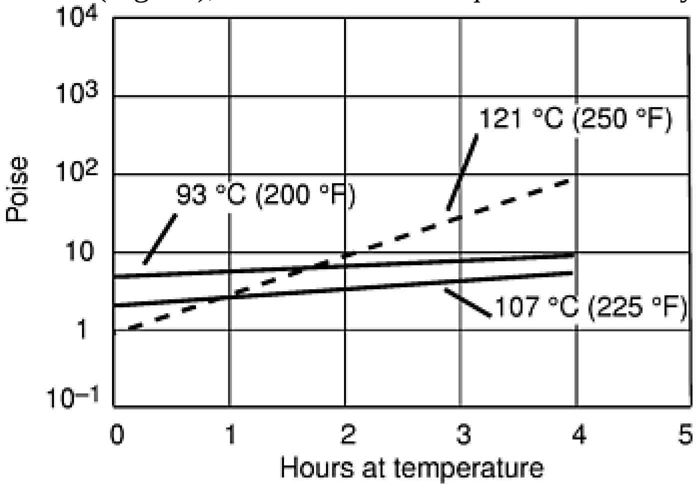

Fig. 15 Viscosity and pot life of BMI resin 5250-4RTM

The RTM process is used to manufacture over 400 F-22 parts. One challenging application is the sine wave spars. Initially, standard prepreg was used, but fiber distortion was encountered due to the complexity of the spar shape. The RTM process solved this and other fabrication problems, while reducing manufacturing cost by 20%. The tight dimensional tolerances provided by the RTM process decreased by half the number of reinforcement parts needed for installing the spars in the wings. The F-22 5250-4RTM applications demonstrate the capability of manufacturing complex parts.

Cure and Post Cure Requirements

One factor that limits wider BMI use is that BMIs require higher cure temperatures than used for epoxies. Tests in this section show that for applications not requiring the highest T_g, the cure temperature can be reduced to 190 °C (375 °F) with no trade-off in mechanical properties (Ref 26). Most civil aerospace applications use 80 °C (180 °F)/wet as the design condition. The 80 °C (180 °F)/wet open-hole compression (OHC) strength is the same whether 5250-4 is cured at 190 °C (375 °F)/6 h or 205 °C (400 °F)/2 h with no postcure or cure using the standard cure followed by postcure (Table 5). The 120 °C (250 °F)/wet OHC is also the same, regardless of cure condition, as was the damage tolerance. The only difference is T_g. The T_g is lower at the lower temperature cures. However, this level of T_g is adequate for uses below about 150 °C (300 °F).

Table 5 Properties of BMI 5250-4 composites with and without postcure

Cure cycle	Open-hole compression 80 °C (180 °F)/wet		Open-hole compression 120 °C (250 °F)/wet		Compression after impact (6.7 J/mm, or 1500 in. · lbf/in.)		Glass-transition temperature (T_g)	
	MPa	**ksi**	**MPa**	**ksi**	**MPa**	**ksi**	**°C**	**°F**
Standard cycle: 175 °C (350 °F)/6 h plus 225 °C (440 °F)/6 h	283	41	262	38	186–200	27–29	282	540
205 °C (400 °F)/2 h	290	42	…	…	193	28	251	484
190 °C (375 °F)/6 h	290	42	262	38	193	28	247	477

5250-4 reinforced with IM-7 was used in all tests. Postcure not required for service below 150 °C (300 °F)

Elevated-Temperature Applications

The 5250-4 matrix can be used at 230 °C (450 °F), but the service life is about 2500 h due to oxidative weight loss. PMR-15, an industry standard condensation polyimide, has higher temperature capability and is usually selected for applications at 230 °C (450 °F) and above. However, PMR-15 has processing disadvantages. It cures by a condensation reaction, and volatiles are formed. The bagging, tooling, and cure cycle must be designed to allow volatile removal in order to consolidate parts. PMR-15 can be RTM processed, but the technique has limitations due to the volatiles formed. Therefore, there existed a need for a BMI that approached the performance of PRM-15 without the processing disadvantages. The 5270-1 matrix was developed to have the highest temperature capability of a BMI resin (Ref 27). There are no volatiles released during cure so 5270-1 processes like an epoxy and can be RTM processed using standard techniques.

High Temperature Aging Comparison. Composites held at elevated temperature are slowly oxidized and lose weight. One of the most critical tests for elevated temperature applications is how well the composite resists weight loss at the service temperature. The industry typically uses side-by-side, isothermal aging for accelerated weight loss testing. Figure 16 shows comparisons of 5270-1, PMR-15, and 5250-4 at 230 °C (450 °F). The composite of 5270-1 loses much less weight than 5250-4 composite. It loses only twice as much weight as PMR-15. Similar results are obtained in 260 °C(500 °F) aging where 5270-1 composite loses only twice as much weight as PMR-15.

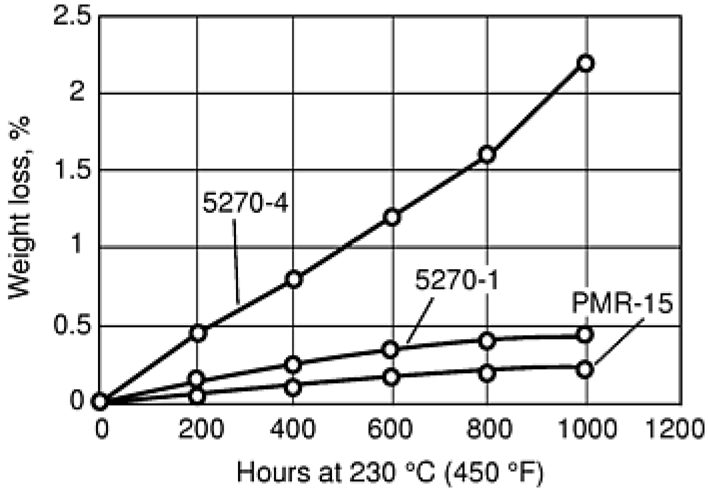

Fig. 16 High-temperature performance of BMI composites versus PMR-15 composites. Reinforcing fiber, T650-35

Since volatiles are not formed during cure, 5270-1 resin can also be processed by standard RTM methods for resins without volatile components. The 5270-1 system can be considered a potential replacement for PMR-15 in current applications, and the first choice candidate when an application requires high service temperature.

Conclusions

New matrix resin classes are accepted by the aerospace composite industry only when they offer significant advantages over epoxy-based systems. The BMI composites offer the advantages of higher temperature capability with epoxy-like processing. Bismaleimide has successfully made the transition from experimental composites in the early 1980s to application on some of the most important aircraft programs. The wide variety of applications shows that BMI composites can be manufactured into an extensive array of parts. The BMI composites now include systems with high damage tolerance, RTM capability, and thermal stability approaching that of PMR- 15. Bismaleimide resins offer the widest service range of any matrix resin class and excellent mechanical properties.

Polyimide Resins

Daniel A. Scola, University of Connecticut

Introduction

POLYIMIDE MATERIALS can be categorized by their temperature capabilities into those with an upper limit of 230 °C (450 °F) for extended time periods, and those capable of extended use up to 315 °C (600 °F). Bismaleimides, phenylethynyl-containing polyimides, and some condensation polyimides such as Avimid-K3 belong in the former category, while those materials such as PMR-15, LARC-TPI, Avimid-N and BPDA/TFMB belong in the latter. In terms of chemistry, there are two general types of commercial polyimides: thermoplastic polyimides, derived from a condensation reaction between anhydrides or anhydride derivatives and diamines, and cross-linked polyimides, derived from an addition reaction between unsaturated groups of a preformed imide monomer or oligomer. The imide monomers or oligomers are also derived from the typical condensation reaction to form the imide group, but polymer formation stems from the addition reaction. For completeness, the chemistry of both types and process conditions to fabricate articles are described in this article. Bismaleimides are not reviewed in this article. (See the article "Bismaleimide Resins" in this Volume.)

Daniel A. Scola, University of Connecticut

Properties and Applications

The specific advantages and disadvantages of two types of polyimides are summarized in Table 1. These are generalized conclusions regarding each type, because there are exceptions, which depend on chemical structure.

Table 1   General attributes of condensation (thermoplastic) and addition-type (cross- linked) polyimides

Polyimide type	Advantages	Disadvantages
Condensation (thermoplastic)	Thermoplastic (reprocessability) Moderate to high glass transition temperatures (T_g) Toughness Excellent thermal and thermo-oxidative stability	Poor processability Volatiles released in processing High pressure required in processing
Addition-type (cross-linked)	Processability Cross linked High T_g No volatiles in processing Low pressure required in processing	Limited reprocessability Brittle Poor thermal and thermo-oxidative stability

The condensation polyimides, which are linear long-chain thermoplastic polymers, have high melt viscosity, thereby requiring high pressures and temperatures for neat resin molding or composite processing. However, the highly aromatic nature of these systems coupled with flexible groups, such as ether, hexofluorosopropylidene, or methylene within the backbone structure, yields materials with good toughness, excellent thermal and thermooxidative stability, and moderate to high glass transition temperatures (T_g).
The addition-type polyimides, derived from preformed oligomers, undergo thermal cross linking or chain extension to form a thermoset. The oligomer molecular weight controls the processability, the degree of cross linking or chain extension, and the T_g. However, because no volatiles are released during processing, and the oligomers have a melt or softening region where the viscosity is relatively low near the temperature region where the addition reaction occurs, moderate to low pressure is required during processing to consolidate the part being fabricated.
Polyimides are finding wide applications because of their unusual properties. The polyimides derived from aromatic dianhydrides and aromatic diamines containing stable flexible units in the backbone exhibit:

- High thermal and thermo-oxidative stability up to 400 °C (750 °F)
- Excellent mechanical properties, both at room temperature and elevated temperatures
- Film- and fiber-forming ability
- Excellent adhesive properties, both at room temperature and elevated temperature
- Nonflammability—will not support combustion

Fluorine-containing polyimides exhibit the properties listed previously, as well as low dielectric constant. Polyimides containing functional or pendant groups in the backbone of the aromatic dianhydride or/and diamine exhibit some of the properties listed previously, as well as selective gas permeability.
Since the mid-1980s, the application areas for high-temperature polyimides have continually grown. This is because of the ability to vary the polymer structure, thereby tailoring the properties for specific applications. Polyimide products are used in a variety of applications, such as coatings, adhesives, composite matrices, fibers, films, foams, moldings, membrane, liquid crystalline displays, and insulation. A list of general application areas by industry is given in Table 2. Specific applications of high-temperature polyimides for aircraft are listed in Table 3. Clearly, the range of applications for the polyimides is a good indication of the ability to modify molecular structure for specific properties. Hundreds of research polyimide materials have been synthesized over the years, but only a few are commercially available at the present time. However, many research polyimides are available from specialty chemical houses. A partial list of available polyimides and their sources is shown in Tables 4 and 5.

Table 2 Applications of polyimides by industry

Industry	Applications
Electronics	Flexible circuits
	Flexible connectors
	Chip carriers
	Tape automated bonding
	High-density interconnect applications
	Photosensitive polyimides
Aircraft	Wire insulation
	Motor windings
	Electrical switches

	Structural adhesives Structural composites Foam insulation Bushings Baffles Flanged bearings Thrust washers Thrust discs Seal rings
Automobile	Electrical switches
Medical	Pacemakers Eye lens implants
Machining	Abrasive cutting wheels
Gas purification	Membranes
Aerospace	Rockets Spacecraft (composite, adhesives, coatings)
Military applications	Composites, adhesives, coatings
Manufacturing	Discs in compressor valve systems

Table 3 Applications of high-temperature polyimide composites in aircraft engines

Sector	Applications
Military engines	Stator vanes Shrouds (fan section) External nozzle flaps Bushings Bearings Intermediate cases Augmenter ducts Fan ducts Nose cones
Commercial engines	Core cowls (nacelles) Union rings (variable vane actuation system) Stator vanes (low-pressure compressor)

	Externals—gear box housing and support structures
	Washers
	Bushings
	Bearings

PTPEI, pendant, terminal phenylethynyl imide oligomer; PPEI, pendant phenylethynyl imide oligomer; 3FDA, 4,4′-(2,2,2-trifluoro-1-phenylethylidene) diphthalic anhydride or dimethyl ester; PEPA, 4-phenylethynylphthalic anhydride; BPDA, 3,3′,4,4′-biphenyl-tetracarboxylic dianhydride or dimethyl ester; 3,4′-ODA, 3,4′-oxydianiline; DPEB, 3,5-diamino-4′-phenylethynyl benzophenone; p-PDA, para-phenylenediamine; 6FDA, 4,4′-(1,1,1,3,3,3-hexafloroisopropylidene) diphthalic anhydride or dimethyl ester; 8FDA, 4,4′-(2,2,2-trifluoro-1-pentafluorophenylethylidene) dipthalic anhydride; BTDA, 3,3′-4,4′-benzophenone tetracarboxylic acid dianhydride or dimethyl ester; TFMB, 2,2′-trifluoromethyl biphenylene diamine or 2,2′-bis(trifluoromethyl)benzidene; BisP, 1,3-bis (4′-aminophenylisopropylidene) benzene; BAX, 1,4-bis (4′- amino benzyl) benzene; DMBZ, 2,2′-dimethylbenzidine; BNDA, 4,4-bis (1,1-binapthyl-2-oxy, 1,1′-binepthyl-2,2′-oxy) dipthalic anhydride or dimethyl ester; BAPP, 2,2-bis (4-aminophenoxyphenyl) propane; ArDA, aromatic dianhydrides; 3FDAM, 4,4′-(2,2,2,-trifluoro-1-phenylethylidene) diphenyl diamine; NE, dimethyl ester of 5-

norbornene 1,2-dicarboxylic acid; PBDA, 4,4′-(1,1′-biphenyl-2-oxy) diphthalic anhydride or dimethyl ester; APB, 1,3-(4,4′-aminophenoxy) benzene; $ArNH_z$, aromatic diamines; TAB, 1,3,5-tris (4-aminophenoxy) benzene; BPADA, 2,2′-bis(phenoxy isopropylidene) 4,4′-diphthalic anydride or Bisphenol A-4,4′-diphthalic anhydride; TPER, 1,3-bis (4-aminophenoxy) benzene; MC's, 1,3 and 1,4 bis (aminobenzyl and aminobenzoyl) benzenes; 1,2,4- OBABTF, 4,4′-oxybis (3-trifluoromethyl) benzamine; 3,5,-DABTF, 3,5-diaminobenzotrifluoride; PDMDA, 3,3′-bis (3,4-dicarboxyphenoxy) diphenylmethane dianhydride; TMBZ, 2,2′,6,6′-tetramethylbenzidine; 2,2′,-BPDA, 2,2′,3,3′,-biphenyltetracarboxylic dianhydride or dimethylester; PE, phenylethynyl end-capped; PPQ, polyphenylquinoxaline (solution sample from H. Hergemrother, NASA Langley Research Center); IP-600, ethynyl end-capped imide oligomer (no longer commercially available); L-20, BTDA/4-BDAF 4,4′-(p-aminophenoxyphenyl-hexafluoroisopropylidene); L-30, BTDA/4-BDAF 4,4′-(p-aminophenoxyphenyl-hexafluoroisopropylidene); Sixef-44, 6FDA/6FDAM, 2,2-(4- aminophenyl)-hexafluoroisopropylidene); PBI, polybenzimidazole

The glass transition temperatures and upper temperature capabilities of the two types of polyimides are listed in Table 6. The thermal properties of the polyimides depend on the presence of flexible units, such as ether, isopropylidene, methylene, hexafluoroisopropylidene, and carbonyl in the backbone of the polymer chain, or bulky side groups pendant to the backbone structure. These groups can also affect solubility. Disruption of regularity by the copolymerization of two dianhydrides with two diamines also affects solubility.

Table 6 Thermal properties of polyimides

An important consideration in the selection of a polyimide for a composite application is resin toughness. An interesting correlation of resin toughness versus estimated cost is shown in Table 7. The polyether imide (PEI) Ultem has the most favorable toughness/cost correlation. As with all polyimides, this property must be balanced between other properties, such as processability, T_g, temperature capability, and mechanical properties.

Table 7 Relationship of resin toughness to cost

Resin type	Interlaminar fracture toughness (G_{Ic}) at 23 °C (73 °F)		Approximate cost		Toughness per unit cost[(a)]
	J/m^2	**ft · lbf/ft^2**	**$/kg**	**$/lb**

Polyimide Resins

Daniel A. Scola, University of Connecticut

Chemistry of Condensation-Type Polyimides

These materials, discovered in 1908 by T.M. Bogert and R.R. Renshaw (Ref 75) and made practical by W.M. Edwards and I.M. Robertson (Ref 76), are derived from polyamic acids by either chemical or thermal treatment over a temperature range from room temperature to 370 °C (700 °F). The polyamic acids are produced by a series of step growth reactions at room temperature from a dianhydride or dianhydride derivative and a diamine. The general reaction for polyimide formation is illustrated in Fig. 1. The structures of several commercially available thermoplastic polyimides are shown in Fig. 2.

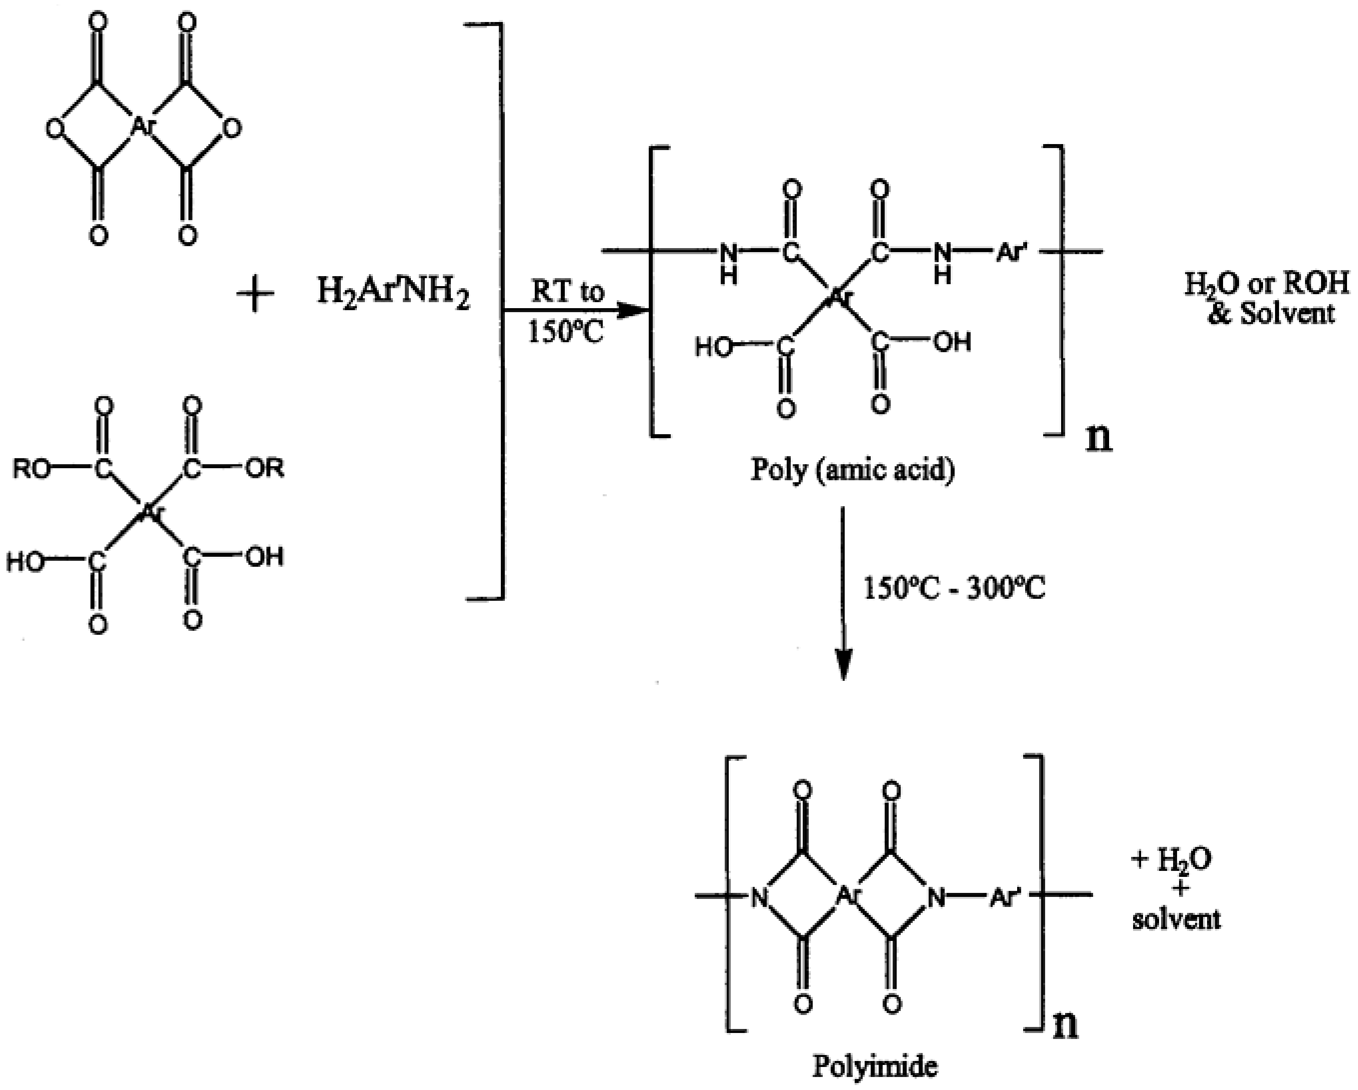

Fig. 1 General reaction for condensation polyimides. Solvents can be NMP, DMF, or m-cresol diglyme.

Synthesis (General). Thermoplastic polyimides are prepared in dimethylacetamide (DMAC) or N-methyl pyrrolidinone (NMP) by dissolving the appropriate diamine in the solvent at room temperature under nitrogen. The dianhydride is added as a solid or a slurry in the solvent while stirring over a period of one-half hour. The reaction is allowed to continue from 6 to 24 h while stirring under ambient conditions, depending on the relative reactivities of the diamines and dianhydride. The polyamide acid solution thus produced can be sampled for determination of intrinsic viscosity or analyzed by gel permeation chromatography (GPC) for molecular weight or analyzed by other methods as required. The polyamide acid solution can be used to prepare polyamide acid or polyimide powder, thin films, supported adhesive tape, and to impregnate unidirectional carbon fiber, carbon cloth, or other fiber/cloth substrate.

Alternatively, thermoplastic polyimides can also be prepared by dissolving the dialkyl ester (methyl, ethyl, or isopropyl) of the dianhydride in ethanol at room temperature, followed by the addition of the aromatic diamine. This polyimide precursor solution can also be used to prepare powder, thin films, supported adhesive tape, and impregnated carbon fiber, carbon cloth, or other fiber/cloth substrate. The polyamide acid can be converted to the polyimide by thermal methods or by chemical methods, described subsequently.

Processing of Polyamide Acid Precursor Solution to Polyimide. The polyamide acid solution can be converted thermally in solution to the polyimide by: the addition of a sufficient quantity of toluene or o-xylene, followed by azeotropic distillation of water in a Dean-Stark trap overnight; by refluxing the polyamide acid solution containing 1 to 2 wt% isoquinoline catalyst (based on solvent) for 6 h; or by the addition of ten-fold excess of acetic anhydride with pyridine or triethylamine catalyst at a 4 to 1 weight ratio, followed by heating at 100 °C (210 °F) for 3 h.

The polyamic acid solution can also be prepared in m-cresol solvent instead of DMAC or NMP at room temperature and converted to the polyimide by refluxing at 200 °C (390 °F) with or without a catalyst (1 to 2 wt% isoquinoline based on m-cresol) for 4 h. The polyimide powder is isolated as described in the following paragraphs.

NMP or DMAC polyamic acid solution is added while stirring vigorously to a methanol/ water (50:50) solution. The precipitated polyamic acid powder is filtered and washed again in methanol and water, then dried at 125 °C for 24 h in a vacuum, or at 200 °C (390 °F) for 4 h in vacuum. The polyamic acid powder is converted to polyimide in an oven at 150 °C (300 °F) for 1 h + 250 °C (480 °F) for 1 h + 275 °C (525 °F) for 1 h.

Alcohol solutions of the diester and diamine composition are concentrated to a solvent-free polyamic acid powder in a vacuum oven at 60 °C (140 °F) for 2 h. The polyamic acid powder is converted thermally to polyimide powder at 150 °C (300 °F) for 1 h + 250 °C (480 °F) for 2 h + 275 °C (525 °F) for 1 h.

Preparation of Polyimide Films from Thermoplastic Polyamic Acid Precursors. Centrifuged NMP or DMAC solutions of the polyamic acids are cast on a clean glass plate and heated at 80 °C (175 °F) in a vacuum for 1 h. The tack- free film is then cured at 100 °C (210 °F), 200 °C (390 °F), and 300 °C (570 °F) for 1 h at each temperature. The film is removed from the glass surface by immersion into warm water. Alternatively, an alcohol solution of the polyamic acid precursor is centrifuged, and then the solution is cast on a clean glass plate using a doctor blade. The film solution is placed in a chamber under flowing nitrogen at room temperature for 4 h to become a tack-free film, and cured according to the schedule described previously.

Chemistry of Addition-Type Polyimides

General structures of several types of addition-type polyimides are shown in Fig. 3. Specific structures of the more common materials are shown in Fig. 4. Generally, these materials are low-molecular-weight imide oligomers containing unsaturated end caps, capable of forming an addition-type reaction. In some cases, these unsaturated groups can also be located as pendant groups in the backbone of the oligomer unit.

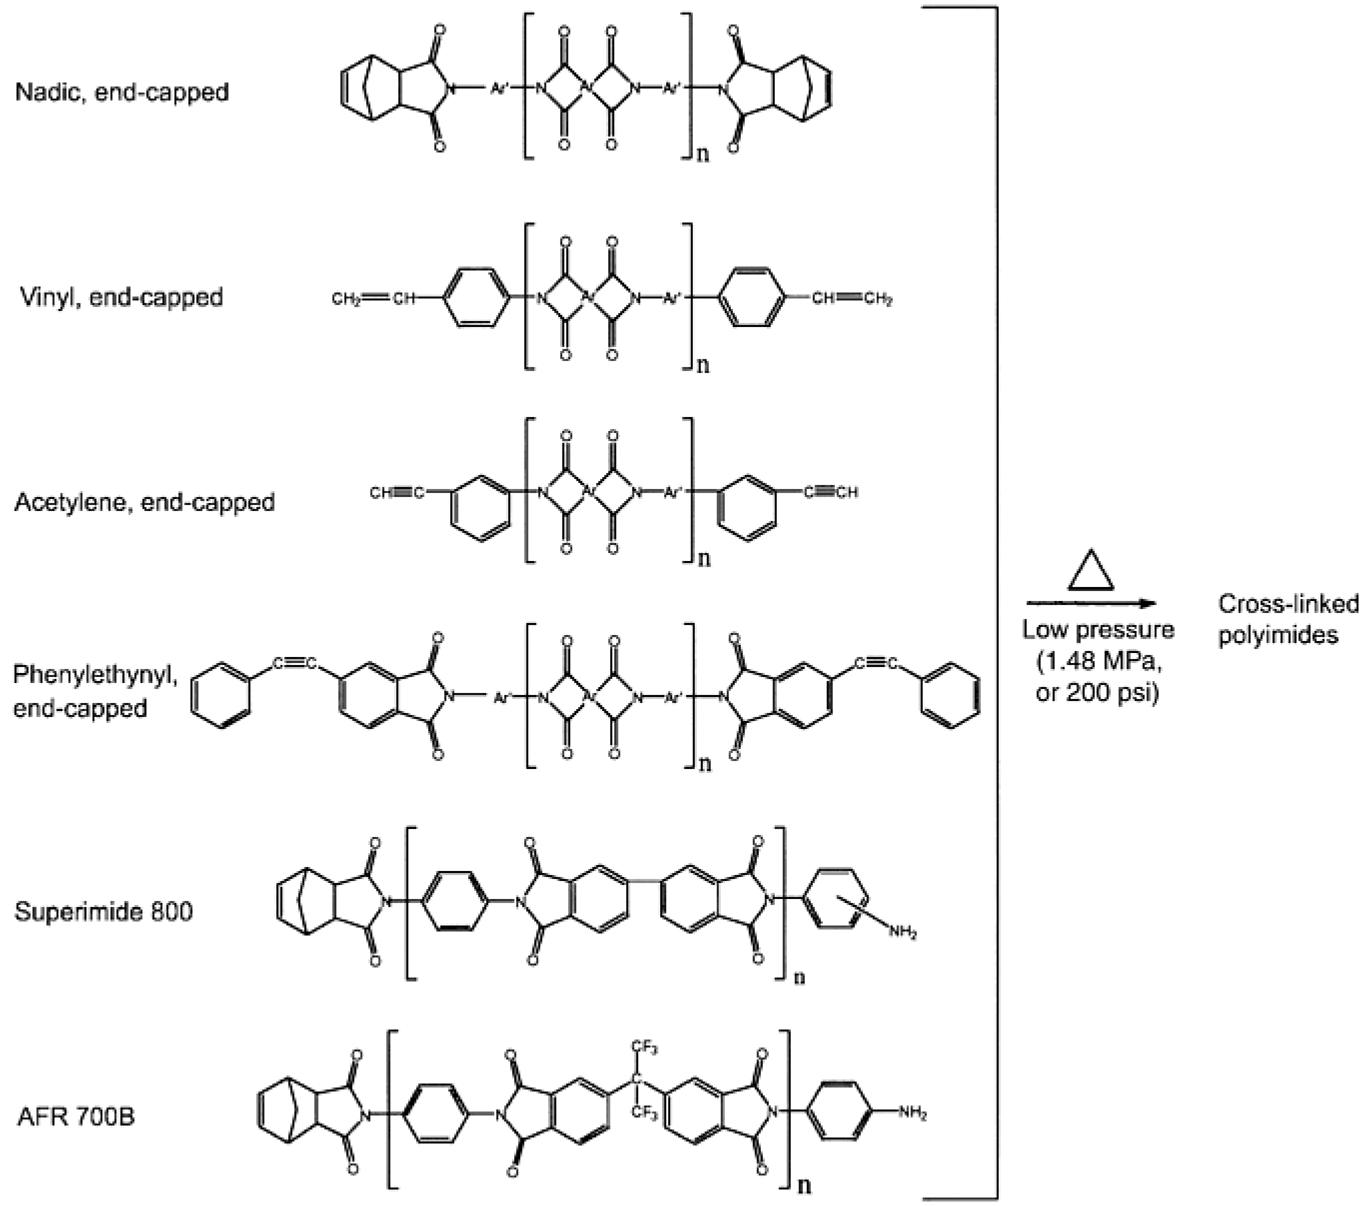

Fig. 3 General structures of addition-type polyimides

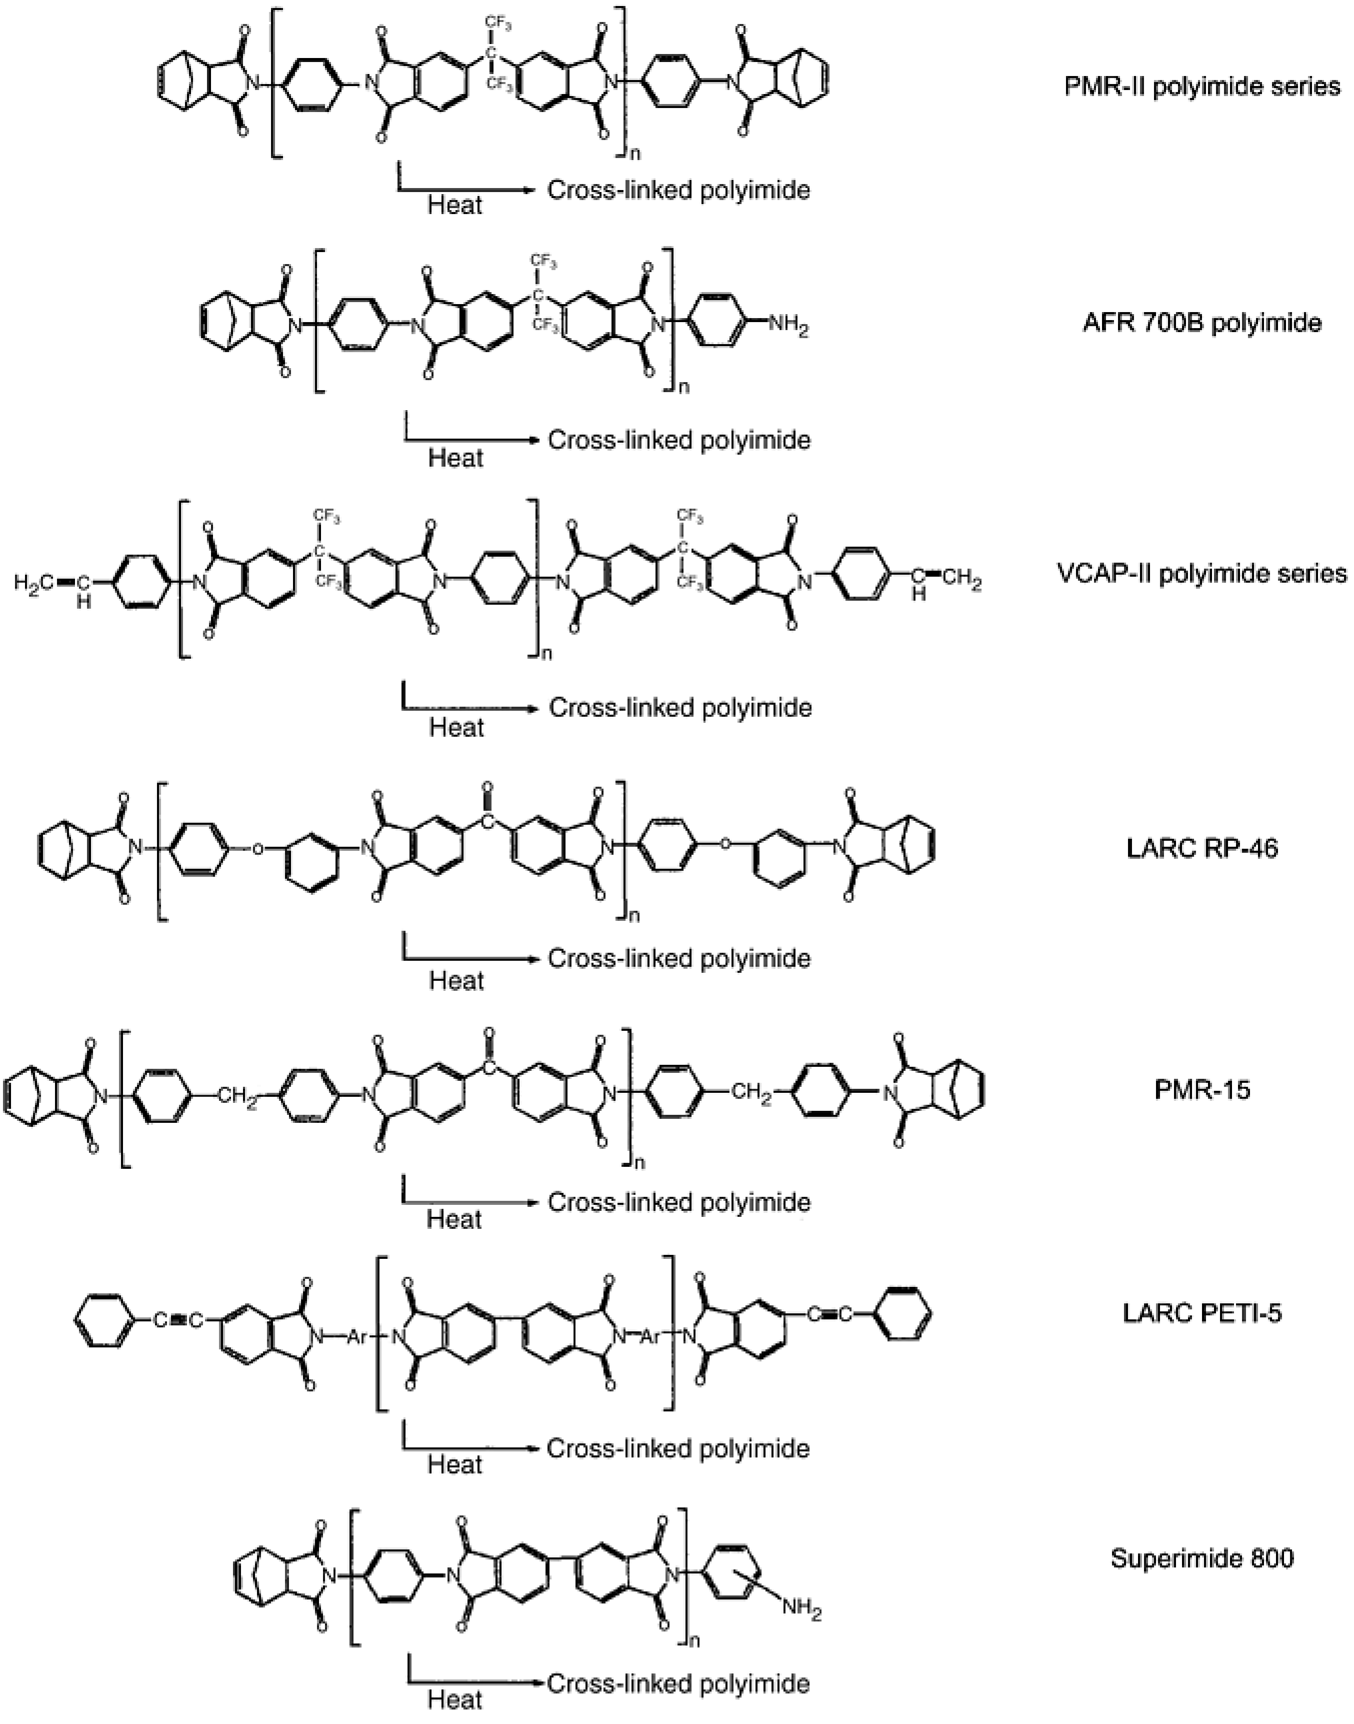

Fig. 4 Structures of selected addition-type polyimides (thermosets)

Phenylethynyl-Containing Imide Oligomers

Since 1985, considerable efforts have been made in the area of phenylethynyl-containing imide oligomers, where the phenylethynyl group can be located at chain ends (77, 78 79, 80 81, 82 83), pendant to the main

chain (Ref 84, 85), as well as pendant and terminal (Ref 13, 14, 86, 87, 88, 89, and 90) to the main chain, shown schematically in Fig. 5. Of the many phenylethynyl end-capped and pendant imide oligomer structures investigated, the phenylethynyl (PE) end-capped imide oligomer, known as PETI-5 (Ref 81) and having a calculated molecular weight of 5000 g/mol, has been extensively characterized as an adhesive (Ref 13, 14, 91, 92, and 93) and as a composite-matrix resin (Ref 13, 14, 94, 95, and 96). This material offered the best combination of properties of the oligomers investigated.

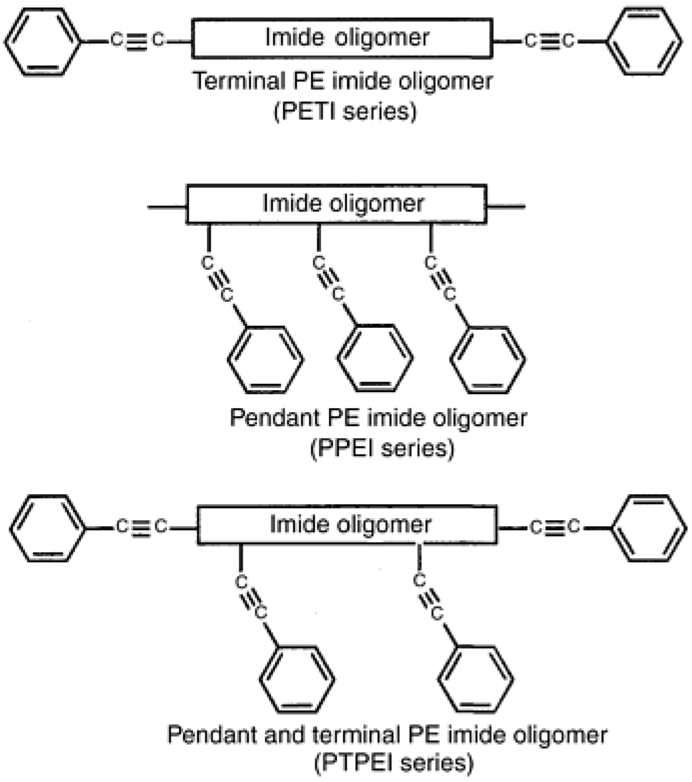

Fig. 5 Schematic of phenylethynyl-containing imide oligomers. Source: Ref 14

The PE end groups are thermally and chemically stable at the conditions necessary to form the imide oligomers. The imide oligomers undergo thermal cure at 370 °C (700 °F) without volatile evolution, to provide polyimides with an excellent combination of thermal stability, mechanical strength, adhesion, and toughness (Ref 13, 14, 81).

The basic chemistry of the PE series of imide oligomers is illustrated by the two reaction schemes (Fig. 5and 6). The PE end-capped imide oligomers to produce the PETI series of polyimides are shown in Fig. 6. Oligomers containing PE groups pendant to the oligomeric chain end-capped with phthalic anhydride (labeled PPEI) and oligomers with pendant and terminal PE groups (labeled PTPEI) are shown in Fig. 7.

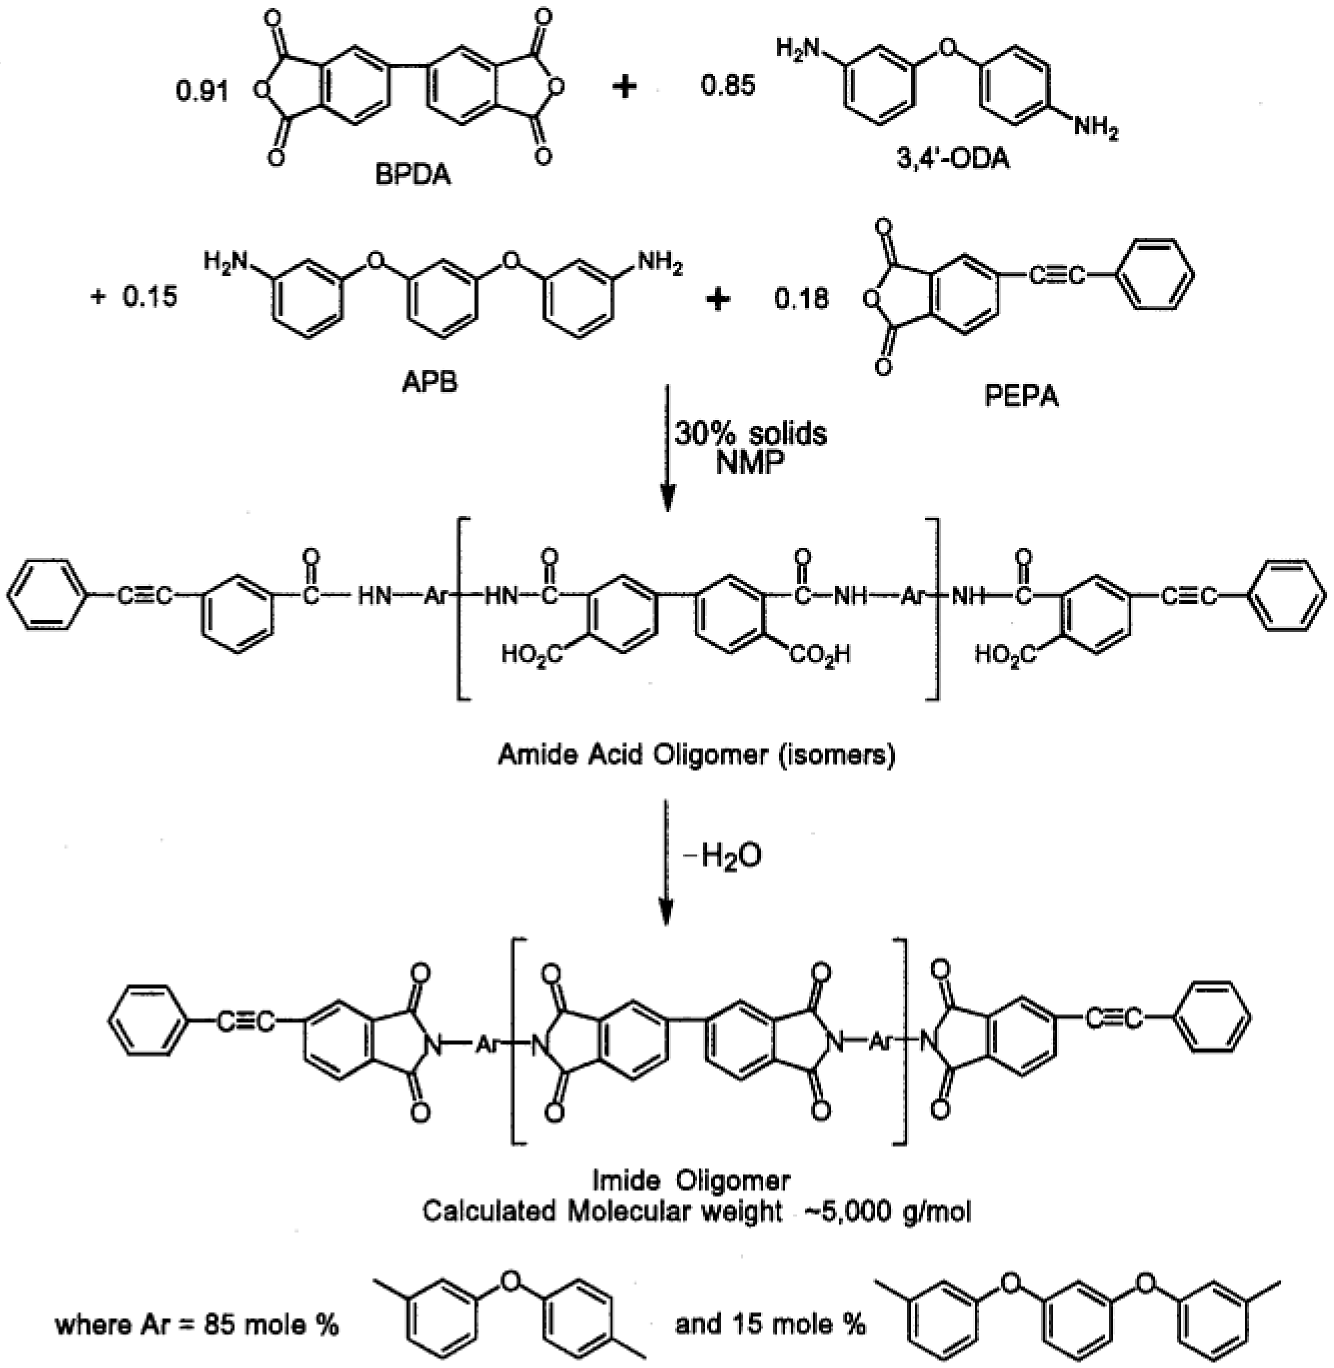

Fig. 6 Phenylethynyl end-capped imide oligomers. Source: Ref 13

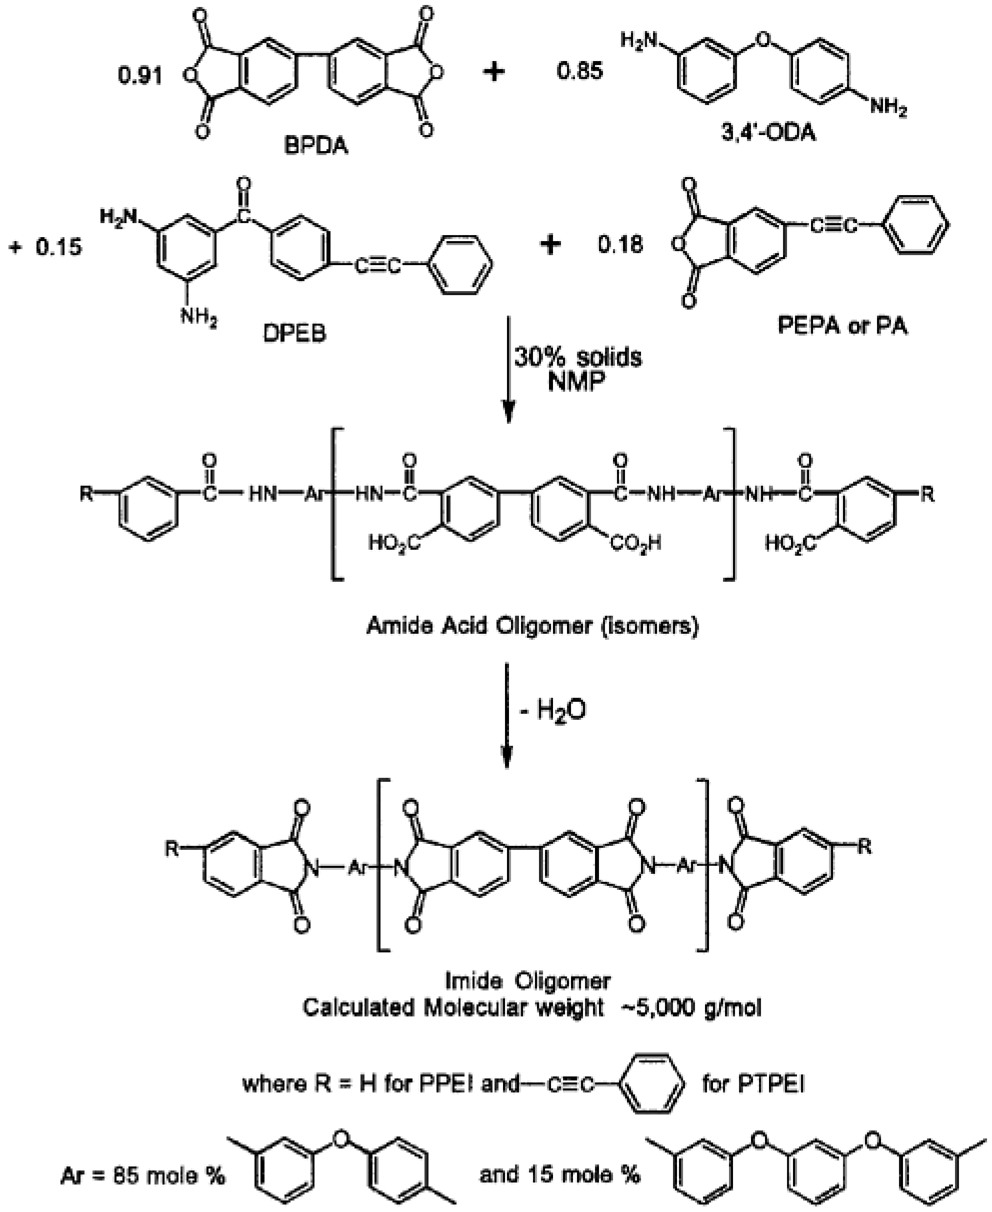

Fig. 7 Phenylethynyl terminal and pendant imide oligomers. Source: Ref 13

Preparation of Phenylethynyl-Containing Imide Oligomers (Ref 13, 14, and 81). The PE end-capped oligomers are prepared from the reactants 3,3′,4, 4′-biphenyltetracarboxylic acid anhydride (BPDA), 3,4′-oxydianiline (3,4′- ODA) and 1,3-bis (3-aminophenoxy) benzene (APB), and 4-phenylethynylphthalic anhydride (PEPA). 3,5-diamino-4-phenylethynyl benzophenone (DPEB) and phthalic anhydride (PA) were added to place PE randomly (pendant) along the oligomeric chain. PEPA and DPEB are added together to form PE terminal to and along the backbone of the oligomeric chain.

The PE oligomers are prepared by dissolving the appropriate diamines 3,4′-ODA, APB, and, in some cases, DPEB in N-methyl pyrrolidinone or dimethylactamide at room temperature under nitrogen. The dianhydride (BPDA) and end-cappers (PEPA or PA, as required) are added in one portion as a slurry in NMP to the stirred diamines. The solids concentration is subsequently adjusted to 25 to 35% (w/w) with additional solvents. A mild exotherm is observed during the first few minutes of the reaction. The solution is stirred for about 24 h at room temperature under nitrogen. Aliquots are removed to determine the inherent viscosity and for GPC analysis to assess molecular weight and molecular weight distribution, or other properties as desired.

The polyamic acid/NMP or DMAC solution is used to prepare thin films, supported adhesive tape, and impregnated unidirectional carbon fiber, carbon cloth, or other fiber/cloth substrate, and cured as described subsequently for film, powder, or composites. The amide acid oligomer is converted to the imide oligomer by adding sufficient toluene or o-xylene to the solution, followed by azeotropic distillation of water in a Dean-Stark trap overnight in nitrogen. The imide oligomers typically precipitate during this imidization process. The

pale yellow powder is isolated by adding the reaction mixture to water, filtering, and washing with water and then methanol. It is dried at 200 °C (390 °F) in air to constant weight. This yellow imide oligomer powder can be used to mold polyimide specimens.

Cross-linked Phenylethynyl-Containing Polyimides (Ref 13, 14, 81). Final cure of phenylethynyl-containing imide oligomers occurs about 370 °C (700 °F) over a 1 to 2 h period. The mechanism of the cure process is not completely understood, but it is believed that the major cure reaction is the ethynyl-to-ethynyl reaction to form double bonds or polyene structures (chain extension) (Fig. 8) (Ref 97, 98, 99).

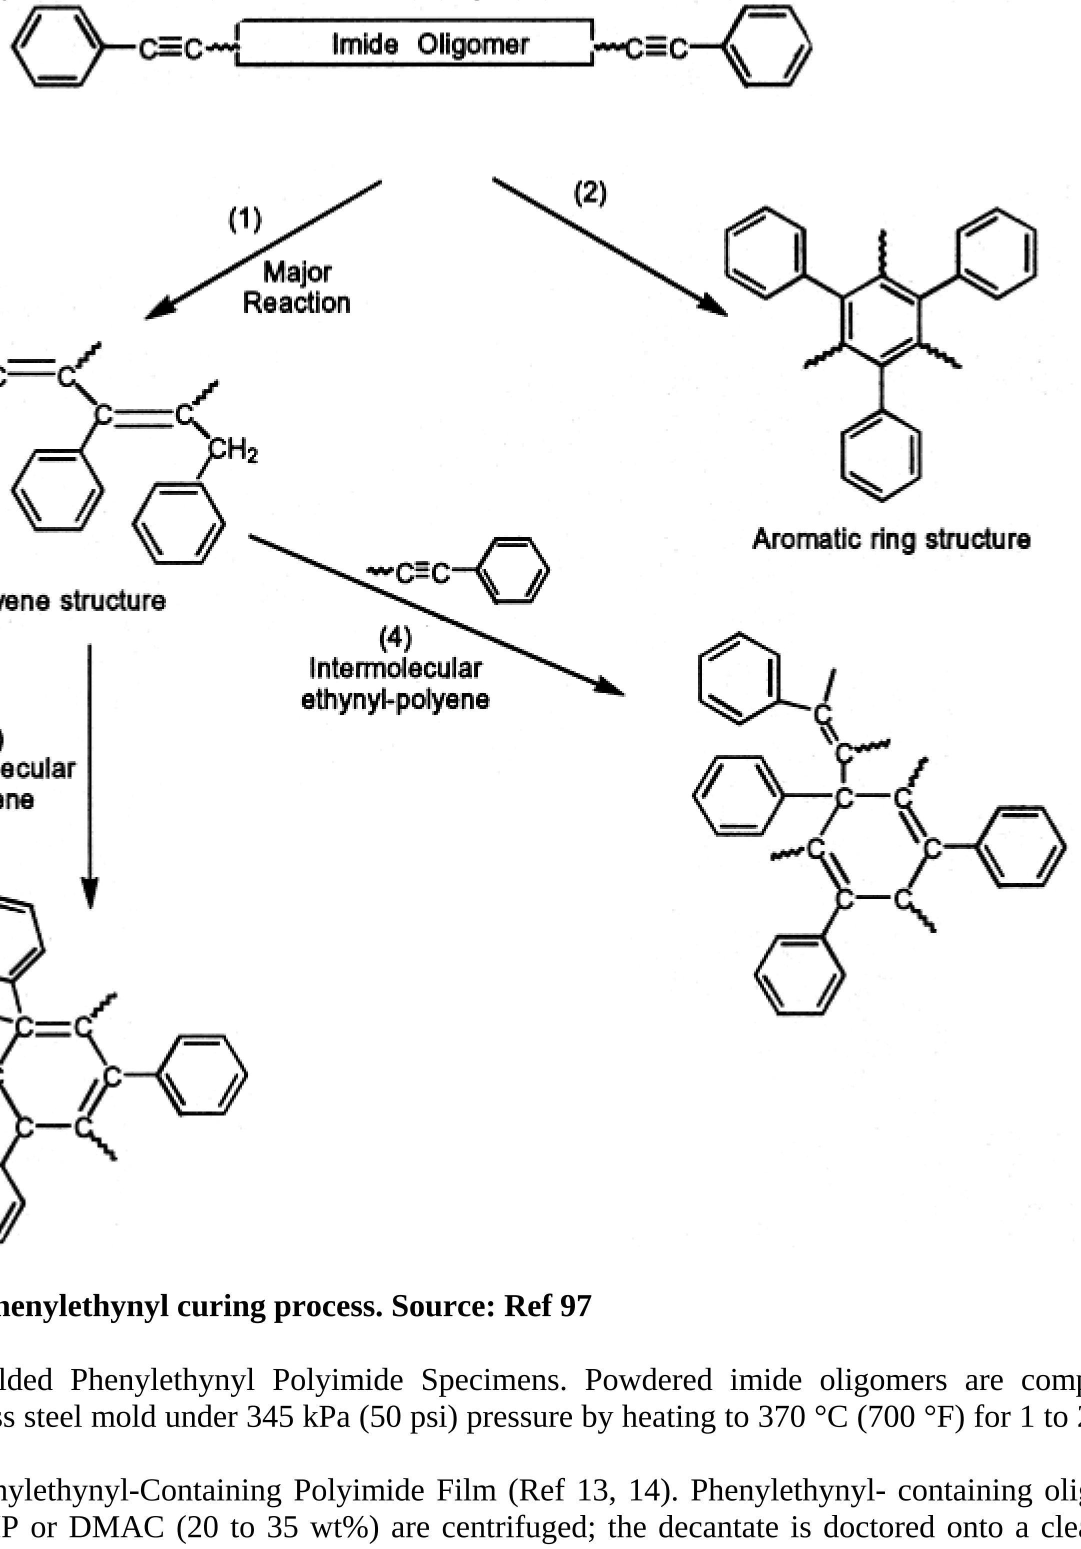

Fig. 8 Proposed phenylethynyl curing process. Source: Ref 97

Fabrication of Molded Phenylethynyl Polyimide Specimens. Powdered imide oligomers are compression molded in a stainless steel mold under 345 kPa (50 psi) pressure by heating to 370 °C (700 °F) for 1 to 2 h (Ref 13, 14).

Preparation of Phenylethynyl-Containing Polyimide Film (Ref 13, 14). Phenylethynyl- containing oligomeric amide acids in NMP or DMAC (20 to 35 wt%) are centrifuged; the decantate is doctored onto a clean plate glass surface and dried to a tack-free surface in 80 °C (175 °F) in a vacuum for 4 h or at 80 °C (175 °F) in an oven in nitrogen for 24 h. The films on glass are imidized by heating at 100, 225, 300, and 370 °C (210, 435, 570, and 700 °F) for 1 h at each temperature. The film is removed by immersion in warm water.

Constituent Properties of Phenylethynyl- Containing Polyimides (Ref 13, 14). The effect of molecular weight of PETI oligomers and cured polymer on inherent viscosity, T_g, and imide minimum melt viscosity is shown in

Table 12. As expected, the inherent viscosities and T_gs for uncured oligomer and imide minimum melt viscosity increase with molecular weight. The T_gs of the cured oligomer are higher for the lower-molecular-weight oligomer, presumably due to higher cross-link density. The tensile properties, neat resin fracture, and adhesive properties of the various PETIs are shown in Table 13. The PE end-capped material with calculated molecular weight 5000 g/mol, PETI-5, was selected for extensive evaluation in composites.

The properties of cured phenylethynyl-containing polymers, comparing terminal (PETI-5), pendant (PPEI), and pendant/terminal (PTPEI) each with a calculated molecular weight of 5000 g/mol, are shown in Tables 14 and 15. PETI-5 has the lowest cured T_g and also the lowest melt viscosity, as expected. The best material, from a processing view, is PETI-5. The tensile properties of unoriented thin films of these same polymers are shown in Table 15. As expected, the PPEI (pendant) and PTPEI (pendant/terminal) polymers demonstrate the best tensile properties at 175 °C (350 °F).

Nadic End-Capped Polyimides

Nadic end-capped polyimides, also called reverse Diels-Alder polyimides (Ref 100, 101) and represented by PMR-15 and RP-46, not only undergo the amidation and imidization reactions to form a low-molecular-weight oligomer typical of condensation polyimides, but also undergo an irreversible Diels-Alder reaction leading to a high-molecular-weight cross- linked polyimide. Processing of this resin is further complicated by isomerization of the endo-nadic end-capped imide oligomer to the exo-isomer (Ref 102, 103). These latter two reactions distinguish the RDA addition-type polyimides from the condensation polyimides.

The first process step is amide formation, which occurs between room temperature and 150 °C (300 °F) (Fig. 9). In the second step, imidization occurs over a temperature range of 150 to ≥250 °C (300 to ≥480 °F). Simultaneously, in the temperature range of 175 to 260 °C (350 to 500 °F), isomerization of the endo- isomer to the exo-isomer occurs (Fig. 10) (Ref 102, 103). Finally, in the fourth step, an irreversible Diels-Alder reaction of the endo/exo- oligomers occurs, yielding the reactive intermediates cyclopentadiene and bismaleimide oligomers (Fig. 11). These recombine to form a stable cross-linked polyimide. The critical steps in the processing of this polyimide are the removal of residual by-products due to the imidization reaction and the removal of low-molecular-weight components formed during the various process steps.

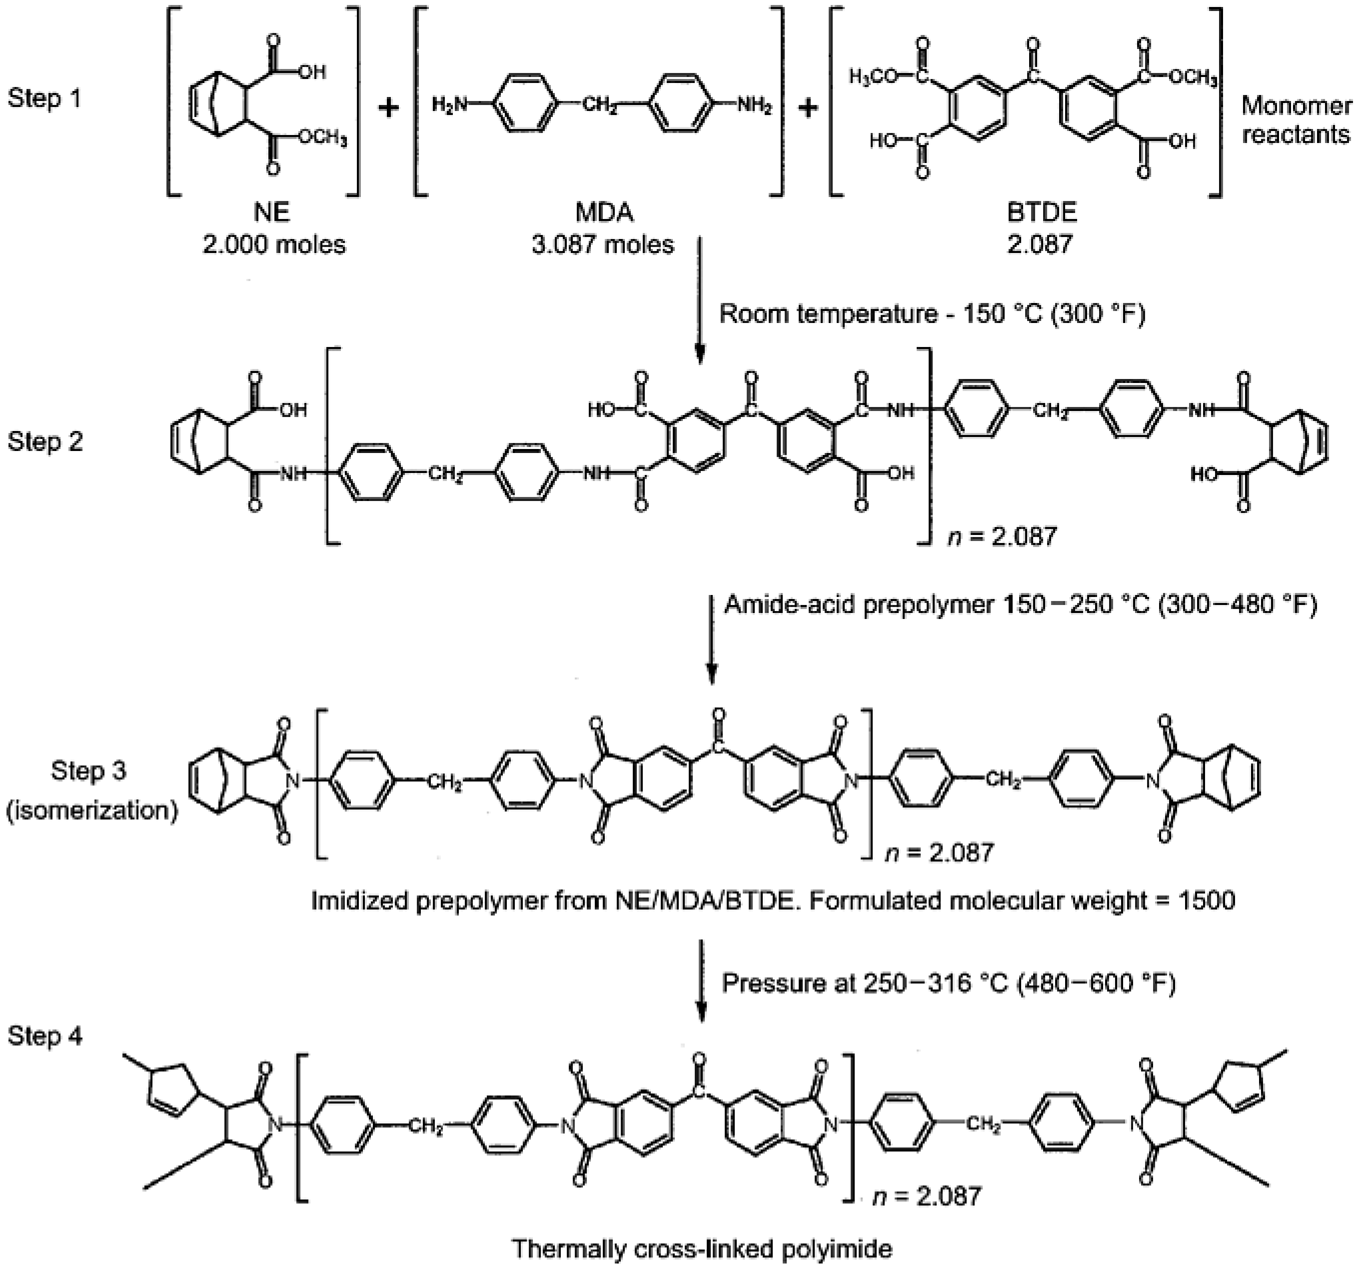

Fig. 9 General reaction scheme for PMR-15 reverse Diels-Alder polyimide. NE, monomethyl ester of nadic anhydride; MDA, 4,4′-methylene dianiline; BTDE, diethyl ester of 3,3′,4,4′-benzophenone tetracarboxylic acid dianhydride. Source: Ref 100, 101

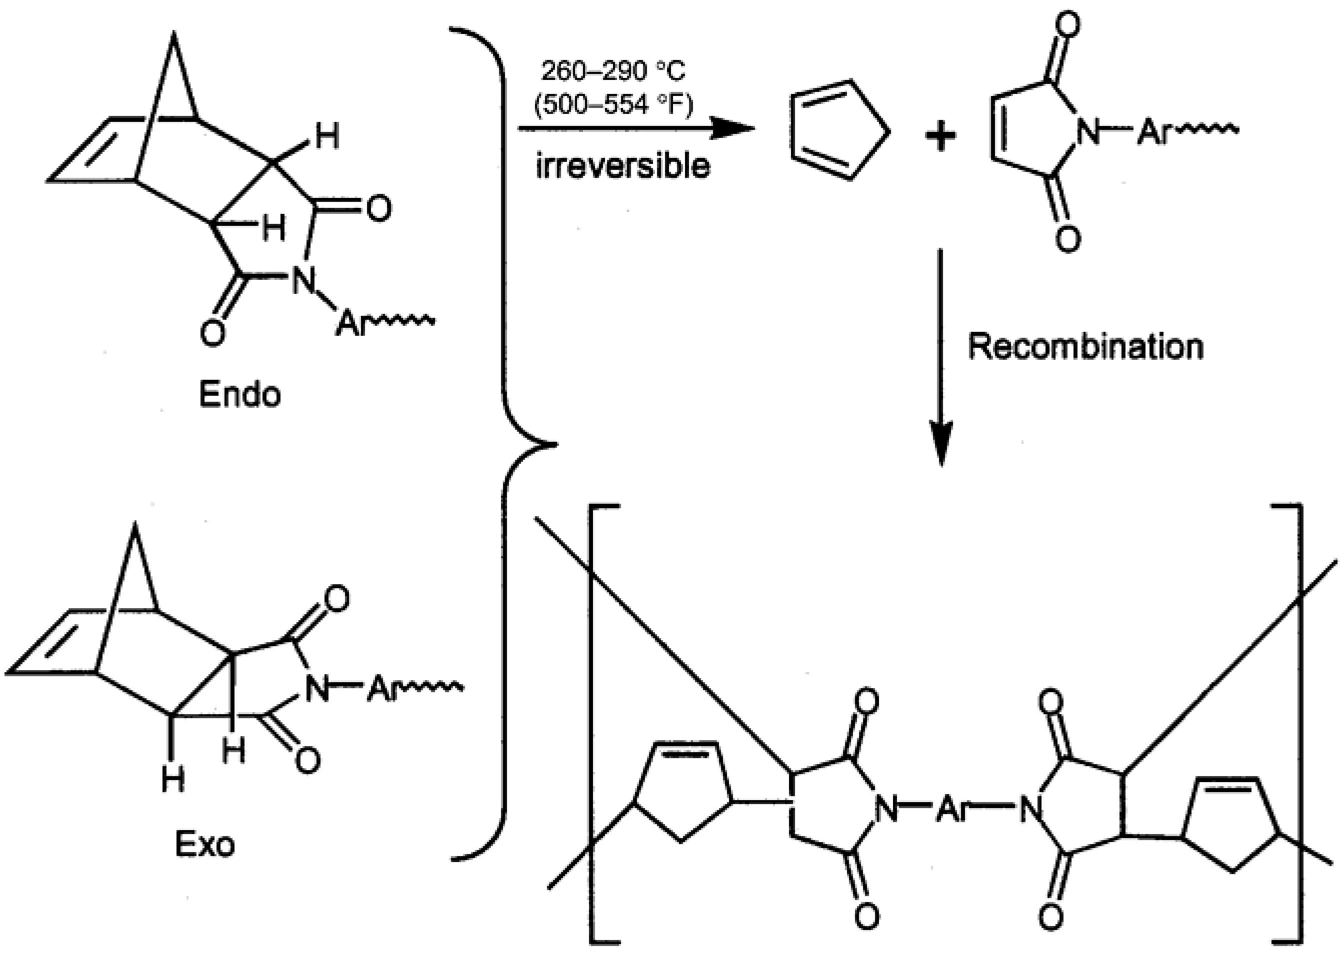

Fig. 11 Reverse Diels-Alder reaction during cure. Source: Ref 104, 105, 106, 107, 108, 109

It should be noted that the cross-linking mechanism for PMR-15 and other related addition polyimides, such as RP-46 and PN-modified PMR polyimide, remains controversial. There are at least three mechanisms that have been proposed in the literature (104, 105, 106, 107, 108, 109). The cross-linking mechanism of PMR-15 described in this article represents just one of these mechanisms.

LARC RP46. LARC RP46 polyimide was developed (Ref 61) as an alternative to PMR-15, because the diamine in PMR-15,4,4′-methylenedianiline (4,4′-MDA) is carcinogenic. LARC RP46 substitutes 3,4′-oxydianiline (3,4′- ODA) for 4,4′-MDA to form a nontoxic nadic, end-capped PMR system, although the mutagenic and carcinogenic effects of this material are unknown. This material has essentially equivalent mechanical property characteristics to PMR-15 in graphite composites, but constituent properties of the neat resin have not been reported. The chemistry of this material is similar to that for PMR-15.

Other Addition-Type Polyimides. There are several other nadic end-capped polyimides similar to PMR-15, but different in the monomer composition and stoichiometry. However, the chemistry of these materials is similar.

PMR-II-30 and PMR-II-50 are examples. The molecular structures are shown in Fig. 4. AFR 700B and Superimide 800 are end-capped with nadic groups on one end of the oligomer chain. These materials differ from PMR-15 in composition and end-cap stoichiometry, and therefore the cross-linking mechanism is more complex than in PMR-15. The structures of these materials are also shown in Fig. 4. In addition to the nadic end-capped materials, the vinyl end-capped PMRs are also available. The ends of this imide oligomer are bonded to vinyl groups. This material cross links by a simple vinyl addition to give a saturated hydrocarbon cross-linked structure. The structure of this material is shown in Fig. 4.

Polyimide Resins

Daniel A. Scola, University of Connecticut

Preparation of Nadic End-Capped Amic Acid Oligomer Resin Solutions

PMR-15 Polyimide. The prepolymer composition of this material consists of three monomers: monomethyl ester of 5-norbornene-2, 3- dicarboxylic acid; dimethyl ester of 3,3′, 4,4′-benzophenone tetracarboxylic acid, and 4,4′-methylene dianiline, in the mole ratio of 2:2.087:3.087 (Ref 100, 101). These monomers undergo a reaction to yield PMR-15 polyimide (Fig. 9).

The idealized structure of the imide oligomer resulting from thermal treatment of this monomer mixture (free of solvent), as well as the molecular weight of each segment of the oligomer, is shown in Fig. 12. The theoretical empirical formula for this oligomer, where *n*= 2.087, is $C_{93.61}H_{59.392}N_{6.174}O_{14.435}$, yielding a molecular weight of 1501.56. Dimethyl ester of 5-norbornene 1,2-dicarboxylic acid (13.285 g, 0.0677 mol) is added to a methanol solution of benzophenone tetracarboxylic acid dimethyl ester (BTDE) (60 wt%) (27.296 g, 0.0766 mol), while stirring at room temperature. The diamine (4,4′- MDA, 20.460 g, 0.10319 mol) is then added to the ester solution. The solution is stirred at room temperature until the diamine dissolves. This resin solution can be used to impregnate glass, carbon, or other cloth materials, as well as to impregnate fiber tows to form unidirectional fiber/resin tape. The resin solution can be used to form films or resin powder.

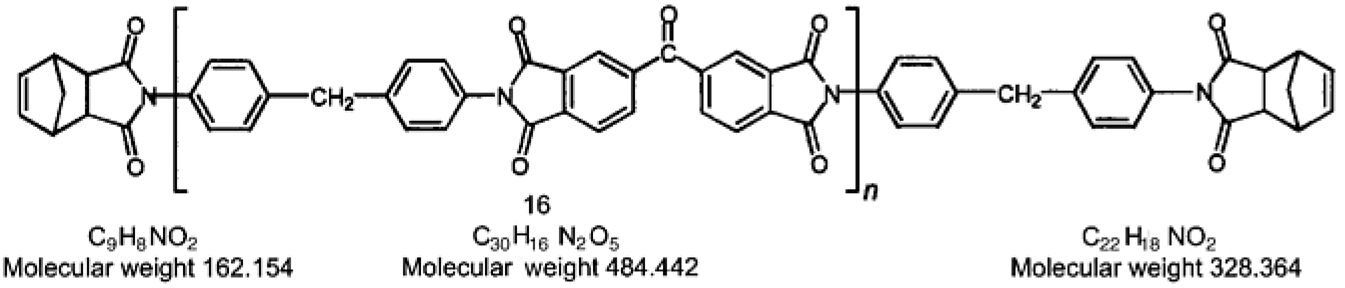

Fig. 12 Idealized PMR-15 structure

Preparation of Resin Powder and Resin Discs. The PMR-15 resin solution is allowed to concentrate at room temperature to a viscous oil. The solution is dried at 60 °C (140 °F) in vacuum for 2 h to a solid foam. The foam is ground to a powder and thermally treated at 125 °C (255 °F) for 1 h and 200 °C (390 °F) for 1 h and 250 °C (480 °F) for 1.5 h to form an imidized oligomer. Resin discs are fabricated by placing the imidized

powder (about 5.0 g) in a 25 mm (1 in.) diam stainless steel mold. The mold is placed in a preheated press (150 °C, or 300 °F). The temperature is raised to 200 °C (390 °F) at 5 °C/min at contact pressure, then a pressure of 28 MPa (4000 psi) is applied at temperature and held for 10 minutes. The temperature is raised to 250 °C (480 °F) at 2 °C (3.5 °F)/min, 4000 psi, held for 10 minutes, and then the pressure is released and reapplied. The temperature is raised to 315 °C (600 °F) at 2 °C/min, 4000 psi, and held for 1 h. The mold is cooled to 275 °C (525 °F) and the pressure is released. The resin disc is removed and postcured at 315 °C (600 °F) for 16 h in the free state or at a higher temperature to increase the glass transition temperature and thermo-oxidative stability. Greater stability is generated when the material is postcured at 370 °C (700 °F) for 24 h.

Preparation of Adhesive Film. The PMR-15 resin solution, prepared as described previously, is brushed onto glass scrim cloth, and the solvent is allowed to evaporate to produce a tacky film. The process is repeated until sufficient resin is deposited on the scrim cloth to give a finished adhesive bond thickness of about 0.13 mm (0.005 in.).

Preparation of Adhesive Bond Specimens. The impregnated glass scrim cloth is cut to the dimensions required for bonding. The cut adhesive scrim cloth is placed on one of the surface- treated specimens to be bonded. The other part of the specimen to be bonded is placed on the adhesive specimen. The bond specimen is placed in a specially designed tool to maintain dimensions of the bonded area. It is placed in a vacuum bag or autoclave, the temperature is raised to 275 °C (525 °F) at 2 °C/min, pressure is applied (700 kPa, or 100 psi), and then the temperature is raised to 315 °C (600 °F) at 100 psi and held for 1 h under these conditions.

Preparation of Films. The PMR-15 resin solution is filtered, the solution is doctored onto a clean plate glass surface, and dried to a tack-free surface at 80 °C (175 °F) in a vacuum. The film is then cured at 150 °C (300 °F) for 1h + 200 °C (390 °F) for 1 h + 250 °C (480 °F) for 1 h + 275 °C (525 °F) for 1 h + 316 °C (600 °F) for 1 h. The film is removed by immersion in warm water.

Polyimide Resins

Daniel A. Scola, University of Connecticut

Constituent Properties of PMR-15

PMR-15 is extremely resistant to most organic solvents, including aliphatic hydrocarbons, ether, ketones, aromatic hydrocarbons, and chlorinated aliphatic and aromatic hydrocarbons. It is hydrolyzed in strong acids and strong bases, including aqueous hydrazine solutions, at elevated temperatures. The constituent materials properties are listed in Table 16.

Table 16 Constituent properties of PMR- 15 polyimide

Property	PMR-15 polyimide
Density, g/cm^3	1.32[(a)]
Glass transition temperature (T_g), °C (°F)	
After 16 h at 316 °C (600 °F)	340 (662)[(a)]
After 1 h at 316 °C (600 °F)	320 (680)
Morphology	Amorphous, cross-linked

Tensile strength (dry) at room temperature, MPa (ksi)	8.6 (5.6)[b]
Tensile modulus (dry) at room temperature, GPa (10^6 psi)	39 (0.57)
Tensile strain-to-failure, %	1.1
Flexural strength (dry), MPa (ksi)	
At room temperature	176 (25.5)[c]
At 288 °C (550 °F)	73 (10.7)[c]
At 316 °C (600 °F)	72 (10.4)[c]
At 343 °C (650 °F)	52 (7.6)[c]
Flexural modulus (dry), GPa (10^6 psi)	
At room temperature	4.0 (0.58)[c]
At 288 °C (550 °F)	2.3 (0.34)[c]
At 316 °C (600 °F)	1.9 (0.27)[c]
At 343 °C (650 °F)	1.8 (0.26)[c]
Fracture toughness	
K_{Ic}, MPa$\sqrt{m}$(ksi$\sqrt{in.}$)	1110 (1010)[d]
	648 (590)[e]
G_{Ic}, J/m^2 (ft · lbf/in.^{2})	280 (1.6)[d]
	94 (0.52)[e]
Izod impact strength, notched, J/m (ft · lbf/in.)	53.37 (1.0)
Equilibrium moisture absorption[e] at 95% relative humidity and 71 °C (160 °F), wt%	4.2
Weight loss, %, at 288 °C (550 °F) in flowing air (100 cm^3/min, or 6 in.^{3}/min)[f]	
After 1000 h	0.3
After 2000 h	0.8
After 3000 h	2.0
Coefficient of thermal expansion[e], 10^6 K	14

Current State of the Art

In terms of commercial availability, the polyimides listed in Table 4 define the current technology. The polyimide materials listed in these tables have application as matrices for composite adhesive coating materials, film-forming materials, and electronic materials. The polyimide materials used to make these components are available as solutions, pellets, powder, adhesives films, impregnated unidirectional fiber tape or cloth, and as freestanding films. Specific polyimides are available in solution for applications in electronic applications. Most of these materials are identified only by specific company designations and not by chemical composition. The processing characteristics for each type of polyimide and their applications have been described previously.

Polyimide Resins

Daniel A. Scola, University of Connecticut

Outlook

Improvement in polyimide processability is essential for the ability to manufacture polyimide parts, such as composites, at costs competitive to other metal parts. In order to improve processability, a reduction in the melt viscosity of the polyimide material is an absolute necessity. For the long-chain high-molecular-weight, highly aromatic thermoplastic materials, such as Avimid-N, LARC-TPI, or BPDA/TFMB, this is not readily possible. Low-molecular-weight end- capped oligomers are potential candidates for the development of polyimide oligomers for improved processability. The phenylethynyl end- capped imide oligomers appear to hold considerable promise, because low viscosity versions of the phenylethynyl end-capped imide oligomers have already been developed and are being tested (Ref 89, 111). Research efforts to replace 4,4′-methylene dianiline (4,4′-MDA) in PMR- 15 with a nonmutagenic and noncarcinogenic diamine will continue both from the health viewpoint and for process improvements (Ref 112). NASA Glenn Research Center is the lead organization behind this research effort (Ref 23, 27, and 32). Therefore, the approach toward developing polyimides with improved processability without undue sacrifice of other desirable properties can be summarized as follows:

- Control of molecular weight
- Blends of low-molecular-weight, low-melting, low-viscosity, reactive phenylethynyl viscosity modifiers with phenylethynyl end- capped oligomers
- Blends of star-shaped, branched, and linear oligomers
- Design of monomers and oligomers with structured features to increase bulkiness, free volume, and prevent interchain interactions
- Change of bonding in the aromatic rings from para to a mixture of para and meta.

There is always the need to lower the dielectric constant of polyimides for application in the electronic and microelectronics industries. Several important publications deal with the influence of fluorine on the dielectric constant (Ref 9, 113, 114, 115, 116, and 117). A novel approach for reducing the dielectric constant of polyimides is the formation of nanofoam polyimides (Ref 118, 119). Basically, this approach replaces polyimide polymer with air, which has a dielectric constant of 1.00.

In addition to processing, research efforts will continue to improve thermo-oxidative stability (Ref 9, 120), improve selectivity of gas separation membranes (121, 122, 123, 124, and 125), develop proton exchange membranes (Ref 126, 127) for fuel cell applications, improve solubility (Ref 16, 128, 129, 130, and 131) for

coatings, and improve optical properties (132, 133, 134, 135, 136, 137, and 138) such as optical anisotropy (Ref 132) for liquid crystal displays. Photosensitive polyimides as photo resists for use in the field of microelectronics is of continued interest (Ref 139). The newest areas of polyimide research involve the development of nanostructured silica- polyimides (Ref 140, 141) and polyimide foam for structural and insulation applications (Ref 142, 143) for use over a temperature range of–250 to 250 °C (–420 to 480 °F).

Phenolic Resins

Shahid P. Qureshi, Georgia-Pacific Resins, Inc.

Introduction

PHENOLICS are thermosetting resins produced by the reaction of phenol or substituted phenol with an aldehyde, usually formaldehyde, in the presence of a catalyst (Ref 1). Phenolic resin composites offer superior fire resistance, excellent high-temperature performance, long- term durability, and resistance to hydrocarbon and chlorinated solvents. This article describes the chemistry of phenolic resins, reviews their characteristics and properties for various composites manufacturing processes, and discusses some representative applications.

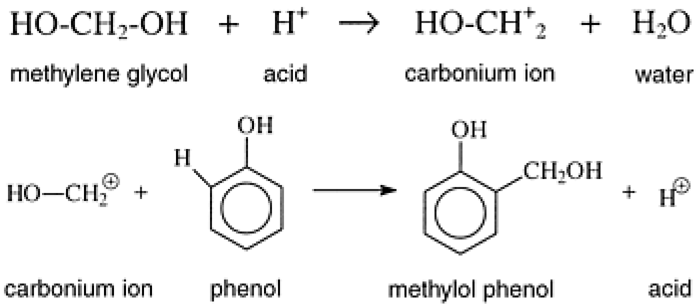
Phenolic Resins

Shahid P. Qureshi, Georgia-Pacific Resins, Inc.

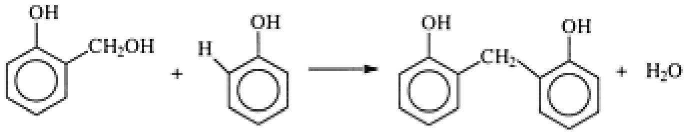
Phenolic Resin Chemistry

In the reaction of the phenol with the aldehyde, the catalyst used and the ratio of formaldehyde to phenol determines the type of resin produced. Phenolic resins based on an acid catalyst and formaldehyde-to-phenol (F/P) molar ratio of less than 0.9 to 1 are called novolacs, and those prepared from an alkaline catalyst and an F/P molar ratio of greater than 0.9:1 are known as resoles. Oxalic and sulfuric acids are used to synthesize novolacs. Aliphatic amines or hydroxides of ammonium, sodium, lithium, potassium, barium, and calcium are used to produce resoles. For both novolacs and resoles, 37–52% formaldehyde solution in water (methylene glycol, CH_2 $(OH)_2$ is commonly used.

For novolac synthesis, the initial reaction is the formation of a carbonium ion by the action of the acid catalyst on the methylene glycol; this ion then reacts with phenol to produce methylolphenol:



In an acidic medium, the methylol group is extremely unstable and will react immediately with an additional phenol or methylolated phenol to produced novolac:



methylol phenol — phenol — diphenyl methane — water

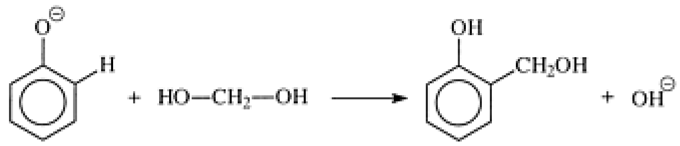
Diphenyl methane is the novolac with the lowest molecular weight. Novolacs are thermoplastic resins and require a coreactant hexamethylenetetramine (HEXA) to become thermosetting resins. The reaction requires heat.

Synthesis of base-catalyzed resole proceeds via addition of formaldehyde to phenol to produce hydroxymethyl phenols:

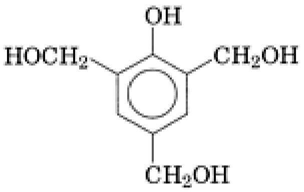
$$C_6H_5OH + NaOH \rightarrow C_6H_5O^- + Na^+ + H_2O$$

phenol — caustic — phenolic anion

This phenolic anion then reacts with the hydrated formaldehyde (methylene glycol) to produce a methylolphenol:



phenolic anion — methylene glycol — ortho methylol phenol — alkali



trimethylol phenol

Resoles contain various orthomethylol and para methylol groups, free phenol, free formaldehyde, water, and/or solvent. Resoles do not require an external catalyst and undergo self-polymerization under heat with evolution of water. The versatility of phenolic resins in a broad spectrum of market areas requires the production of novolac and resole resins in a variety of physical states, such as powder, hot melt, solvent-based, or aqueous solution resins.

Novolac powders with HEXA are commonly used in molding compounds with chopped glass and carbon fibers. Other applications include the binder in brake linings, grinding wheels, foundry molds, and general molding compounds. In more recently developed composite applications, novolac/HEXA are not used because they do not meet processing and cure requirements of composite fabrication processes.

Phenolic resole resins are commonly used in manufacturing of fiber reinforced composites. The use of phenolic resins in glass and carbon fiber composites is growing, primarily due to their low flame spread, low smoke generation, and low smoke toxicity properties (Ref 2, 3), which are achieved without the use of mineral fillers or fire retardant additives (Fig. 1 and Tables 1 and 2). In some specialty applications, the demand is increasing for high-temperature phenolics. If properly formulated and cured, phenolics perform much like high-temperature polyimides (Ref 4). Phenolics also provide excellent chemical resistance, to such compounds as chlorinated and hydrocarbon solvents (Ref 5). Interestingly, with all these superior properties, phenolics are relatively inexpensive.

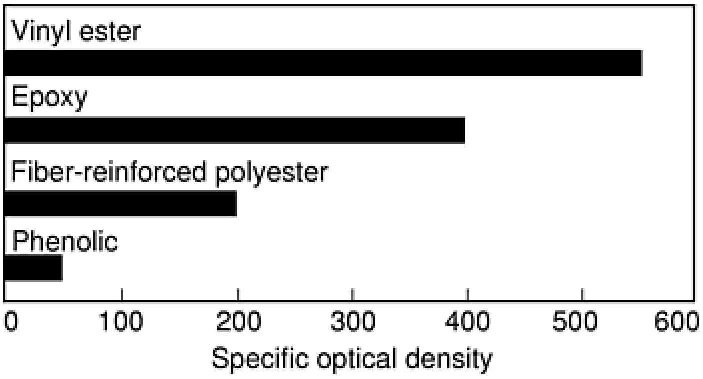


Fig. 1 Smoke optical density (ASTM E 662) comparison of selected resins

Table 1 Flame spread index and smoke density comparison of thermosetting resins (ASTM E 84 tunnel test)

Resin	Flame spread index	Smoke density
Phenolic	10	10
Halogenated polyester	15	600–800
Halogenated vinyl ester	45	600–800
Methacrylate vinyl ester with 150 phr aluminum trihydrate	20	40

phr, parts per hundred parts resin

Table 2 Pittsburgh smoke toxicity test results for selected resins

Material	LC_{50}[(a)], g
Phenolic	86.5
Unsaturated polyester	34.0
Halogenated polyester	9.1
Epoxy	23.0
Polyvinyl chloride	8–30

(a) C_{50} indicates the mass of material required to cause smoke concentration that is fatal to 50% of test animals after 30 minutes of exposure when burned at 822 °C (1510 °F). Lower values indicate greater toxicity.

In the 1980s, the Federal Aviation Administration tightened aerospace fire specifications for smoke and heat release tests. The purpose was to increase the evacuation time for passengers in airplane fires to exit safely. Glass and carbon fiber composites made with phenolic resins met these severe fire specifications. Today, phenolic composites are the material of choice for walls, ceilings, and floors of aircraft interiors (Ref 6). Since 1990, the use of phenolic resins has been gradually increasing for nonaerospace applications, which include mass transit, construction, marine, mine ducting, and offshore structures (Ref 7, 8, 9, 10, 11, 12, and 13). These areas traditionally used other resins, such as polyesters, vinyl esters, and epoxies. These resins are being replaced with phenolics for specific applications with stringent fire resistance requirements.

To participate in the growing market, phenolic resin manufacturers have responded to the current and future market needs and have tailored the resin chemistry for the following state-of- the-art fabrication processes: solution/hot-melt process, pultrusion, vacuum infusion, filament winding, sheet molding, and hand lay-up (Ref 5, 13, 14, and 15). Typical viscosity and cure characteristics of phenolic resins for these processes are summarized in Table 3.

Table 3 Phenolic resins for composites

Composites manufacturing process	Resin type (solvent)[a]	Viscosity at 25 °C (77 °F)		Catalyst	Cure temperature	
		Pa · s	cP		°C	°F
Filament winding	PF (water)	0.5–2.0	500–2,000	Acid	65–95	150–200
	PRF (water/alcohol)	0.5–2.0	500–2,000	Formaldehyde	25–65	75–150
Hand lay-up	PF (water)	0.5–2.0	500–2,000	Acid	25–80	75–180
Pultrusion	PF (water)	2.0–10.0	2,000–10,000	Base	165–245	325–475
	PRF (water/alcohol)	2.0–10.0	2,000–10,000	Formaldehyde	165–245	325–475
Sheet molding and bulk molding	PF (water)	1.0–2.0	1,000–2,000	Base	150–175	300–350
Solution	PF (water/alcohol)	0.3–1.0	300–1,000	Base/neutral	120–175	250–350
Hot melt	PF (water)	50–100	50,000–100,000	Base/neutral	120–175	250–350
Honeycomb	PF (water/alcohol)	0.5–1.0	500–1,000	Base/neutral	120–175	250–350

(a) PF, phenol formaldehyde; PRF, phenol resorcinal formaldehyde

Further details on fabrication processes, phenolic technology, and recent applications for phenolic composites are detailed below.

Phenolic Resins

Shahid P. Qureshi, Georgia-Pacific Resins, Inc.

Phenolic Prepregs

The solution process involves impregnation of unidirectional fiber, woven fabric, or nonwoven fabric with phenolic resin having viscosity from 0.3–1.0 Pa · s (300–1000 cP) at 25 °C (77 °F) with 40–75% solids. Methanol, ethanol, isopropanol, and ketones are common solvents. For the solution process, the substrate is passed through a resin-containing bath and then into a heated vertical or horizontal tower for removal of solvent and water and B-staging. Process parameters are adjusted to achieve desired combination of flow, resin content, tack, and volatiles. The treated material, called *prepreg*, is rolled for storage and shipping. Phenolic prepregs offer significantly longer storage life than epoxy prepregs due to the nature of the phenolic chemistry. Prepregs are cured under heat (120–175 °C, or 250–350 °F) and pressure (345–3450 kPa, or 50–500 psi) to prepare laminates. Manufacturers of phenolic prepregs are Cytec-Fiberite, M.C. Gill, Hexcel, J.D. Lincoln, Lewcott Corporation, and Aerocell.

Conventional applications of solution-based thermal cured phenolic composites are in ballistic components. Typical properties are summarized in Table 4 (Ref 5). The composites are prepared with unmodified resin (Borden SC1008, GP 445D05) and polyvinyl butyral and with woven fabric of aramid, S-glass, or ultra-high molecular weight polyethylene. The composites are used in helmets, land vehicles, and military aircraft. Other traditional applications of solution prepreg include a carbon-carbon composite. The phenolic/carbon fiber prepreg is cured and carbonized to achieve carbon-carbon composite (Ref 16). These composites are used when high temperature performance is critical; current applications include rocket motors, aerospace engine components, aircraft brakes, and racing car brakes.

Table 4 Properties of phenolic prepreg resins and composites

Property	Value
Flexural strength (ASTM D 790), MPa (ksi)	620–690 (90–100)
Flexural modulus (ASTM D 790), GPa (10^6 psi)	28–31 (4.0–4.5)
Tensile strength (ASTM D 638), MPa (ksi)	415–485 (60–70)
Compressive strength (ASTM D 695), MPa (ksi)	485–620 (70–90)
OSU heat release (ASTM E 906)	
At 2 min, kW · min/m^2	15
At peak, kW/m^2	30

NBS maximum smoke density (ASTM F 814)	15 (max)

Composite: 14-ply, 7781 glass, 30–32% resin, cured at 175 °C (350 °F) for 1 h at 1380 kPa (200 psi).

Phenolic Honeycomb

Phenolic prepregs based on carbon, aramid, or glass fibers are used as face sheets on Nomex honeycomb to construct sandwich panels for aerospace applications such as cargo liners, walls, galleys, ceilings, and floors. The sandwich panel structure is selected due to its high strength-to-weight ratio. For densification, Nomex honeycomb is also treated with either solvent or waterborne phenolic resole resins (Ref 17). There is no alternate resin that meets the adhesion, low flammability, and processing requirements of Nomex honeycomb. For aerospace honeycomb applications, the honeycomb phenolic resin should meet requirements, such as those specified in MIL-R-9299C (now cancelled). This spe cification calls for the extensive evaluation of mechanical properties at room temperature and at 260 °C (500 °F). Several commercial resins, such as SC1008 (Borden) and GP 5236, GP 445D05, and GP 307T35 (Georgia- Pacific), have achieved the requirements outlined in this specification. Compressive, tensile, and flexural properties of phenolic/glass laminates (containing at least 14 plies) meet MIL-R- 9299C specification requirements and are similar to those reported for epoxy and polyester composites (Ref 18 and 19). Sandwich panels based on Nomex honeycomb, prepreg face sheets, and Tedlar (polyvinyl fluoride) decorative film have been used for ceilings and side walls of aircraft interiors (Boeing 8-222 specification).

The honeycomb manufacturing process is shown in Fig. 2. An aramid paper is used to manufacture untreated honeycomb. The honeycomb is coated with multiple layers of phenolic resin for densification of the honeycomb core. By using face sheets of phenolic composite for epoxy composites with a honeycomb core, the highest strength-to-weight and stiffness-to-weight ratios for many configurations can be obtained. Key aerospace requirements for the panels are low heat release, low smoke, and high peel strength (adhesion of cured prepreg to Nomex). For aircraft interiors, strength and flammability requirements continue to increase, and modified phenolics that achieve higher peel strength and maintain the flammability behavior of phenolics have been developed (Ref 6).

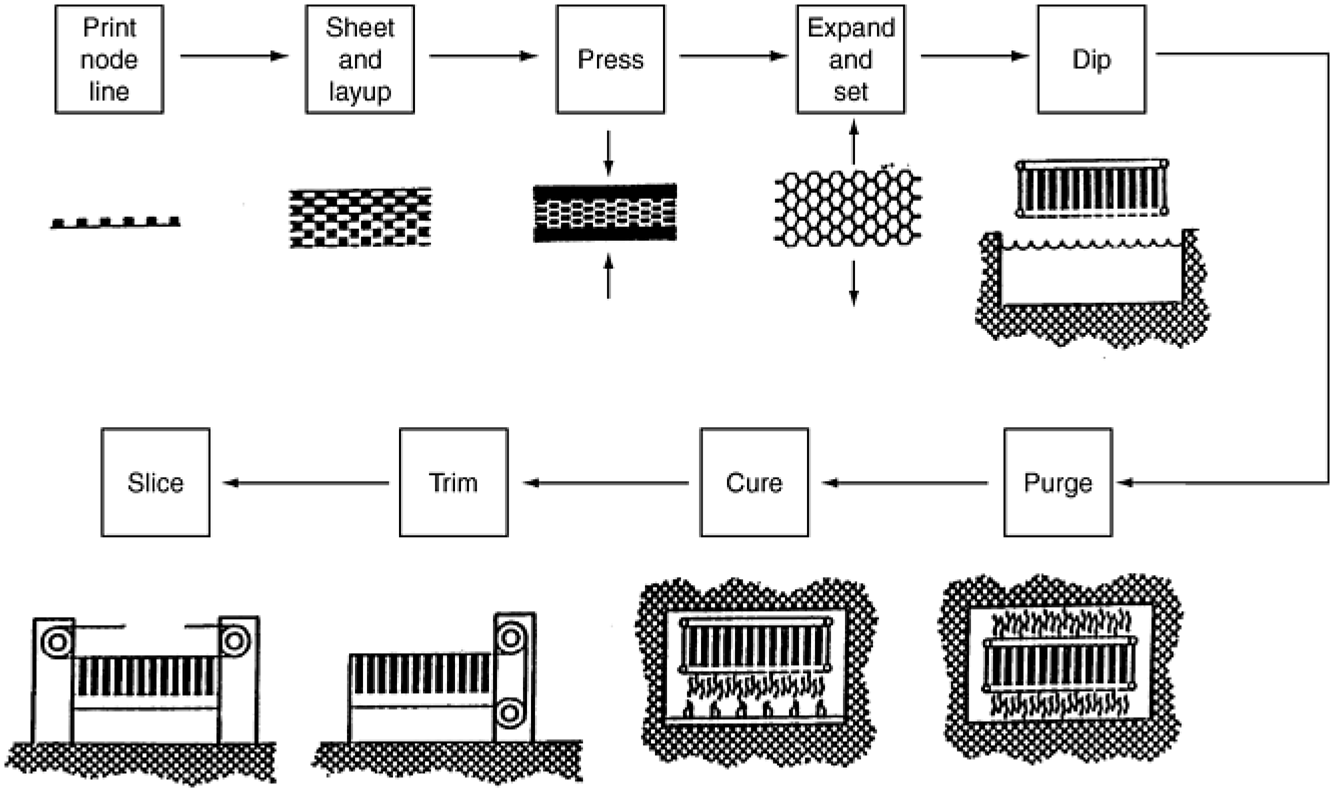

Fig. 2 Honeycomb manufacturing process

The following two prepreg products are commercially available: SP-2400 (Ref 6), which was developed for Boeing 8-226 specification, and Bakelite epoxy-modified phenolic (Ref 20 and 21), which is used for floors of the Airbus 340. Three Boeing specifications are summarized in Table 5.

Table 5 Boeing phenolic prepreg specification requirements for aircraft interior structures

Property	Sandwich panels and laminates (BMS 8-226)	Crushed core glass fiber (BMS 8-222)	Crushed core graphite fiber (BMS 8-274)
NBS maximum smoke density at 4 min	20 max	20 max	20 max
OSU heat release			
At 2 min, kW · min/m²	30–65	65	30–65
At peak, kW/m²	45–65	65	45–65
Peel strength in 76 mm (3 in.) width, N/m (lbf/in.)	1750 (10)	1050–1750 (6–10)	875–1225 (5–7)
Flexural strength, MPa (ksi)	61–138 (8.8–20.0)	83–110 (12.0–16.0)	124–143 (18.0–20.7)

The sandwich panels are also used in California's Bay Area Rapid Transit (BART) subway cars. Until 1979, BART passenger subway cars had relatively lenient flame spread and smoke specification requirements. A fire broke out onboard a BART subway train in the Transbay Tunnel, killing a fireman and injuring 46 passengers. As a result of this tragedy, the California Public Utility Commission ordered BART to use phenolic composites for ceilings, sidewalls, and endwalls (Ref 22).

Phenolic Resins

Shahid P. Qureshi, Georgia-Pacific Resins, Inc.

Phenolic Pultrusion

Pultrusion is a cost-effective process that provides composites on a continuous basis. Fibers are pulled through a resin bath and then through the heated die. At the end of the die, sufficiently cured and rigid composite is pulled and cut to desired length. The most commonly used resins are unsaturated polyesters and vinyl esters with peroxide catalysts; these composites are useful in marine applications, power transmission, and construction. Phenolic resole resins are used to manufacture pultruded composites when low flammability is needed. Thermal-cured (without an external catalyst) and formaldehyde-cured resorcinol resins have been successfully converted to pultruded composites. Phenolic resins with viscosity of 2–10 Pa · s (2,000–10,000 cP) and 68 to 75% solids have been processed through the pultrusion equipment (Ref 10, 13, and 23). The viscosity range desired for the process is achieved through residual water, phenol monomer, and/or ethanol. Due to low viscosity, fillers (clay, zinc borate, and/or aluminum trihydrate) at the 10 to 20% level can be used to obtain a smooth surface. Compared to polyesters, phenolic pultruded parts contain higher fiber volume (due to solvent loss and to counteract the inherent brittleness of phenolics); however, the mechanical properties are similar (Ref 10). Mechanical properties of phenolic and polyester pultruded composites are compared in Table 6 (Ref 10).

Table 6 Properties of glass-fiber- reinforced phenolic and polyester pultruded composites

Property	Phenolic	Polyester
Tensile strength, MPa (ksi)	310 (45)	483 (70)
Flexural strength, MPa (ksi)	359 (52)	607 (88)
Compressive strength, MPa (ksi)	352 (51)	310 (45)

Source: Ref 10

In the phenolic pultrusion process, Strongwell has conducted extensive research and has manufactured phenolic grating for offshore oil platforms. The grating can withstand direct flame contact without major structural damage. Also, it has low thermal conductivity and the strength of steel grating at a lighter weight than steel. Phenolic grating can withstand 1.75 times the load of equivalent steel grating. This combination of properties

was not available with alternate organic matrix materials. Therefore, phenolic grating has replaced steel grating at several offshore oil platforms.

For these first commercial applications of phenolic grating, glass fiber and mold release suppliers have developed phenolic-compatible mat, roving, and mold release chemicals. Phenolic resins from Georgia-Pacific and Borden Chemical have been qualified (Ref 14 and 23) for the grating applications. Research work continues (Ref 23, 24, and 25) to improve the strength and toughness of phenolic pultruded composites to extend their applications into structural areas such as walkways, decking for tunnels/mass transit, and automotive, aircraft, and marine structures. To extend into structural applications, toughened phenolic resin technology is needed. The market requirements are faster line speeds and at least 20% higher strength than the first-generation products. In this area, the line speed has been improved from 25–76 cm/min (10–30 in./min) (Ref 25), and a 20% improvement in strength has been achieved (Table 7).

Table 7 Properties of catalyzed phenolic pultruded composites

Property	Latent base catalyst, phr[(b)]		
	0	**5**	**10**
Line speed, cm/min (in./min)	76 (30)	76 (30)	76 (30)
Glass-transition temperature (T_g), max[(a)], °C (°F)	308 (586)	326 (619)	335 (635)
Flexural strength, MPa (ksi)	403 (58.5)	417 (60.5)	481 (69.8)
Flexural modulus, GPa (10^6 psi)	14.8 (2.14)	16.1 (2.33)	16.5 (2.39)
Short beam shear strength, MPa (ksi)	24.8 (3.6)	25.5 (3.7)	29.0 (4.2)

Pultruded bar, 64 × 3 mm (2.5 × 1/8 in.). Pultrusion temperature conditions: zone 1, 205 °C (400 °F); zone 2, 230 °C (450 °F); zone 3, 245 °C (475 °F). Fiber roving, Johns Manville 507AA-13; mat, CertainTeed Uniflo U528.

Phenolic Resins

Shahid P. Qureshi, Georgia-Pacific Resins, Inc.

Phenolic Filament Winding

Filament winding of phenolics has been well established in the industry. Phenol-formaldehyde resins with an acid catalyst and resorcinol resins with paraformaldehyde catalyst are currently used. The process of filament winding with phenolic systems is little different in principle from winding with other systems such as vinyl esters, polyesters, and epoxies. The processing requirements include the following:

- Resin viscosity of 0.5–2.0 Pa · s (500–2000 cP)
- Pot life for resin/catalyst mixture must be greater than 30 min
- Gel time at 80 °C (180 °F) must be 90–150 s
- Cure temperature must be 65–95 °C (150–200°F)

Resin manufacturers have developed latent acids for filament winding phenolic resin (Ref 13, 26, 27, and 28). The latent catalyst gives pot lives equal to those of polyester mixes, while maintaining the cure speed required by fabricators. After a 50–80 °C (120–180 °F) cure, filament- wound pipes give adequate strength and dimensional stability and glass-transition temperatures (T_g) from 95–150 °C (200–300 °F). If a higher T_g is needed, the pipes are removed from the mandrel and then post-cured for T_g improvement. Table 8 shows the T_g development with cure of a filament-wound pipe (Ref 29).

Table 8 Flexural properties and glass- transition temperatures for filament-wound pipes

Property	Polyester	Latent acid cured phenolic
Resin content, %	43.1	38.7
Flexural strength, MPa (ksi)	460 (66.7)	386 (56.0)
Flexural modulus, GPa (10^6 psi)	10.5 (1.53)	15.9 (2.3)
Glass-transition temperature (T_g),°C (°F)	120 (250)	120 (250)
After postcure[(a)]	130 (270)	155 (310)
After postcure[(b)]	135 (275)	205 (400)
After postcure[(c)]	140 (280)	230 (450)

(a) 30 min at 150 °C (300 °F).

(b) 30 min at 150 °C (300 °F) + 30 min at 175 °C (350 °F).

(c) 30 min at 150 °C (300 °F) + 30 min at 175 °C (350 °F) + 30 min at 205 °C (400 °F)

Due to superior fire resistance, phenol-formaldehyde-based filament-wound composites are currently being used for ventilation ducting in mining and tunneling. Applications include such projects as the Channel Tunnel and the Thames Water London Ring Main. The pipes are used in mining to carry methane. Besides being fire safe, they are extremely light to handle (approximately a quarter of the weight of steel), and the installation rates are up to six times faster than those for the equivalent steel pipe. Phenol- resorcinol-formaldehyde resins have been used since the 1980s in Factory Mutual clean room ducting applications (Fig. 3) (30, 31).

Fig. 3 Factory Mutual filament-wound phenolic ducting. Courtesy of Composites USA

Filament wound phenolic composites are being used for offshore oil platform water piping systems. The state-of-the-art technology is based on a filament wound epoxy resin system. To meet the severe fire requirements, the epoxy pipes required a thick layer of intumescent coating. To eliminate this labor intensive and costly procedure, Ameron Fiberglass Pipe Group developed phenolic pipes that have passed the fire and high-temperature tests without the intumescent coating. The filament-wound pipe, based on a polysiloxane-modified phenolic system, demonstrated higher mechanical properties and improved weathering resistance than the pipes without the siloxane modification (Ref 32). The piping system (pipes, joints, and adhesives) under jet fire certification must withstand 5 minutes of exposure in dry state, followed by 15 minutes of exposure, filled with flowing water at 1000 kPa (10 bar) pressure. The piping system will not only survive a fire, but will also deliver pressurized water where it is needed at the critical times.

For protection of damaged utility and transmission poles, PoleCare Industries, a subsidiary of Chemical Specialties, Inc., has wrapped the poles with latent-acid-cured phenolic resin and glass fabric composites. This approach is more cost-effective than replacing the pole, due to the complexity of the system supported by the pole. Repaired phenolic-wrapped poles perform better than new ones. The composite wrap increases strength, and the fire resistance is an advantage for farming areas, where fields are burned off, and in regions such as California, where wildfires are a continual threat. The long-term durability of the phenolic-wrapped pole is currently being monitored by nondestructive tests. After five years in the field, the wrapped poles show no apparent degradation in performance or durability (Ref 5).

Phenolic Sheet Molding Compounds

The use of phenolics for sheet molding compounds (SMC) has been researched since the 1980s (Ref 33). The technology challenge was to match resin viscosity, handling, and cure properties of the polyester SMC to avoid any special processing and equipment adjustments for fabricators and end users. Both acid-catalyzed and base-catalyzed phenolics have been investigated. An acid-catalyzed system is not acceptable due to corrosion of the existing polyester molds. For SMC processes, resin requirements are low viscosity (greater than 1.5 Pa · s, or 1500 cP, at 25 °C, or 77 °F), high solids (less than 75%), and minimal levels of monomers (phenol, formaldehyde) and solvents (water, alcohol). A typical SMC composition is shown in Table 9. The SMC product is aged/matured to achieve desired release and flow for molding. The maturation time depends on the level and type of catalysts. Recently, latent-based catalysts were found effective in reducing the maturation time without any reduction in shelf life of the matured SMC.

Table 9 Typical composition of a phenolic sheet molding compound

Material	Content, parts by weight
Phenolic resin (GP 652D58)	100.0
Base catalyst (GP 012G23)	2.0
Calcium oxide	1.5
Clay	60.0
Chopped glass fiber	60.0
Release agent	1.0

Typical cure, 150–205 °C (300–400 °F) for 2–5 min

Quantum Composites has commercialized nonacid phenolic SMC products for specific aircraft and military applications. In the aerospace industry, phenolic SMC products have been successfully produced by Kaiser Compositek since 1993 as air scoops in inner fan duct for aircraft engine structures. Phenolic SMC was chosen because of the ease of molding to the required shape with light.

Recently, a chopped carbon fiber/phenolic SMC product, Enduron 4685 by Fiberite, was used to manufacture the base and cover of the IBM Think Pad 701 (Ref 34). Key attributes of carbon fiber/phenolic SMC are high thermal resistance (since newer computers generate more heat) and a very low shrinkage value.

Phenolics for Hand Lay-Up

The hand lay-up or wet lay-up process is widely used for making composites with chopped strand mat and polyester resins. Resin requirements are a viscosity of 0.5–2.0 Pa · s (500–2000 cP), 10–60 min pot life for resin/catalyst mixture, and 60–80 °C (140–175 °F) cure temperature. Due to the market demand, phenolic technology was advanced to achieve polyester-like processing, mechanical properties (Table 10), pot life, and cure speed.

Table 10 Properties of phenolic and polyester hand lay-up composites

Property	Phenolic	Polyester
Flexural strength, MPa (ksi)	225 (32.6)	235 (34.1)
Flexural modulus, GPa (10^6 psi)	12.4 (1.8)	9.7 (1.4)

Waterborne phenolic resole resins with sulfonic acid and phosphate ester catalyst are used for hand lay-up processes. The latent phosphate ester (Ref 27) or phosphonic acid (Ref 28), in conjunction with p-toluene sulfonic acid, was effective in meeting pot life and cure speed requirements of the hand lay-up process. Due to the condensation cure and solvent loss, phenolic laminates are more porous than polyester laminates. This shortcoming is addressed using a phenolic-based surface coat. A thixotropic phenolic-based surface paste is available. The paste is brushed or sprayed on the mold and allowed to partially cure before the glass is applied and the hand lay-up process is completed. The surface paste-coated panels are then subjected to the desired paint color. This is a three-step process, compared to the two-step process of lay-up and gel coating for polyester laminates; fabricators have requested a pigmentable phenolic-compatible gel coat to eliminate the painting step. Recently, acrylic gel coats that show good adhesion to the phenolic composite substrate have been introduced. Developmental work continues to meet the needs of the mass transit industry with phenolics.

In Europe, hand lay-up phenolic composites have been used in mass transit since 1988, after a fire broke out at the King's Cross Station, which killed thirty-one people and injured several hundred others. In response to this tragedy, the British government established a Code of Practice (BS 6853) that includes flame spread and smoke limitations for composites used in underground railways. Phenolic composites from Georgia-Pacific and Borden Cellobond products are the only composites that meet the code requirement (Ref 22). Most of the underground railways in France and the Scandinavian countries have followed the specifications of the United Kingdom and switched to phenolic composites.

For mass transit applications in the United States, the current flame spread index requirements (less than 35, per ASTM E 162) and smoke emission specifications (smoke density at 4 min less than 200) for passenger rail vehicles can be met with fiber-reinforced polyesters and vinyl esters. However, with an increasing awareness for reducing fire hazards and improving passenger safety, the United States may follow the example of Britain. If the smoke specification requirement is reduced to less than 20, the use of phenolics will be required (Ref 35).

Recently, phenolic hand lay-up, latent-acid- cure technology has been used to manufacture large (1.8 by 5.4 m, or 6 by 18 ft) panels for constructing composite homes. American Structural Composites (Reno, NV) demonstrated the advantages of phenolic composite homes compared with homes built with traditional construction materials. The phenolic panels eliminate the possibility of termite damage and provide better fire safety and easier construction (Ref 36).

Phenolic Resins

Shahid P. Qureshi, Georgia-Pacific Resins, Inc.

Conclusions

In the 1990s, phenolic resin technology advanced to meet the processing requirements of state-of-the-art composites fabrication processes. Phenolic resin composites offer superior fire resistance, excellent high-temperature performance, long-term durability, and resistance in hydrocarbon and chlorinated solvents. These benefits are available at no additional cost, compared to other thermosetting resins. Mechanical properties of the composite depend on the fabrication process, resin content, and fiber configuration. Fire safety attributes are less sensitive to these variables; they are more a function of the resin/fiber ratio. In recent years, the technology improvements in phenolic resins include the development of low-emission resins, latent acids for desired pot life/cure temperature, and modifiers for higher strength. Application of phenolic composites continues to increase where fire safety is a primary requirement.

Cyanate Ester Resins

Susan Robitaille, YLA Inc.

Introduction

CYANATE ESTER (CE) RESINS are a family of high-temperature thermosetting resins— more accurately named polycyanurates—that bridge the gap in thermal performance between engineering epoxy and high-temperature polyimides. In addition to their outstanding thermal performance, CE resins have several desirable

characteristics that justify their higher cost in many applications. They possess a unique balance of properties and are particularly notable for their low dielectric constant and dielectric loss, low moisture absorption, low shrinkage, and low outgassing characteristics. Despite their relatively high cost they have found wide applications in electronics, printed circuit boards, satellite and aerospace structural composites, and low-dielectric and radar applications. They can be formulated for use as high-performance adhesives, syntactic foams, honeycomb, and fiber- reinforced composites and are often found in blends with other thermosetting resins such as epoxy, bismaleimide, and engineering thermoplastics (Ref 1).

E. Grigat (Ref 2) first successfully synthesized aryl cyanate monomers in the early 1960s, and in 1963, a process was developed to produce the monomers commercially. In the 1970s, the first patents for CE resins were awarded to Bayer AG and Mobay. These patents focused primarily on their use in printed circuit boards (PCBs), using a bisphenol A-based prepolymer. In the late 1970s, patents were licensed to Mitsubishi Gas Chemical and Celanese. Mitsubishi marketed a CE and bismaleimide blend under the name BT resin. Both blended and 100% CE resins systems were initially targeted into the PCB industry. In the 1980s, Hi-Tech Polymers, formerly Celanese, was instrumental in the commercial development of CE resin technology by producing and characterizing a wide array of different polymer backbones with CE functionality. Dave Shimp and Steve Ising of Hi-Tech Polymers are noted for their great contribution to the applications and development of CE polymers during this period (Ref 1, 2, and 3).

By the mid 1980s, work was proceeding on the development of commercial CE and CE/epoxy blends for aerospace and PCB applications. This work was undertaken because of keen interest in improving the hot/wet performance of composites for both structural composites and electronic applications. Cyanate esters were selected for development because of their excellent low moisture-absorbing characteristics and high mechanical and thermal performance. But, due to their high cost and lack of a comprehensive database, they did not penetrate into the large commercial aircraft and structural composite industry. They did, however, find acceptance for dimensionally critical applications in space structures where weight-to-stiffness trade-offs allow higher materials costs. Lower-cost CE resins and CE blends with epoxy and with bismaleimide were eventually developed and entered the electronics industry; these lower-cost resins and blends currently account for approximately 80% of CE use. Estimated CE resin use in 1999 was approximately 400,000 lb (Ref 4).

Cyanate Ester Resins

Susan Robitaille, YLA Inc.

Cyanate Ester Chemistry

Cyanate ester resins are available as low-melt crystalline powder, liquid, and semisolid difunctional monomers and prepolymers of various molecular weights. Higher molecular weight resins are also available as solid flake or in solution. Prepolymers are formed by controlling the cyclotrimerization of monomers in an inert atmosphere, then thermally quenching the resin when it approaches the desired molecular weight.

The most widely used method for commercial production of CE resins is the low-temperature reaction of a cyanogen halide, such as cyanogen chloride, with alcohol or phenol in the presence of a tertiary amine. The low reaction temperatures are desirable in order to reduce the formation of the undesirable by-product diethylcyanamide, a volatile contaminant. It is also important to fully react the phenol during the synthesis, because free, unreacted phenol will catalyze the cyclotrimerization reaction, and significantly reduce shelf life of the resin, and increase the potential for an uncontrollable exothermic reaction during heating.

Due to the extreme hazard of handling and manufacturing with cyanogen halides, there are few companies in the world that are capable of producing commercial quantities of CE resins. As of 2001, Mitsubishi Gas Chemical, Lonza, and Vantico are the main suppliers of CE monomers and prepolymers.

Optionally, cyanogen bromide can be used instead of cyanogen chloride. Because it is a solid, it is easier to handle safely; however, it is more likely to form diethylcyanamide by reacting more aggressively with the tertiary amine. This can be avoided by substituting potassium or sodium hydroxide for the amine or by using alcoholates directly (Ref 1).

Commercially, CE resins are available in monomer and prepolymer forms with several different backbone structures. The general structure of CE resins is a bisphenol, aromatic, or cycloaliphatic backbone with generally two or more ring-forming cyanate functional groups (-O-C≡N-). The differences in backbone and the substituent pendent groups result in a variety of structure/property relationships. Table 1 describes the available physical forms of the monomers or prepolymers, their approximate cost, and the applications for each of the resin types. Materials suppliers formulate these basic components into proprietary systems by combining different CE resins or blending them with other thermosets or thermoplastics, or by adding catalysts, fillers, and flow and toughness modifiers. Cure, or conversion to a thermoset, occurs by cyclotrimerization of three functional groups to produce a triazine ring. The cured polymer forms a three-dimensional cross-linked network consisting of triazine rings linked to the backbone structure through ether groups. Figure 1 depicts the reaction from monomer to prepolymer to thermoset network. The resulting cured matrix has several interesting characteristics. In most cases, this type of linkage provides greater flexibility and higher strain to failure of the cured polymer than multifunctional, unmodified epoxies and bismaleimide resins (Ref 3, 5).

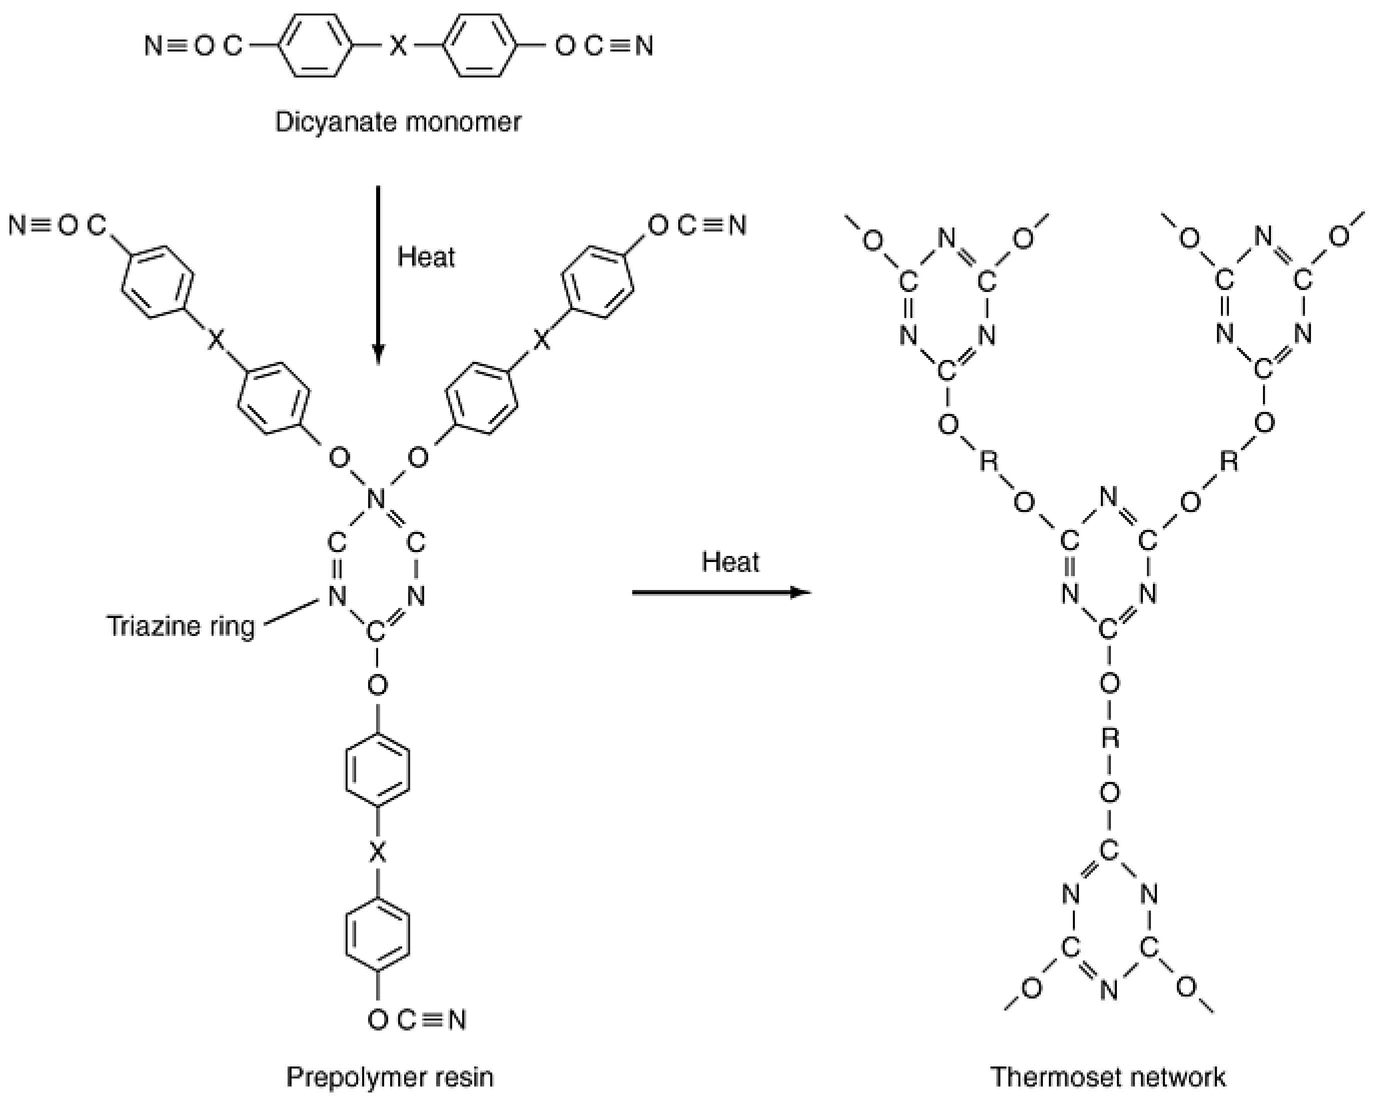

Fig. 1 Cure of cyanate resins by cyclotrimerization of cyanate ester monomer and prepolymer

Table 1 Available forms of cyanate ester resins

Form	Structure	Physical state	Cost		Applications
			$/kg	**$/lb**	
XU366, 378		Viscous liquid, amorphous semisolid	29–34	65–75	Telecommunication satellites, radomes, adhesives (120 °C, or 250 °F, cure)
Bisphenol A dicyanate		Crystal powder, viscous liquids, solid flake, solution	9–14	20–30	Radomes, multilayer high-speed printed circuit boards, solvent for thermoplastics
Ortho methyl dicyanate		Crystal powder, semisolid, amorphous solid	11–14	25–30	Radomes, primary structures, flexible circuitry, high-speed printed circuit boards, adhesives
L-10 monomes		Low viscosity liquid or crystal	36–45	80–100	Radomes, satellites, syntactic foams, primary structures, solvent for thermoplastics
XU7187 dicyclopentadiene		Semisolid amorphous (0.7L is core shell rubber toughened)	36–50	80–110	Telecommunications or satellites, primary structures, structural syntactic cores, radomes, adhesives
Phenol triazine PT-30, 60		Viscous liquid or semisolid amorphous	27–34	60–75	High-temperature applications: wet winding, carbon-carbon, ablatives

The selection of catalyst is important to the curing process of CE resins. Studies performed by D. Shimp et al. show that cure rates can vary depending on the type, addition level, and whether or not a reaction accelerator is used. The most common type of catalysts are chelates and carboxylate salts of transition metals. The metals act as coordination catalysts and complex with the -OCN groups, bringing three reactive groups together to form the triazine ring structure. The reaction does not evolve any volatiles. The transition metal used to catalyze the polymerization does not play an important role in the final properties of the fully cured polymer. This means that the same triazine ring structure will be produced, regardless of the type of transition metal selected; however, it does directly affect its percent conversion and cure rate at specific temperatures, which in turn affect the glass transition temperature (T_g) and the thermal oxidative and hydrolytic stability of the cured system.

Cyanate ester resins are autocatalytic at temperatures above 200 °C (390 °F) and can be cured without catalyst. Their heat of reaction is higher than epoxy resins, which can be problematic if attempting fast cure cycles of thick laminates or compounding large masses of polymer at elevated temperatures. The heat of reaction for the OCN groups are approximately 105 kJ/mole compared to 50 to 58 kJ/mole for epoxy systems. Cyanate ester resins are also sensitive to contaminants and impurities, especially phenols, transition metals, amines, Lewis acids, alcohols, and water, which will all increase the reaction rate (Ref 1, 6).

Properties and Characteristics

Many of the beneficial characteristics of CE resins contrast with those of epoxies and are directly related to the chemical structure of the resin. The most attractive attributes of CE chemistry evolve from the cured matrix structure. While there are differences in performance depending on the backbone structure and formulation, all forms contain a notably low concentration of dipoles and hydroxyl groups in the cured structure. They can also have a moderate cross-link density and high free volume. These result in lower moisture absorption, higher diffusivity, low cure shrinkage, low coefficient of thermal expansion (CTE), and low dielectric constant and dielectric loss when compared with epoxy and bismaleimide (BMI) systems. These attributes are particularly attractive for stable structures, PCBs, and radar and low dielectric applications. Figure 2 is a graph of moisture absorption of CE neat resins (RS-3) and an epoxy (3501-6), both cured at 180 °C (360 °F). The cured resins were conditioned at 100% relative humidity and 25 °C (77 °F) for more than 1000 days. The moisture absorption behavior comparison between the CE and epoxy resins shows that the CE reaches moisture equilibrium quickly and at much lower total absorption level. This is also reflected in the overall lower coefficient of moisture expansion of CE resins when compared to epoxies.

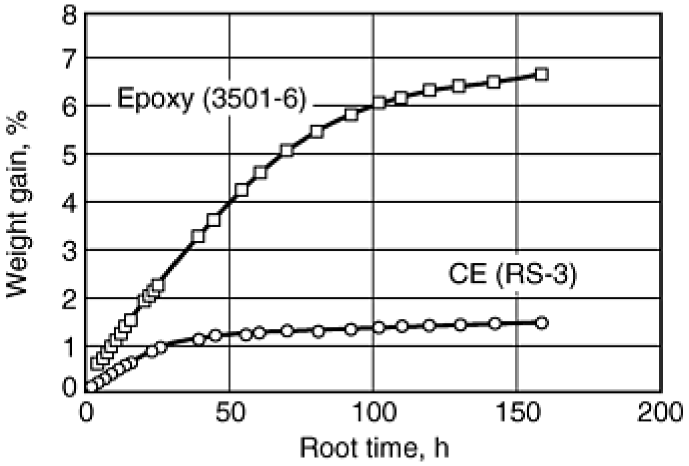

Fig. 2 Moisture absorption of 180 °C (360 °F) cured epoxy and CE neat resins at 100% relative humidity and 25 °C (77 °F) for more than 1000 days

The resin modulus and toughness characteristics depend, in part, on the backbone structure and cross-link density of the polymer. For satellite structures, improved toughness and elongation to failure result in fewer microcracks due to thermal cycling and a more stable structure. Figure 3 compares microcracking of several CE and epoxy resins, all of which are space-qualified systems. The laminates were made using XN- 70A, a 690 GPa (100 × 10^6 psi) modulus pitch fiber at 60% fiber volume. The CE systems produced fewer microcracks overall after 2000 cycles, with the microcrack density increasing rapidly from zero to 500 cycles and then stabilizing. The exception to this stabilization is the lower- temperature curing epoxy system (130 °C, or 270 °F) that appears to continue microcracking after 2000 cycles.

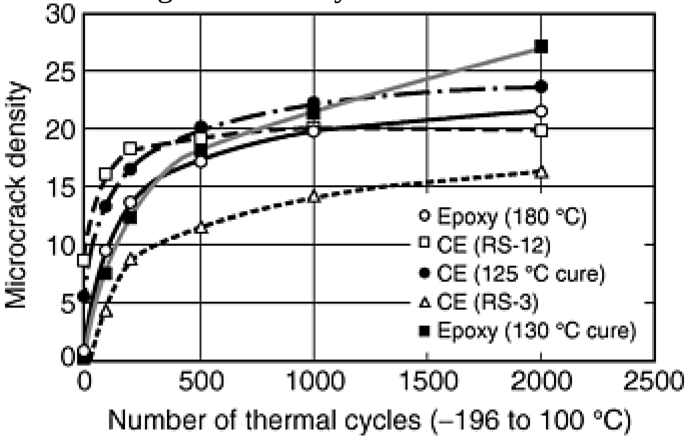

Fig. 3 Comparison of microcracking behavior of cyanate ester and epoxy laminates (reinforced with graphite fiber XN70A, modulus >690 GPa, or 100 × 10^6 psi). Source: Nippon Graphite Fiber Corporation

Cyanate ester can be toughened by the same mechanisms used for epoxy resins, with the expected change in the balance of modulus, T_g, and strain to failure. The ability to modify and toughen CE-based resins makes them appropriate for adhesives and toughened composite applications. One prepolymer system available from Vantico, XU71787 0.07l, incorporates a proprietary submicron core shell rubber particle. It is very efficient in improving the fracture toughness (K_{Ic}) of the matrix at low concentrations without significantly reducing the T_g of the resin. A comparison of mechanical and physical properties of cured neat resins used to formulate matrix systems is found in Table 2. All resins were cured at 175 °C (350 °F) and postcured to >95% conversion. This table shows the differences in the commercially available resins. Additional data are available from the materials suppliers (Ref 3, 7, 8).

Cyanate Ester Resins

Susan Robitaille, YLA Inc.

Processing

Cyanate ester resins have prepreg processing requirements similar to epoxy and BMI resins and are prepregged using traditional hot-melt and solution-coating processes. The preferred method of incorporating reinforcements is by hot-melt or other solvent-free processing due to possible contamination by water when using solvent-coating processes. For the PCB prepregs, solvent impregnation is used because of better production efficiencies for solution coating large volume, low-flow systems.

Cyanate esters also have composite processing characteristics similar to epoxy resins. They are available as hot-melt prepregs, tow preg, wet-winding resins, molding compounds, resin transfer molding (RTM) resins, adhesive systems, and syntactic core materials. They can be consolidated using autoclave, vacuum bag, press, pultrusion, RTM, Seemans composite resin injection molding process, or vacuum-assisted resin transfer molding methods.

Curing of CE resins and prepregs is generally performed at elevated temperatures. Low-temperature cures are possible but will result in a system with significantly shorter out times as well as overall low cyanate conversions, <80%, without postcuring. Low conversions of OCN groups can cause poor hydrolytic chemical stability, low T_g, brittleness, and higher dielectric properties. Postcuring should be considered if optimal properties are required, especially at elevated service temperatures. In order to achieve adequate conversions of the OCN reactive groups and useable room temperature out times, most resin systems are formulated to cure at temperatures between 120 and 180 °C (250 and 360 °F). It is recommended that CE resins be postcured to 235 to 315 °C (455 to 600 °F) for structural service temperatures at or above 180 °C (360 °F).

For structural laminates, a chelated metal catalyst, such as cobalt or copper, is typically used. Other catalysts used to cure CE resins include zinc, manganese, and iron. Metal chelates will give longer pot life than metal carboxylates, and the addition of active hydrogen compounds, such as nonyl phenol, acts as co-catalysts and solvents for the metal coordination catalyst. They play an important role in percent conversion at temperature, resulting in longer pot life. For practical reasons, some metal catalysts should be avoided because, in the

presence of moisture, they can promote hydrolysis of the OCN groups to form carbamates. The formation of carbamates reduces the ultimate T_g and thermal stability of the resin and can lead to delamination at elevated temperatures, due to the decomposition of carbamate structure to CO_2 gas and an amine group. Metal catalysts that promote the formation of carbamates are tin, lead, antimony, and titanium, and, to a lesser extent, zinc (Ref 6, 9, 10).

The formation of carbamates in CE resins is one of the few disadvantages of CE resins when compared to BMI or epoxies. It is generally accepted that, for most high-performance composites, exposure to moisture contamination during the cure must be controlled. In the case of CE, the most predominant contamination problem by far occurs when the resins are exposed to moisture during the cure process. Carbamate contamination of CE systems due to the reaction with moisture in structural composites has been noted since the early 1990s, when the first structural parts were fabricated for space structures using low CTE composite tooling. Shimp et al. have characterized the reaction (Ref 3). The general reaction for the formation of carbamate is shown in Fig. 4.

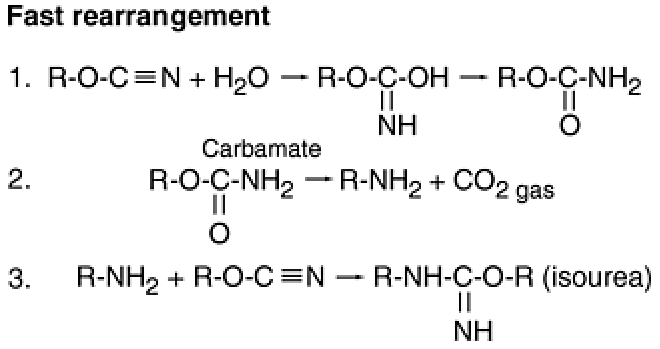

Fig. 4 Reaction of cyanate ester and water, formation and decomposition of carbamate, reaction of amine with OCN group. Source: Ref 3

Carbamate formation can occur when moisture is able to diffuse into the laminate or adhesive and react with the polymer system during the cure process. This problem is most noticeable on structures that are cured against undried composite tools, with moisture-laden bagging materials, fibers, foam, or honeycomb cores. The formation of the carbamate group proceeds by hydrolysis of the OCN functional group to form a carbamate. With additional heating above 150 °C (300 °F), the carbamate group decomposes and forms an amine and carbon dioxide. The carbon dioxide gas can cause blistering and delamination, as noted by Shimp and Ising (Ref 7) in early postcured Kevlar (DuPont) laminates. The amount of carbamate formed is also dependent on the catalyst used in the formulation; zinc catalysts promoted the carbamate formation more than copper or cobalt. During thermal decomposition of the carbamate into carbon dioxide and amine, it is possible for unreacted OCN groups to react with the amine and form a more stable linear polymer structure, or isourea (Ref 1, 3, and 9).

Moisture contamination problems do not always result in blistering or delamination. For composites cured against undried composite tooling, the problem generally is restricted to the tool surface of the laminate. In severe cases it can be detected as a rough, friable surface on laminates. If the formation and/or decomposition of the carbamate structure has occurred, the surface of the laminate will be soluble in a ketone such as acetone or methyl ethyl ketone. Depending on the cure conditions, Fourier transform infrared examination of the extract can detect the carbonyl peak at around 1750 cm^{-1}. This can be misleading; if the carbamate has decomposed fully due to elevated cure temperatures and is no longer present, only a much stronger-than-normal NH stretch peak around 3500 cm^{-1} may be detected. A characteristic change of the cured cyanate, if carbamates have been formed, is a decrease in the T_g of the resin.

In order to alleviate the risk of moisture forming carbamates during cure, some easy precautions and techniques can be used. These include predrying and dry storage of composite tools, drying and outgassing of foam cores, drying fabrics, and modifying the cure cycle to remove moisture from the materials before the cure reaction begins. Even changes in the vacuum bag lay-up, for instance, allowing a good path for trapped moisture to be removed from the vacuum bag and keeping the part under an active vacuum throughout the cure, have been found to be useful in minimizing the problem. The reaction of water and CEs proceeds very slowly at room temperature and is generally not a problem as long as good materials storage practices are used. This should include the use of heat-sealable aluminum-coated Mil bags, storage with desiccant, and avoiding long-term or repeated moisture contamination.

Another useful tool to determine the potential presence of carbamates and their decomposition on suspect parts is detailed electron spectroscopy for chemical analysis (ESCA), which is used for determining elemental and chemical bond information for elements that have atomic numbers greater than helium. This method can be used to determine the existence of carbamate groups (seen as carbonyl -C=O) or the amine and subsequent isourea structure formed from carbamate decomposition. ESCA will also detect other potential surface contaminates, such as silicone and fluorine (Ref 11).

Properties For Selected Applications

Space Applications. The ability to save weight by replacing heavier metal structures with composites has been a common thread for justifying the use of more-expensive composites for the last twenty-five years, especially for space applications. Depending on the launch platform used, it is estimated that each pound of weight removed from the structure at launch saves between $5,000 and $30,000. Epoxy and BMI resins were the first systems to be used for satellite composite structures, but problems soon became apparent with these systems. Matrix microcracking during thermal cycling with unmodified systems reduced structural stiffness and caused instability. Rubber-toughened resin systems did not hold up to radiation exposure, losing strength, stiffness, and thermal performance. Epoxy and BMI resins absorbed moisture while being stored prior to launch and, in the vacuum of space, outgassed absorbed moisture, resulting in structural instability as the matrix changed dimensionally and degraded thermal performance. Outgassing also produced condensation of moisture on sensitive reflectors, mirrors, and optics, reducing signals or making them inoperable.

The characteristics that make CE resins a more-suitable choice for space structures and ultimately led to their wide acceptance were their low outgassing, good cryogenic temperature performance, low cure shrinkage, low microcracking from thermal cycling, good radiation resistance (Ref 11, 12), and low coefficient of moisture absorption, low CTE, and low density. Table 3 shows typical laminate performance of 180 °C (360 °F) cured CE prepreg resin systems on carbon, graphite, Kevlar, and quartz fibers. The values are averages of commercially available 100% CE prepreg systems that are qualified for satellite and radome applications.

(a) Precision Measurements Instruments Corp. test method

Combining the CE resins with ultrahigh modulus pitch and polyacrilonitrile (PAN) fibers (modulus >517 GPa, or 75 × 10^6 psi) allows the design and fabrication of near-zero CTE composite structures of unparalleled stiffness and stability. Control of CTE is of special interest for space applications such as antennas, reflectors, optical benches, signal devices, feed horn, mux cavities, arrays, and mirrors. It allows the fabricator to build structures that are dimensionally stable during thermal cycling in the space environment from–160 to 180 °C (–250 to 350 °F), allowing improved signal and focal accuracy.

Radomes. Advancements in radar systems, microwave communications, and targeting and tracking electronics using higher frequencies and energy levels has contributed to more-demanding conditions for electromagnetic windows. The frequency ranges required by these systems are between 600 MHz and 100 GHz. Some of the advanced, high-powered systems require materials that are not only transparent to the electromagnetic signal, but can perform at the elevated temperatures that can be produced as the signal passes through the structure. The placement of radomes as primary structure on advanced aircraft requires that they perform well both structurally and electromagnetically. Because of the excellent mechanical properties and very low dielectric properties of cyanate ester, thinner, lightweight structural radomes can be produced, reducing signal loss over a wide frequency range. Their low moisture absorption also provides consistent signal performance.

Reinforcements for these structures are typically glass, quartz, Kevlar, or Spectra polyethylene fibers. Syntactic core materials and lightweight molding compounds can be produced easily using CE resins, and, by adding modifiers and fillers, the dielectric properties can be tuned to specific dielectric constant and loss tangent values. In addition to the contribution CE resins make to low dielectric applications in radomes, they are also

suitable for radar-absorbing structures. By combining several layers of material, each with different radar absorbing, transmitting, and canceling properties, the radar signature of a structure can be significantly reduced (Ref 13).

Printed Circuit Boards. The largest application for CE resins is in the electronics industry. In many of the most-demanding applications, CE resins have replaced epoxy novolac systems. The primary reasons are their high T_g (>220 °C or 430 °F), low dielectric properties, very low chloride levels, low moisture absorption, and their ability to be formulated to meet UL 94 flammability requirements. The greatest use in the electronics industry is in multilayer circuit boards and mulitchip modules, which account for 70 to 80% of CE resin usage.

The demand for higher processing speeds and higher frequency capability requires the use of materials with very low dielectric loss properties. The large volume use of CE resins requires formulations that are capable of high-speed prepreg and laminating techniques. Prepreg used for PCB applications is often produced using the solution-coating process and is catalyzed for fast laminating cycles, which increase the throughput of the PCB product. Many PCB cyanate ester formulations are modified with epoxy, BMI, and thermoplastic blends and provide superior bonding to copper foils and higher glass transition properties when compared to FR-4 epoxy laminates (Ref 13).

Cyanate ester resins are compatible at high loading levels with many inorganic fillers, particles, flakes, nanofillers, glass and ceramic balloons, and fibers and can be combined with high- conductivity (>900 W/m · K) fillers and fibers to produce molded heat sinks for thermal management applications.

Cyanate Ester Resins

Susan Robitaille, YLA Inc.

Outlook

Cyanate ester resins offer excellent benefits when compared to other thermoset resins. Currently, the use of CE resins in composites has been restricted by their high cost. New developments for CE resins are focused on lower-cost solutions for synthesizing the resins, resin blends, and copolymers and fully understanding the cure mechanism to allow lower cure temperatures with high conversions. Additionally, work is being pursued to identify modifications for lower moisture absorption, lower coefficient of moisture expansion, and improved dielectric properties. Throughout the development of new CE resins, one area that continues to be investigated is changes in backbone chemistry. This work is ongoing, by functionalizing different polymer backbones with

cyanate functional groups and characterizing the subsequent properties, enabling new uses or improvements in CE properties.

In the electronics industry, the performance requirements of PCBs are continually increasing, and rapid advancement is being made on the performance limits of the epoxy resins. Ultimately, CE resins will become the materials choice for this market, but their potential will be limited by their high cost. It is essential that economical manufacturing methods and raw materials supplies be developed. Lowering the cost of CE resins in order to meet the demand and cost constraint of the electronic market will not only lead to CE resins expanding into more electronic components, but will aid in their acceptance into large aerospace and commercial markets.

Thermoplastic Resins

Lee McKague, Composites-Consulting, Inc.

Introduction

THERMOPLASTICS have attractive mechanical properties for many supersonic aircraft requirements and for most commercial aircraft requirements. They also offer dimensional stability and attractive dielectric characteristics. Good flame-retardant and wear-resistant characteristics also are common. Table 1 qualitatively compares current-generation thermoplastics and thermosets.

Table 1 Qualitative comparison of current thermoplastics and thermosets

Characteristic	Thermoplastics	Thermosets
Tensile properties	Excellent	Excellent
Stiffness properties	Excellent	Excellent
Compression properties	Good	Excellent
Compression strength after impact	Good to excellent	Fair to excellent
Bolted joint properties	Fair	Good
Fatigue resistance	Good	Excellent
Damage tolerance	Excellent	Fair to excellent
Durability	Excellent	Good to excellent
Maintainability	Fair to poor	Good
Service temperature	Good	Good
Dielectric properties	Good to excellent	Fair to good
Environmental weakness	None, or hydraulic fluid	Moisture
NBS smoke test performance	Good to excellent	Fair to good
Processing temperatures, °C (°F)	343–427 (650–800)	121–315 (250–600)
Processing pressure, MPa (psi)	1.38–2.07 (200–300)	0.59–0.69 (85–100)
Lay-up characteristics	Dry, boardy, difficult	Tack, drape, easy
Debulking, fusing, or heat tacking	Every ply if part is not flat	Typically every 3 or more plies
In-process joining options	Co-fusion	Co-cure, Co-bond
Postprocess joining options	Fastening, bonding, fusion	Fastening, bonding
Manufacturing scrap rates	Low	Low
Ease of prepregging	Fair to poor	Good to excellent
Volatile-free prepreg	Excellent	Excellent
Prepreg shelf life and out time	Excellent	Good
Health/safety	Excellent	Excellent

This article addresses thermoplastic resins used as matrix materials for continuous fiber reinforced composites. The focus is on materials suitable for fabrication of structural laminates such as might be used for aerospace applications. Chopped fiber reinforced molding systems are not discussed. High-temperature polymers suitable only for manufacture of small parts, such as washers and bushings, also are not included. Secondary attention is paid to materials whose elevated-temperature properties limit their applications to sporting goods or other low-service- temperature products.

Thermoplastic Resins

Lee McKague, Composites-Consulting, Inc.

Background

First-Generation Resins. Thermoplastic resins for structural composites began to receive serious attention in the 1980s. This resulted because composite structures made with first-generation thermosetting resins were easily damaged by low-velocity impacts, such as from a dropped wrench. Some fighter aircraft structures were being delaminated by such impacts. Alarmingly, a delamination could be formed without leaving visual evidence on the impacted surface. Worse yet, subsequent structural loads could cause enlargement of the delamination.

Previous decades had focused on high performance, that is, low structural weight. In the 1980s, new attention was placed on achieving an acceptable level of damage tolerance and durability. Significant investigations were launched to devise test methods to characterize damage tolerance and durability (Ref 1, 2, 3, 4, 5, 6, and 7) and to establish threshold requirements. The favored method of evaluating damage tolerance of a composite has evolved to be testing for compression strength of a laminate after it sustains an impact of 6.67 J/mm (1500 in. · lbf/in.). This test has been conducted per Suppliers of Advanced Composite Materials Association (SACMA) method SRM 2R-94. Although SACMA is no longer an active organization, testing companies in the United States still use the test method. An alternate procedure is National Aeronautics and Space Administration (NASA) 1142-B11.

Searches were initiated for tougher materials, and thermoplastic polymers were identified as a candidate option. They were perceived as inherently tough and resistant to damage from low- velocity impacts. Significant programs were funded by the U.S. Air Force, the U.S. Navy, and NASA.

Thrusts from Department of Defense (DoD) and NASA programs spurred research by various companies. Altogether, these efforts sought to identify suitable thermoplastic resins, to develop composite products, to learn how to fabricate aircraft components, and to characterize resulting performance. Because needs were centered first on improving composite performance in fighter aircraft, thermoplastics were sought that also could yield attractive elevated-temperature properties.

Fighter platforms evolving during the 1980s typically were designed to perform at speeds up to Mach 2.0 to 2.2. At these speeds, aerodynamic friction can cause adiabatic and stagnation heating of aircraft skins to temperatures of 132 to 171 °C (270–340 °F). An acceptable material would have to have good retention of mechanical properties at these temperatures, as well as being resistant to impact damage at ambient temperatures.

Most of the many distinct thermoplastic polymers have found commodity applications that typically have modest service temperature requirements. Less than a dozen polymers have been considered for engineering applications at higher temperatures, such as are required for many aerospace structural composites. The restrictive factor has been the relationship of processing to elevated-temperature properties.

Many polymers may have a glass transition temperature (T_g) or melting temperature (T_m) that seems high. However, the stiffness and mechanical performance of thermoplastics progressively diminish as these points are approached. To have good properties at temperatures of 132 °C (270 °F) or higher, the T_g or T_m must be well above the intended use temperature. Yet, only above T_g or near melting do thermoplastics become soft enough for the mechanical forming or shaping required for manufacturing parts.

Based on the author's experience, an approximate rule of thumb is that polymer softness sufficient for part processing must occur 180 °C (325 °F) or more above the intended maximum structural use temperature. Adequate composite stiffness at the intended use temperature results from this margin. Another desirable result is resistance to creep when elevated-temperature design loads are applied. Restated, this rule of thumb means that component manufacturing operations have been required to occur well above 315 °C (600 °F).

These high temperatures, together with the typical lack of tack of thermoplastic prepregs, have required processing techniques that are significantly different from those used for thermosetting composites. One low-cost technique has been lay-up and heat consolidation of a flat laminate, followed by thermoforming to the required part shape (Ref 8). Both consolidation and thermoforming might be done in a press.

Depending on size or shape of contoured parts, another technique has involved heat tacking of each ply during lay-up. This compensates for lack of tack that otherwise would allow plies to slip off the contoured tool. It also better enables thickness tailoring of the laminate. Such lay-up usually is followed by autoclave consolidation.

Autoclave process parameters for consolidation can involve compacting at pressures of 1.38 to 2.07 MPa (200–300 psi) and temperatures as high as 343 to 382 °C (650–720 °F). At such autoclave conditions, preparation for processing is much more difficult. Ancillary materials for vacuum bagging must possess high-temperature resistance; bagging films such as Kapton or Upilex are required. In addition, bagging must be done more carefully. One of the highest-temperature tough thermoplastics is polyether etherketone (PEEK). Autoclave processing of PEEK is done at a nominal temperature of 380 °C (715 °F), and the process cycle is long because of autoclave heat-up and cool-down times.

Altogether, these factors have meant higher cost. In the early 1990s, such cost disadvantages caused some companies to stop marketing certain thermoplastic composites. Development of new, innovative approaches has been required to combat high costs.

Second-Generation Resins. As previously noted, durability and damage tolerance requirements created a drive toward increased application of thermoplastics. However, the emerging market threat of thermoplastics spurred development of a second, tougher generation of thermosetting resins. As illustrated in Fig. 1, these tougher thermosetting resins improved by a factor of 1.3 in compression strength after impact (CSAI). Open-hole compression strength (OHCS), another critical design property, also improved. However, by comparison composites made with polyetherimide (PEI) and PEEK had CSAI values more than twice as high as the first-generation graphite/epoxies, also illustrated in Fig. 1.

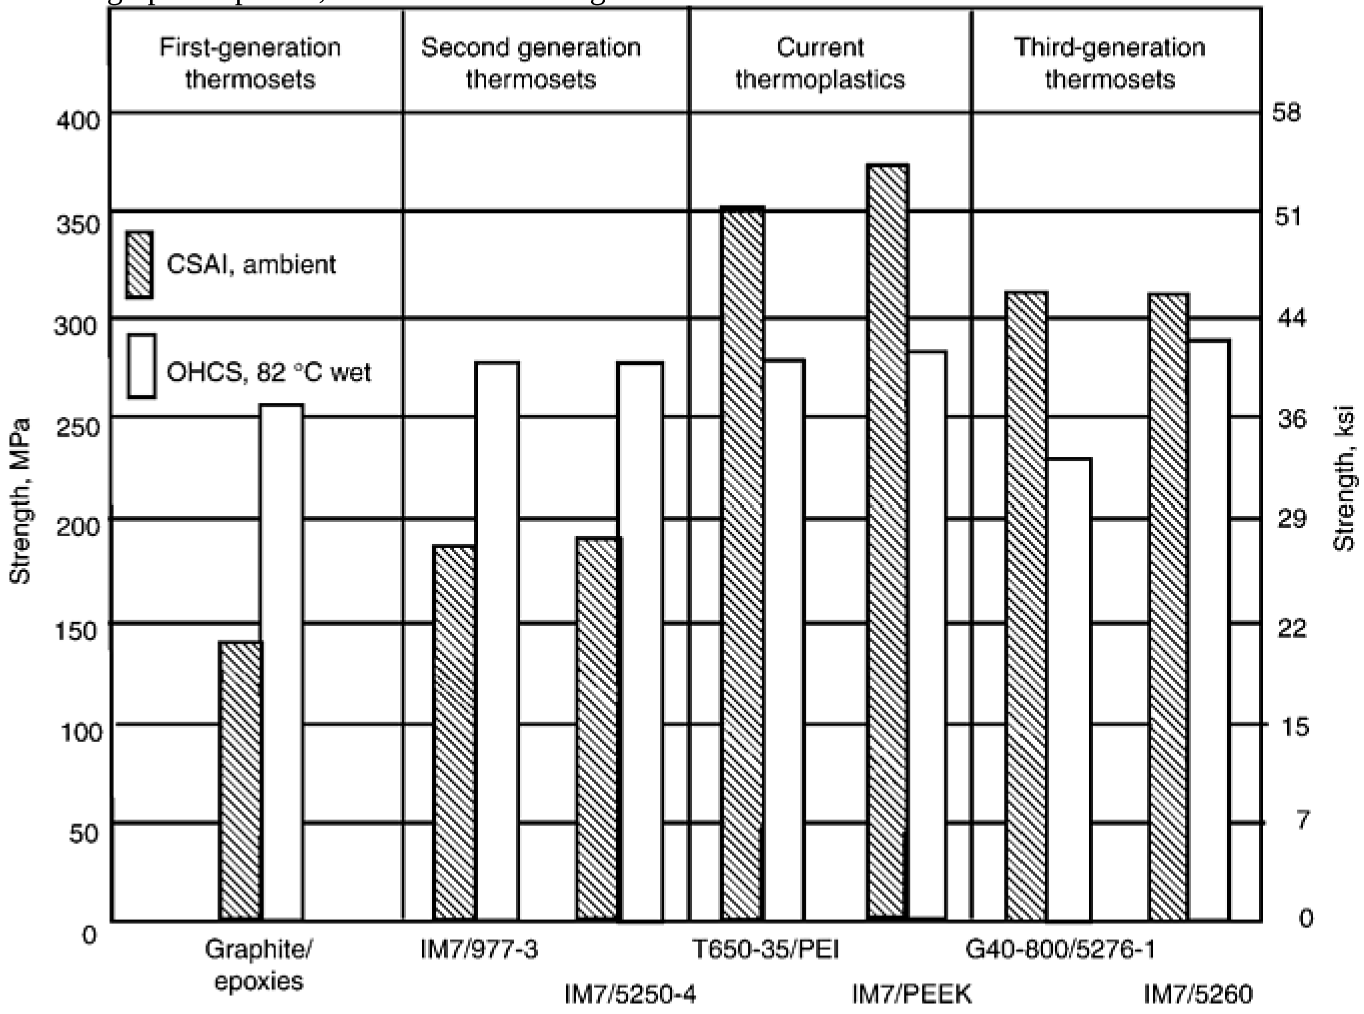

Fig. 1 Compression properties of thermosets and thermoplastics. Source: Ref 9 and manufacturer data (PEI, Hexcel Corp.; PEEK, Cytec Fiberite)

Meanwhile, the military was pressed by timing requirements for new programs, such as the F-22 and the F-18E&F. Based on many tests and evaluations, it was concluded that improvements provided by second-generation thermosets would satisfy mission requirements. Although thermoplastics still required extensive development of processing methods, these thermosets processed the same as—and even better than— first-

generation thermosets. This led emerging military programs to use materials such as IM7/ 977-3 graphite/epoxy and IM7/5250-4 graphite/ BMI (Ref 9). As a consequence of these factors, applications of thermoplastic composites to military aircraft during the 1990s were quite limited.

Third-Generation Resins. Recently, a third generation of thermosets has achieved CSAI and OHCS values that approach those of PEI and PEEK, also shown in Fig. 1. Based on military experience, some members of this later generation of thermosets appear likely to meet most durability and damage-tolerance requirements while preserving much of the lower-cost processing options generally offered by thermosets. Despite this potential rivalry, thermoplastics are gaining applications as their advantageous characteristics become better known and as new, cost-effective processing methods evolve.

One such significant application of thermoplastics is to commercial aircraft, which do not sustain supersonic flight temperatures. Here, the demand for excellent damage tolerance and durability dominated decisions. Consequently, resins that would be marginal or unacceptable in many military aircraft applications could easily meet many commercial aircraft performance requirements.

In addition to impact resistance, thermoplastics offer excellent abrasion resistance. They exhibit attractive dielectric properties, and these properties are not significantly shifted by moisture absorption. In most cases, high-temperature thermoplastic composites also have excellent environmental and solvent resistance.

Thermoplastic composites have promised these and other advantages. Capturing these advantages has been slow, due in part to reduced military spending on aircraft. In the commercial sector, significant recent progress has been made in understanding where and how to use thermoplastic composites and how to reduce the costs of structures. For some thermoplastic resins, manufacturing approaches have been developed that yield very favorable processing costs. Perhaps more significantly, they open up component assembly options that enable large total- cost savings. As a result, commercial applications of thermoplastics have blossomed.

Categories and Characteristics

Thermoplastic materials are divided into categories based on fundamental differences in morphology. These morphologies are described as crystalline, semicrystalline, and amorphous.

Semicrystalline materials have domains of highly ordered molecular structure (crystallites) having well-defined melting points. Crystalline development is a thermodynamic and transport phenomena controlled by balance in mobility and free energy of molecules. Cooling rate can influence crystalline content and distribution (Ref 10).

The effects of crystallinity are similar to cross linking in that resin stiffness and solvent resistance increase with increasing crystalline content (Ref 11). Above the T_g softening occurs more gradually in crystalline materials than in amorphous materials and progresses toward a melting point that is characterized by a sudden change to an apparent liquid state. In this respect, crystallinity is quite different from cross linking, where the material thermally degrades without entering a liquid state.

Semicrystalline materials typically exhibit very good chemical resistance. Unlike thermoset composites, a great degree of useful strength and stiffness may remain well above the T_g of these thermoplastic composites.

Amorphous, high-temperature resins have randomly ordered molecular structures and do not exhibit a sharp melting point. Instead, they soften gradually with rising temperature. Amorphous resins lose their strength quickly above their T_g, even when reinforced with continuous fibers. Physical aging effects, creep behavior, and sensitivity to fatigue also are more pronounced.

At the beginning of 2000, only a few thermoplastic polymers have emerged to dominate the aerospace field. These high-temperature polymers are PEEK, PEI, polyphenylene sulfide (PPS), and polyetherketone ketone (PEKK). Although PEKK exhibits excellent properties, its applications have progressed at a slower rate.

Chemical structures of these and some midtemperature-range thermoplastic materials are illustrated in Fig. 2. Table 2 compares T_g, processing temperature range, and morphology for several polymers.

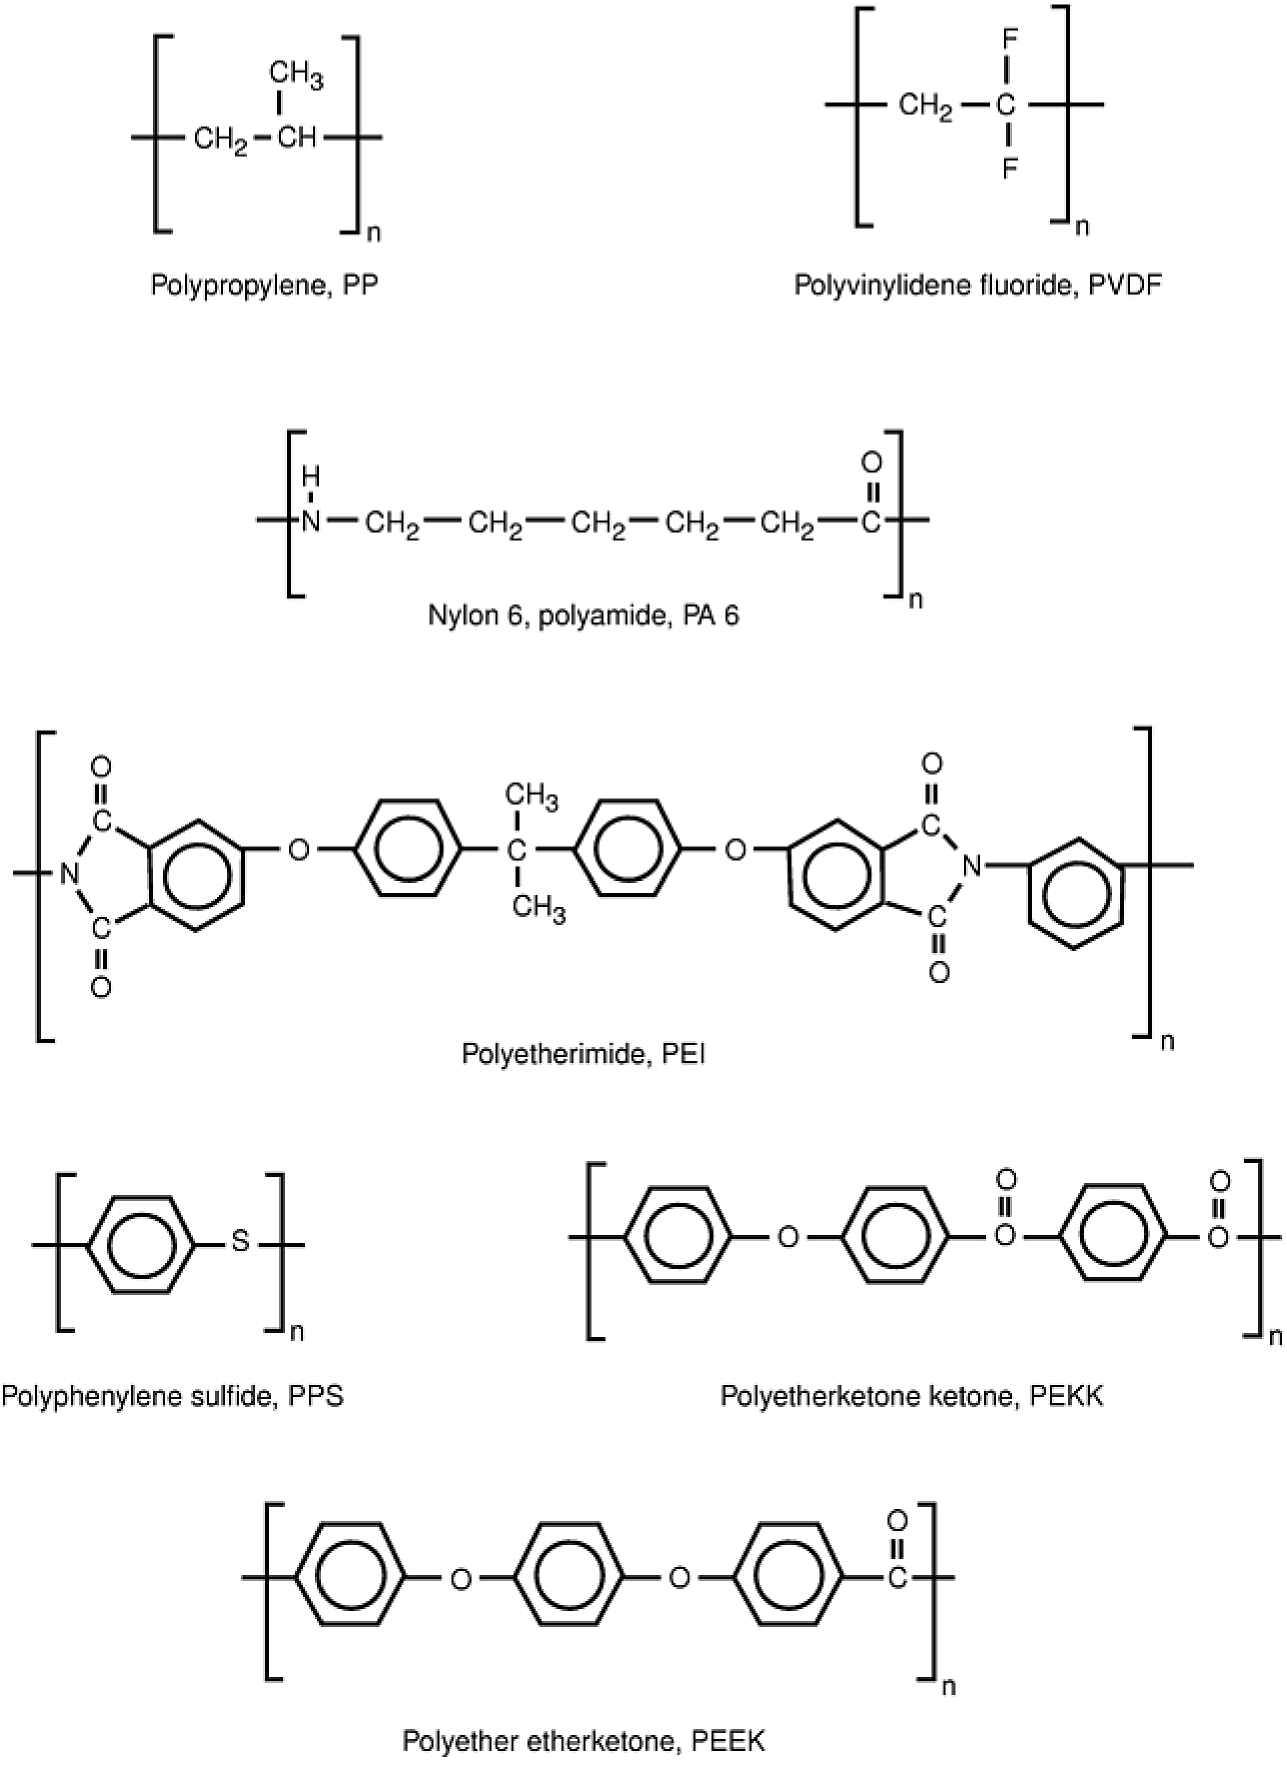

Fig. 2 Chemical structures of mid- and high-temperature thermoplastics

Table 2 Characteristics of mid- and high-temperature thermoplastics

Polymer	Glass transition temperature (T_g)		Melting point		HDTUL(a)		Processing temperature		Type of morphology
	°C	°F	°C	°F	°C	°F	°C	°F	
Polypropylene (PP)	–4	25	170	338	99	210	191–224	375–435	Crystalline

Of these polymers, PEEK has become one of the most widely known and used materials. Through work toward a variety of aerospace requirements, such as the F-22 fighter aircraft, mechanical properties have been well characterized (Ref 13). Effects of various environmental agents—including solvents, acids, hydraulic fluids, and fuels—have been assessed with favorable results. Other materials that have been well characterized are PPS and PEI, reinforced with either glass or carbon fibers (Ref 14, 15, and 16). Some of these properties are presented and discussed in the section “Properties” in this article.

Product Forms

Thermoplastic composite materials are available in a variety of forms, as are thermosetting composites. There are significant differences, however. Perhaps one of the most significant differences is that fabric reinforced thermoplastic prepreg typically have been sold in discontinuous sheet form rather than in roll form. Usual size has been 107 by 366 cm (48 by 120 in.). Also, fabric forms often have been sold as consolidated laminates involving some number of plies with either standard or custom ply orientations.

Unidirectional prepreg has been sold in roll form, but with a maximum roll width only one- fourth to one-fifth that typical of thermosetting prepreg. The standard width has been 30.5 cm (12 in.), but almost any more narrow width has been available. Slit tape and single tow forms have become commonly available.

For various reasons, not all combinations of thermoplastic resin/reinforcement are actively marketed. It is common to find PEEK applied to unidirectional material but not to fabric material. Polyetherimide and PPS, on the other hand, are more commonly marketed with fabric forms.

Thermoplastic Resins

Lee McKague, Composites-Consulting, Inc.

Impregnation

The operations used to combine thermoplastic resins with fine-diameter reinforcing fibers are both a science and an art. They are the domain of companies whose business is manufacture and marketing of prepreg or semipreg materials.

Semipreg is the term often used with thermoplastic materials because the resin may be more nearly a coating rather than an impregnation. This is more typical with fabric reinforcements than with unidirectional reinforcements.

No particular attempt is made here to distinguish between prepreg and semipreg for any particular material combination. In any case, material suppliers typically regard the exact method and set of parameters used for a particular resin/ fiber combination to be proprietary. Discussion here, then, is merely for the purpose of providing a general introduction to the operations and issues associated with the production and use of thermoplastic-matrix composites.

As indicated in Table 1, impregnation with thermoplastic resins is much more difficult than with thermosetting resins because thermoplastics generally are much more viscous. Increasing temperature lowers the viscosity, but in some polymers decomposition can result before very low viscosity is realized.

Many thermoplastics are insoluble by most organic solvents, or their properties are significantly degraded by attempts to thin them using solvents. The consequence is that thorough impregnation can be extremely difficult. Some polymers, however, are readily soluble in select organic solvents. This enables fairly conventional solvent impregnation and is a method that has been used for PEI composites.

Four strategies have been advanced to deal with impregnation difficulties. Two strategies involve heat plus mechanical methods, and the other two involve delivering the thermoplastic in a form that enables intermixing with the reinforcing fibers prior to melting of the resin.

One of the mechanical methods is based on the fact that the viscoelastic behavior of thermoplastics is non-Newtonian (Ref 17). As a result, it is possible to achieve a significant reduction in viscosity through shear thinning. This type of approach could be considered for a viscous polymer that was insoluble in any environmentally acceptable solvent. It is believed that this method is not widely used.

The second, more common mechanical method involves stacking a film layer over fabric. The resin film is heated above the melt or softening temperature and forced into the fabric with pressure, such as from a press platen.

One of the intermixing strategies involves drawing or spinning the resin into fibers that then are commingled with the reinforcing fibers (Ref 18). The resinous fibers of this mixed fiber bundle are then melted or softened. If commingling is adequately achieved, then effective impregnation is achieved. The process to form the thermoplastic fibers represents an added cost, but in volume this can be a very small cost.

The second intermixing strategy involves combining powdered resin with the reinforcing fibers. Electrostatic attraction methods are used in a fluidized bed process to apply the powder coating. The polymer then is melted to form the prepreg (Ref 19, 20). Sometimes the material may be sold prior to resin melting, so that the drapable, no-tack material achieves its actual impregnation after part lay-up—during the part consolidation step. Mechanically producing powders with very small particle sizes represents an added cost that can be larger than the cost of drawing the polymer into fibers. However, the net cost of combining the polymer and fibers can be less than for solvent impregnation (Ref 21). For some polymers, an alternate strategy involves precipitation from reactors, but sizes tend to be quite a bit larger than for mechanically formed powders.

Processing

Lay-up of thermoplastic composite panels and parts is conceptually similar to lay-up with thermosetting composites in that plies are cut to shape and applied ply by ply. Beyond this similarity, however, the processes are quite different. The difference is driven by the typical lack of tack inherent in most thermoplastic prepregs.

For parts of certain size having contour, the first ply may be held to the tool by tape at the corners or by some other suitable method. Then, each subsequent ply must be heat tacked to the one below it. The heat-tacking process is analogous to a spot-welding process. A standard soldering iron with a blunt-shaped tip is applied with light pressure after heating the tip to a suitable temperature that is well above the T_g of the resin. For some thermoplastics the tip may be heated to as much as 500 °C (932 °F). This causes local melting and fusion of the resin to the ply below.

Fiber placement processes can be used to create a part using slit tape or tow prepreg. The entire surface of the slit tape or tow is heated as it is being laid, fusing it to the layer below. If the part is a body of revolution, then the process is similar to filament winding (see the article "Filament Winding" in this Volume). If the part is

more nearly planar, then special care in the design of the part, tooling, and process may be necessary. As the laminate is built up, out-of- plane forces sufficient to cause warping or bowing away from the tool may result from nonsymmetry of the plies, and microcracking of the matrix also might result. In such a case, it may be necessary to create a part that is not optimum from a structural standpoint, but that approximates pairwise symmetry during the lay-up to total laminate thickness.
The fiber-placement process may provide adequate in situ consolidation, but for other lay-up methods it generally will be necessary to consolidate laminates after lay-up is complete. If the part is flat or nearly so, consolidation can occur either in a press or an autoclave. Press consolidation is somewhat easier, but in many production shops, press sizes are smaller than autoclave sizes.
Forming. As mentioned in the discussion of material forms, a common fabric reinforced product form is consolidated sheet, analogous to plywood except that it can be thermoformed whereas plywood cannot. From such sheets, patterns are cut that are subsequently formed to the required shape of the intended part. Figure 3 illustrates this method for multipart fabrication of rib stiffeners.

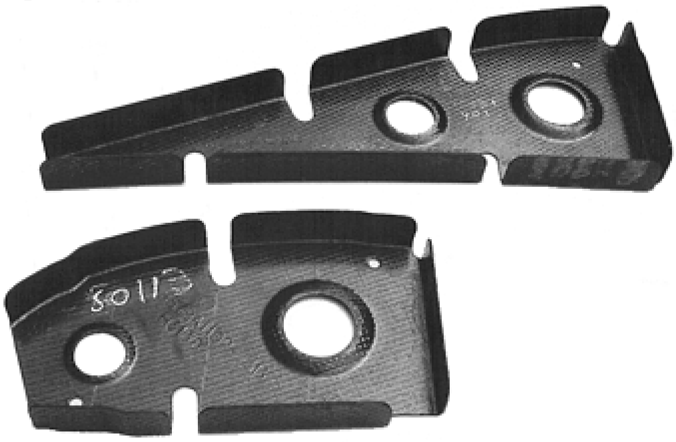

Fig. 3 Dornier 328 landing flap ribs, thermoformed from pattern blanks. Courtesy of Ten Cate Advanced Composites bv

Several processes are used to create part shapes with consolidated sheet material. Typically, these processes are analogous to sheet metal forming, drawing, and bending operations. The processes include roll forming, mold or die forming, and diaphragm forming.
Assembly of elements or parts into a component can be accomplished without the need to drill holes and install fasteners. Although such conventional assembly can be employed, it is the unique ability of thermoplastics to undergo postforming remelting and fusion that can be especially attractive.
Fusion bonding enables structural components to be assembled without use of mechanical fasteners. All of the components to be joined can be heated and fused together. This can be accomplished with externally applied heating methods, by resistance heating of screens or wires placed at the interfaces, or by induction heating involving the reinforcing fibers. All of these methods can produce excellent adhesion. However, if the entire part details are heated to fusion, special tooling may be required to prevent dimensional distortions. If the resin is in the semicrystalline state, a higher temperature will be required for fusion bonding than if the resin is in the amorphous state.
A similar, but different, approach is to place a lower-melting thermoplastic film between the faying surfaces, such as a film of PEI between two PEEK-matrix parts (Ref 22). All of the elements or parts can be heated together with contact pressure applied to the bond areas, and with less rigorous tooling requirements. Polyetherimide and PEEK are uniquely miscible, helping make the resulting interface quite strong.
Process Temperature Effects. For many thermoplastics, high-temperature properties and resistance to environmental fluids result from achieving the semicrystalline state. Once the semicrystalline state is achieved, those regions of the material exhibit a higher melting point than the adjacent, amorphous-state material. In addition, it has been found that crystallinity and crystalline morphology influence fracture toughness of carbon/PEEK (Ref 23).
Fiber diameter may affect PEEK morphology. The smaller, 5 μm IM6 fibers exhibit better fracture toughness than the larger 7 μm AS4 fibers. However, differences in total energy under the stress-strain curves may cause much of this (Ref 24). Since IM7 fibers are similar in diameter and properties to IM6 fibers, similar effects can be expected.

Some influence over the extent of crystallinity is achieved by controlling the rate of cooling from the melt phase. Polyether etherketone has a characteristic limit of about 30% conversion to the semicrystalline state. Faster cooling can reduce the extent of crystallinity. While an increased level of crystallinity improves solvent resistance and strength, it also creates a more brittle material. A slow cooling rate of 1 °C/min results in a 40% reduction in fracture toughness of AS4/PEEK compared with fast cooling at 50 °C/min (Ref 24). For most parts this is good news with respect to processing because faster cooling means shorter cycle time. However, it also suggests that a very thick PEEK laminate might have properties that vary through the thickness.

Process temperatures, as well as cooling rates, have a significant influence on final morphology and the resulting properties. In carbon/thermoplastic polyimide composites, processing at temperatures above T_g caused reduction in and even irreversible loss of crystallizability (Ref 25). This same kind of behavior has also been reported for carbon/PEEK (Ref 10).

From this information it is clear that processing parameters, fiber size, and possibly fiber surface characteristics interact in the establishment of crystallinity. Together, these findings suggest that there is much yet to be determined about reinforcement, processing, and property interrelationships in thermoplastic composites.

Thermoplastic Resins

Lee McKague, Composites-Consulting, Inc.

Costs

Much has been said about the cost benefits of manufacturing thermoplastic composite parts; however, a more important consideration is matching the right material and process to the application. Thermoplastics, if not properly targeted and processed, can be much more expensive than thermosets. However, when properly targeted and processed, thermoplastics can offer extremely attractive cost benefits.

An example of missing the mark in touting thermoplastics has been the focus on not needing refrigerated storage or of not having out-life limitations. Although these are genuine benefits, they offer trivial cost savings against costs in an efficiently run thermoset manufacturing shop. Savings from eliminating refrigerated storage can quickly and easily be overwhelmed by significant losses in other areas.

One such area of potential cost liability is in lay-up. Throughout the history of composites, the largest recurring labor-cost contributor has been putting the composite material into the shape of the intended part. Basically, 40 to 60% of the total finished-part cost is involved in this portion of part fabrication. Ply-by-ply lay-up on a

contoured tool is a time-consuming process step. This is true when one is using thermoset material that has ideal tack qualities. When using thermoplastic material that has no tack, heat tacking of each ply easily can double or triple lay-up time.

Lay-up costs can be turned from liability to advantage by lay-up and consolidation of flat laminates, followed by thermoforming to the desired part shape. Flat laminate lay-up is quick and does not require ply-by-ply heat tacking. For small parts, the laminate can be large enough so that multiple copies of the required pattern blank can be cut from it after consolidation, as is illustrated by Fig. 3. To a significant degree, the labor involved in lay-up of material for one part provides laid-up material for other parts as well. Current methods and strategies, however, tend to limit such approaches to constant thickness laminates. Without internal part ply-drops, the inherent benefit from tailorability of composites is missed. Also, the shape of the part, together with elongation that might occur perpendicular to the fibers, must be geometrically compatible with a starting blank that is flat. Appreciable elongation parallel to the fibers does not occur.

Another strategy for conquering lay-up costs is to employ computer-controlled tape or tow placement machines. A heating device located at the roll nip, the place where the slit tape or tow meets the surface of the part being built, causes melting of the thermoplastic to a degree sufficient to achieve tacking and in situ compaction.

Although no rigorous cost-analysis studies are known to be publicly available at the time of this writing, it can be assumed that thermoplastics will benefit from automated placement methods as do thermosetting materials. A number of studies have shown that total manufacturing costs can be reduced 20 to 35% by use of automated material-placement machines. With thermoplastics, though, total savings from hot tape lay-up will be larger than with thermosets because compaction occurs during lay-up, and autoclave cure is not required.

Generally, production volumes must be substantial to effectively amortize the cost of automated placement equipment. Cost of such equipment can range from approximately $2 million to $7 million (U.S. dollars), depending on the size of the equipment required and the sophistication needed for process control. Most machines currently cost closer to the high end of this cost band.

Processing parts in an autoclave is another way to spend more money than would be required with thermoset composites. The high softening and melt temperatures involved with structural thermoplastics, and the higher consolidation pressures needed for compaction combine to require a more expensive autoclave and to complicate the recurring autoclave processing. Choices of vacuum-bagging materials are limited to more expensive products, and the reliability of sealing and survival is severely challenged.

Consequently, if one autoclaves an element or structure that will be joined to another element or structure by mechanical fastening, then there is more likely to be a cost disadvantage in using thermoplastics. In such a case, one would want to justify the material selection on the basis of some unique property or structural benefit. Thermosets have made great strides since the initial thrust toward thermoplastics, and some now offer most of the benefits available from thermoplastics.

If, however, the element or structure will be joined to another thermoplastic structure by fusion bonding, then the liability of having made the element or structure in an autoclave will be negated. In this case, the polymer in the elements or structures melts and joins them together in the same way that the plies in a laminate are fused and bonded together. Assembly of structural elements by mechanical fastening is time consuming and expensive. Usually it is more expensive than lay-up of the part. Fusion bonding, by comparison, is very cost effective and can enable a large reduction in total component costs.

In fact, the opportunity to unitize structural details, whether through autoclave processing or some other approach to manufacturing, is extremely significant (Ref 26). In Europe, Dassault Aviation, Eurocopter, and Aerospatiale are actively pursuing the use of thermoplastics for fabrication of unitized fuselage structure (Ref 27). This development involves automated fiber placement of PEEK tape, together with in-process fusion of skin and understructure details. An approach of this nature can yield extremely attractive cost advantages and damage resistance.

Of course, the thermoset community also is pressing toward the advantages of structural unitization. It now is feasible, and practical, to achieve with thermosets any assembly that might be pursued with thermoplastics. With care in the design approach, the result can be even lower in cost than with thermoplastics.

Properties

The thermoplastic resins discussed in this article can each be combined with a number of different fibers and fabrics. Glass and carbon fibers are the most prevalent choices.

Table 3 contains typical property values for polymers combined with 7781 style E-glass fabric. Polyether etherketone is not represented in this group, because its high performance and its comparatively difficult, high-temperature processing make it unattractive to combine with glass fabric. It has been used, however, with unidirectional S2 glass; Table 4 compares PEEK and PEKK properties for unidirectional S2 glass reinforcement.

Table 3 Properties of glass fiber reinforced thermoplastic-matrix composites (7781-8HS E-glass reinforcement)

Table 5 compares design properties of PEEK, PEKK, and PEI reinforced with unidirectional carbon fiber reinforcements. Polyetherimide and PPS resins have been extensively characterized with carbon fabrics. Table 6 contains typical property values for PEI and for PPS combined with both 5HS and plain-weave carbon fabrics (Ref 14, 15, and 16). Neither PEEK nor PEKK appear to have been well characterized with carbon fabrics, that is, with respect to design properties.

Environmental resistance of thermoplastics generally is quite good. Depending on the grade of the material, PEI may be much less resistant than PPS or PEEK. The most commonly used grade of PEI is Ultem 1000, which is soluble in chlorinated solvents such as methylene chloride and chloroform. In the late 1980s methylene chloride was being used by the Air Force as a paint stripper, so it was a significant detriment to consideration of PEI for military aircraft. Such use of methylene chloride has been discontinued.

Hydraulic fluid (Skydrol) also has been found to attack PEI. As a result, use of Ultem 1000 is confined to the interior of commercial aircraft such as Airbus A3XX. Another grade of PEI, Ultem D5000, is fairly inert with respect to hydraulic fluid. At this time, use of this grade has not become prevalent. Table 7 qualitatively compares the effects of various environmental agents on PEI (Ultem 1000), PPS, PEKK, and PEEK.

Table 7 Environmental resistance of selected thermoplastic resins

Environmental agent	PEI[a]	PPS[a]	PEKK[b]	PEEK[b]
Water or humidity	Good	Excellent	Excellent	Excellent
JP-4, JP-5 fuels	Excellent	Excellent	Excellent	Excellent
Hydraulic fluid (Skydrol)	Very poor	Excellent	Excellent	Excellent
Methylene chloride	Poor	Good	Excellent	Good
Methyethylketone	Poor	Excellent	Excellent	Excellent
Ethylene glycol	Good	Excellent	Excellent	Excellent

Note: PEI is Ultem 1000 Grade.

As indicated in Table 7, thermoplastics generally have excellent resistance to degradation effects from water, either immersed or from high humidity. They also have very good dielectric properties, making them useful for radomes. Thermoset materials are hygroscopic, and absorbed moisture causes a gradual shift in dielectric behavior, degrading performance.

Table 8 summarizes representative thermal properties of various thermoplastic composites.

Table 8 Thermal characteristics of carbon reinforced thermoplastics

Properties	T300/PEI[a]	AS4/PEEK[b]	AS4/PEKK[b]
Density, g/cm^3 (lb/in.^{3})	1.51 (0.055)	1.61 (0.058)	1.58 (0.057)
Specific heat, J/kg ·°C (Btu/lb ·°F)	1264 (0.302)	1100 (0.263)	860 (0.205)
Thermal conductivity

Applications

Work to apply thermoplastic composites to commercial aircraft has been underway since the early 1990s. An early application was the main landing gear door of the Fokker 50 aircraft (Ref 28, 29). Certification of this structure was completed in March 1998.

Thermoplastic composites are gaining recognition for their toughness and for attributes that can enable recurring cost savings. A wide variety of applications have been made that range from tertiary and secondary structures to primary structures that required Federal Aviation Administration (FAA) certification. An example of primary structure is the pressure floor panels of the Gulfstream V aircraft, which received certification in December 1996 (Ref 30).

To date, applications of thermoplastic composites have ranged from small, simple, structural details such as ribs or spars up to relatively large, unitized structures. Table 9 lists some of the applications that have been made. This list is intended to convey a sense of potential use and is not inclusive of all current applications of thermoplastics. In gathering this list it appears that the lower processing temperature, lower material cost, and amorphous character of PEI favor processing it into parts more so than the semicrystalline PPS or the higher-temperature PEEK.

Table 9 Applications of various polymers

Polymer	Applications
Polyetherketone ketone	RC-135 parabolic and blade radomes
Polyether	Airbus A320 vertical stabilizer brackets
etherketone	EH 101 helicopter floor
	F-117 rudder assembly
	F-22 weapons bay doors
	F-22 access covers

	OH-58D helicopter horizontal stabilizer
	Rafale engine tunnels
Polyphenylene	Airbus A330-200 rudder nose ribs
sulfide	Airbus A340 aileron ribs
	Airbus A340-500/600 fixed-wing leading-edge assemblies
	Airbus A340-500/600 inboard wing access panels
	Airbus A340-500/600 keel beam connecting angles
	Airbus A340-500/600 keel beam ribs
	Airbus A340-500/600 pylon panels
	Fokker 50 main landing gear door
Polyetherimide	737 smoke detector pans
	737/757 galleys
	747 stowage bins
	767 aircraft acoustical tile
	767 and other Boeing aircraft brackets
	Airbus A320 bulk cargo floor sandwich structural panels
	Airbus A330-340 lower wing fairings
	A3XX main stair case (developmental)
	Beluga heavy-duty entrance floor panels
	Dornier 328 landing flap ribs
	Dornier 328 ice protection plates
	Fokker 50 ice protection plates
	Fokker 50 trailing-edge wing shroud skins
	Fokker 70/100 structural floor panels
	Galleys on most commercial aircraft models
	Gulfstream G-V structural floor panels
	Gulfstream IV and V rudder ribs
	Gulfstream IV and V rudder trailing edges
	LearJet air steps
	M829E3 SABOT

Figure 4 illustrates the fixed wing leading edge assemblies of the Airbus A340-500/600. This is one of the largest thermoplastic structures made for aircraft exteriors. It is a cost-saving application representing the structural unitization potential enabled by the melt fusion characteristics of thermoplastics. Outer shell and rib stiffeners are fused together without use of mechanical fasteners.

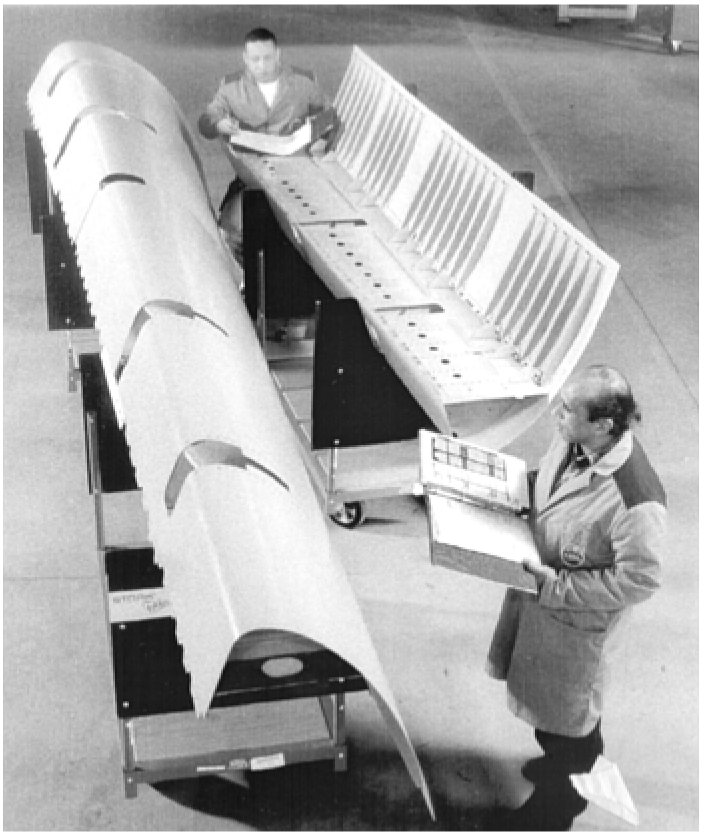

Fig. 4 Airbus A340-500/600 unitized, fixed-wing, leading edge (J-nose) assemblies. Courtesy of Fokker Aerostructures

As mentioned in the previous section, thermoplastics can maintain excellent dielectric properties during service because of their low moisture absorption. This stability has led recently to application of PEKK reinforced with 7781 style quartz fabric for radomes (Ref 31). Figure 5 illustrates a PEKK radome on the Air Force RC-135 aircraft.

Future Directions

It is clear that elevated-temperature structural performance requires a material with a high T_g or melt temperature. However, it also is clear that process temperatures required for high-temperature systems, such as PEEK, inhibit component manufacturing. This has been a retarding force that has slowed the progress of thermoplastics toward the wide acceptance and use in production applications that thermosets have enjoyed. Boardiness and lack of tack of the prepreg materials have made lay-up difficult and expensive. Because of such qualities it has not been possible to use thermoplastics in the same manner as thermosets. New strategies have been necessary, and this need has slowed progress and acceptance.

High nonrecurring costs for elevated-temperature manufacturing equipment, and high recurring costs for elevated-temperature manufacturing operations are detriments. Pursuit is questionable, then, of even higher temperature thermoplastics because of the potential for further negative impacts on equipment costs and recurring manufacturing costs. In the foreseeable future, therefore, principal work is likely to center on currently applied materials.

Based on these factors, conjecture about future development involving existing materials leads toward development of more cost-effective manufacturing methods. If thermoplastic composites are approached with the same perspective as for thermoset composites, thermoplastics usually will fail to deliver competitive costs. Hence, new design and manufacturing strategies will be required.

Heretofore, thermoplastic prepreg manufacturing limitations with fabrics have led to production of plywood-sized sheets. This has led to creation of plywoodlike laminates, sold to part fabricators. This has robbed designers of one of the most valuable aspects of composites: tailorability that involves internal buildups or ply-drops to reinforce selected regions of a part that will be most highly loaded. Some parts (relatively few) can be made effectively with constant thickness.

Whether at the prepregger or at the part fabricator's facility, there will need to be more effective means to lay-up tailored laminates. This need most likely will result in new forms of lay- up equipment. One form might be equipment that creates the equivalent of warp-knit materials such as are evolving with thermosets. Here, sheet material would be produced that incorporate ±45 orientations along with the traditional 0/90 orientations.

Another means to improve tailorability is toward less labor-intensive methods of laying up small components. These would be components that are not candidates for fiber placement and whose shape and performance requirements are not compatible with thermoforming of sheet material. This might lead to development and use of a flexible cobot, that is, a robot that is integrated into human operations—controlled by human operators and coordinated with their activities. After an operator has positioned a ply, such a device might help by forcefully holding the ply in place against a contoured tool while heating to fuse or spot tack it to the ply below.

An additional, obvious manufacturing endeavor is further improvement in fiber-placement machines and processes, moderation of capital equipment costs, and generalization of the kinds of components for which fiber placement is advantageous. The dynamics of in situ consolidation will need to be modeled and better understood.

Still another obvious effort is toward increased unitization of structures. An emerging example is Dassault's hot tape lay-up and fusion of thermoplastic skin over thermoplastic stiffeners. Melt fusion processing provides a means to eliminate the high costs of drilling and countersinking holes and of buying and installing fasteners.
Pursuit of approaches to increase the “pull- off” capability of a melt-fused member can be expected. Success in this might enable wider spacing of stiffeners, improving structural efficiency and further reducing costs.
Conjecture about the future also leads to development of new applications. The author suggests that use of thermoplastic composites may expand toward cryogenic applications, particularly for cryogenic tanks. Factors that may lead in this direction are: (1) some thermoplastic composites may be resistant to microcracking effects from cryogenic exposures (Ref 32), and (2) hot-head fiber placement or winding methods may enable more cost-effective manufacture of such tanks (Ref 33, 34).
The latter factor also may favor extending applications into a variety of additional parts that are bodies of revolution. Such parts might be used *as* bodies of revolution, such as fuselage structure, or, two or more pieces might be cut out of such a body to serve such functions as leading edges, fairings, and cowlings.

Molding Compounds

Introduction

MOLDING COMPOUNDS are plastic materials in varying stages of pellets or granulation that consist of resin, filler, pigments, reinforcement, plasticizers, and other ingredients ready for use in a molding operation. This article describes sheet molding compounds, bulk molding compounds, and injection molding compounds. Additional information about the resins and reinforcements used in these materials is provided in other articles in this Section. Detailed information on processing is provided in the Section “Manufacturing Processes” in this Volume (see, for example, the article "Compression Molding").

Sheet Molding Compounds

Sheet molding compound (SMC) refers to both a material and a process for producing glass-fiber-reinforced polyester resin items. The material is typically composed of a filled, thermosetting resin and a chopped or continuous strand reinforcement of glass fiber. The uncomplicated SMC processing machine (Fig. 1) produces molding compound in sheet form that is not unlike that of rolled steel. The size of the machine is designated by the width of the sheet it produces. Machine manufacturers generally offer a range of sizes from 0.6 to 1.5 m (2 to 5 ft), the most common being 1.2 m (4 ft).

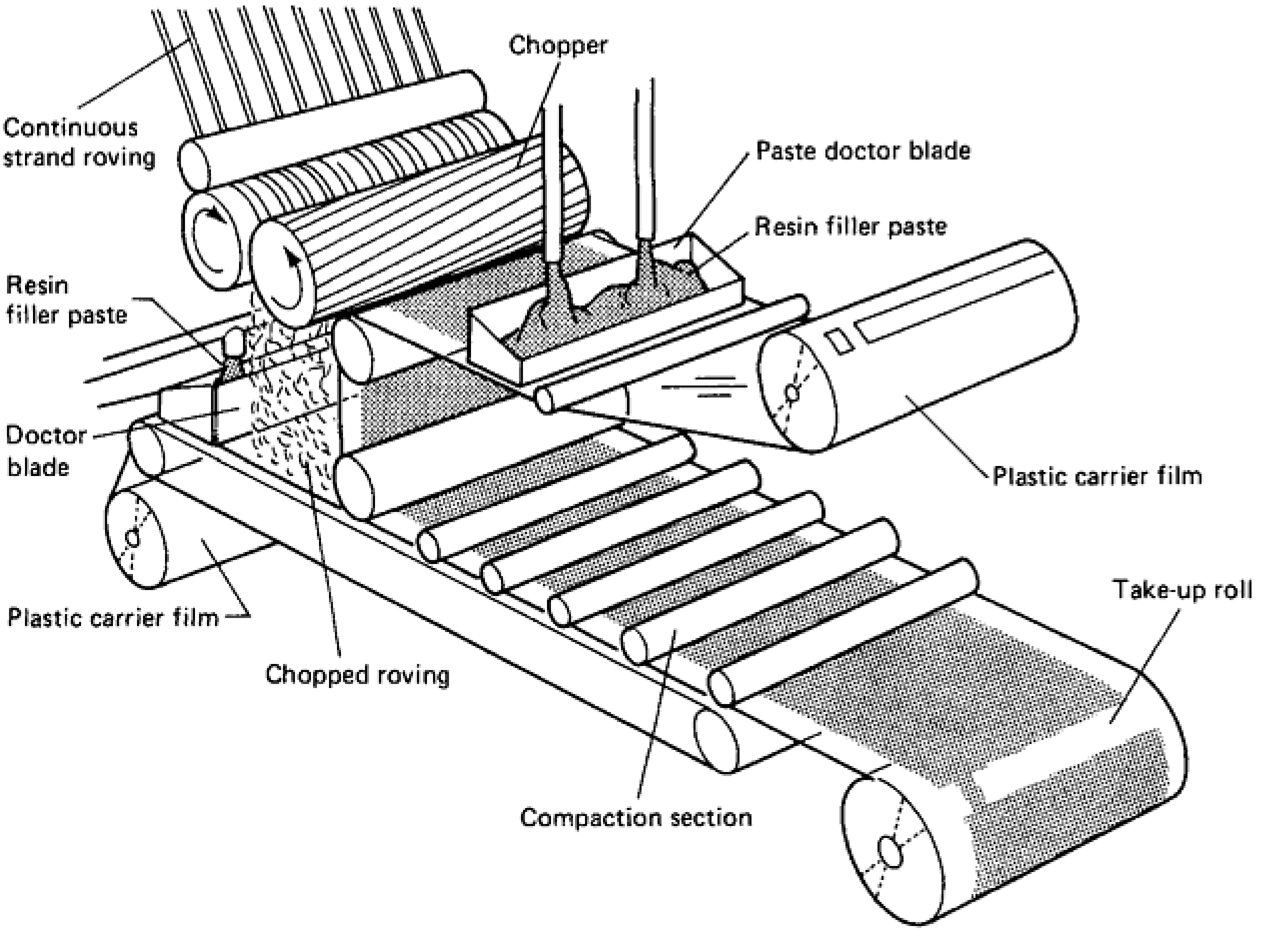

Fig. 1 Sheet molding compound processing machine

The process starts in the paste reservoir (below the chopper in Fig. 1), which meters a specified amount of resin filler paste onto a plastic carrier film. The paste consists of several ingredients, which can be changed to fit the particular needs of specific processing conditions and applications. The carrier film passes under a chopper, which cuts glass roving into 25 mm (1 in.) lengths. After the glass falls to the resin bed, another carrier film with another layer of paste is added on top, sandwiching the glass between the two layers.

When the paste is first mixed and put in the SMC machine, it has the consistency of pancake batter. After maturation, when the thickening agents have had the opportunity to react, the material attains the consistency of heavy putty or caulking compound. Once matured, all carrier film is removed, the SMC material is cut into charges, and the charges are placed in matched metal die molds made of machined steel. A high- tonnage hydraulic press then applies molding pressure. The application of heat and pressure causes the SMC to flow to all areas of the mold. Heat from the mold, normally 150 °C (300 °F), also activates the catalyst in the material, and cure or cross linking takes place. The part is then removed from the mold.

A number of advantages can be credited to the SMC compression molding process:

- High-volume production
- Excellent part reproducibility
- Low labor requirement per unit produced
- Minimum material scrap
- Excellent design flexibility (from simple to very complex shapes)
- Parts consolidation
- Weight reduction

Material Components

With an unsaturated polyester resin system as its base, the resin paste incorporates other materials for desirable processing and molding characteristics and optimal physical and mechanical properties. Glass-fiber reinforcements improve the performance of polyester by upgrading mechanical strength, impact resistance, stiffness, and dimensional stability. Other additives are catalysts, fillers, thickeners, mold release agents, pigments, thermoplastic polymers, polyethylene powders, flame retardants, and ultraviolet absorbers, all of which are mixed by the SMC manufacturer to exact proportions for specific resin paste formulations. Some ingredients, such as release agents and thermoplastic syrups, can be added by the resin supplier. As described below, each additive provides important properties to the SMC, either during the processing and molding steps or in the finished parts. Additional information on additives provided in Ref 1.

The catalyst initiates the chemical reaction (copolymerization) of the unsaturated polyester and monomer ingredients from a liquid to a solid state. This is the primary purpose of a catalyst. Heat from the mold causes the catalyst to decompose, which activates the monomer and polyester to form cross-linked thermosetting polymers.

Catalysts are only a small part of an SMC resin formulation. Generally, the addition of 0.3 to 1.5 wt% of catalytic agents will adequately promote the cross-linking reaction. Organic peroxides are the principal catalysts used for SMC resin pastes. The temperature at which the curing process is to be carried out usually determines the selection of a catalyst. For any given catalyst- resin system there is an optimal temperature at which peroxide decomposition initiates the monomer-resin polymerization process. Since SMC is usually molded at temperatures of 132 to 165 °C (270 to 330 °F), catalysts that are the most effective as polymerization initiators over this temperature range are the ones used most often.

Fillers enhance the appearance of molded parts, promote flow of the glass reinforcement during the molding cycle, and reduce the overall cost of the compound. Commonly used fillers include calcium carbonate, hydrated alumina, and clay. Calcium carbonates are readily available and can be added to polyester resin in large amounts, while still maintaining a processable paste. They assist in reducing shrinkage of the molded parts and in distributing glass reinforcement for better strength uniformity. Hydrated alumina fillers are incorporated in SMC formulations to provide flame retardancy while maintaining good electrical properties. They are used in most electrical and appliance applications and in some construction applications where material requirements call for specific Underwriters' Laboratories (UL) standards established for flame spread, burning, and smoke density. Kaolin clays are sometimes combined with calcium carbonates or hydrated aluminas. When they represent 10 to 20% of the total filler weight, the clays serve to control paste viscosity, promote flow, and improve resistance to cracking in molded parts.

Thickeners include calcium and magnesium oxides and hydroxides. They initiate the reaction that transforms the mixture of SMC ingredients into a handleable, reproducible molding material. Usually 1 to 3% of the SMC resin formulation is thickener. It is the final ingredient added to the resin mix, and it begins the chemical thickening process immediately.

The thickening reaction must:

- Be slow enough to allow wet-out and impregnation of the glass reinforcement
- Be fast enough to allow the handling required by molding operations, as soon as possible after the impregnation step, in order to keep storage inventories low
- Give a viscosity at molding temperatures that is low enough to permit sufficient flow to fill out the mold at reasonable molding pressures
- Give a viscosity at molding temperatures that is high enough to carry the glass reinforcement along with the resin paste as it flows into the mold
- Level off in the moldable range to give a long shelf life

A typical thickening curve is shown in Fig. 2.

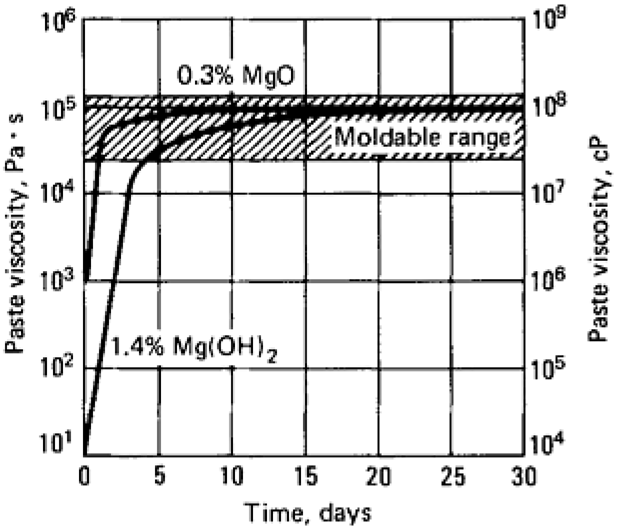

Fig. 2 SMC paste thickening curve

Release agents are common components of SMC formulations. They are selected on the basis of their melting points being just below that of the molding temperature. In theory, the release agent at the molding compound-mold surface interface melts upon contact and forms a barrier against adhesion.

Commonly used internal release agents include zinc stearate, calcium stearate, and stearic acid. Zinc stearate has a melting point of 133 °C (272 °F) and can be used at molding temperatures up to 155 °C (310 °F). Calcium stearate, with a higher melting point of 150 °C (302 °F) can be used at molding temperatures up to 165 °C (330 °F). Stearic acid should be used only if molding temperatures are below 127 °C (260 °F).

Mold release agents must be used at the lowest concentration possible to do an adequate job, which normally is a concentration less than 2 wt% of the total compound. Excessive amounts can reduce mechanical strength, cause objectionable cosmetic appearance on the molded part surface, and affect paint and/or bond adhesion characteristics.

Pigments are supplied as either dry powders or paste dispersions. Two advantages of paste dispersion pigments are that there are fewer agglomerates in the SMC resin paste and that they can be added at lower concentrations than dry powders. Pigment concentration generally is 1 to 5 wt% of the resin paste. Pigments can affect the cure time and shelf life stability of SMC systems and may accelerate or inhibit the reactivity of the catalyst-resin system. Thus, preevaluation of the reactivity of a specific pigment is essential.

Thermoplastic polymers are combined with polyester resins to achieve low polymerization shrinkage for many SMC applications. Shrinkage is primarily controlled by varying the polyester/thermoplastic ratio. It is possible to attain near-zero shrinkage in molded parts when thermoplastic polymers are added to polyester resins at concentrations of 40 wt% of the total resin system.

There are a number of thermoplastic additives that are compatible with polyester resins developed for SMC low-shrink and low-profile systems. Among those in use are acrylics, polyvinyl acetate, styrene copolymers, polyvinyl chloride (PVC), PVC copolymers, cellulose acetate butyrate, polycaprolactones, thermoplastic polyester, and polyethylene powder.

Flame Retardants. As a filler, hydrated alumina compounds normally satisfy most UL requirements, but more stringent flammability classifications necessitate the use of flame-retardant additives. These additives are used in conjunction with hydrated alumina fillers and halogenated polyester resins to provide maximum retardancy performance. Flame-retardant additives recommended for SMC are antimony trioxides, tris (2,3,-dibromopropyl) phosphates, chlorinated paraffins, and zinc borates. Two of these additives are often combined at 1-to-1. ratios to offer more selective properties. About 3 to 5% of the SMC formulation consists of these additives.

Ultraviolet (UV) absorbers can be added to SMC resin blends when the molded parts need to withstand extended exposure to sunlight. Generally, SMC resins are stabilized with approximately 0.1 to 0.25% of UV absorber of the benzotriazole or benzophenone type.

Physical Properties

The typical SMC properties shown in Table 1 represent a broad range of data on composites having 15 to 30% glass reinforcements. Many of these properties were tested on specific SMC formulations to better define their suitability for various end-product applications. Standard test methods, developed by ASTM and others, were used. Mechanical properties were obtained on both dry (as-molded) and wet (2 h submersion in boiling water) test specimens. Additional properties normally reported on dry specimens include Izod impact (notched and unnotched), Barcol hardness, water absorption, and heat distortion.

Table 1 Typical mechanical properties for sheet molding compounds with 15 to 30 wt% glass fiber

Tensile modulus, GPa (10^6 psi)	**11–17 (1.6–2.5)**
Tensile strength, MPa (ksi)	55–138 (8–20)
Elongation at failure, %	0.3–1.5
Compressive strength, MPa (ksi)	103–206 (15–30)
Flexural modulus, GPa (10^6 psi)	96–138 (1.4–2.0)
Izod impact strength, notched, J/m (ft · lbf/in.)	430–1176 (8–22)
Dielectric strength, kV/cm (V/mil)	120–160 (300–400)
Heat distortion temperature, °C (°F)	150–205 (300–400)
Thermal conductivity, W/m · K (Btu · in./h · ft^2·°F)	0.19–0.25 (1.3–1.7)
UL flammability class, V	945
Rockwell hardness number	H50–H112
Specific gravity	1.7–2.1
Density, g/cm^3	1.7–2.1
Coefficient of thermal expansion, 10^{-6}/K	15–22

It should be noted that most standardized laboratory tests are, at best, a simplification or approximation of what may happen to a finished part in use. The shape and dimensions of the test specimens and the procedure by which they are molded practically never duplicate those of any end product.

Mixing Techniques for SMC Resin Pastes

The three types of resin paste mixing techniques for an SMC operation are batch, batch/ continuous, and continuous.
Batch mixing is an economical method adequate for preparing small amounts of resin paste for short production runs or for evaluating an experimental formulation. All raw materials can be mixed in a single mixing unit. The disadvantages are:

- Material efficiencies are low (generally considered to be 85% or less); the resin paste often becomes too thick for good wet-out of the glass.
- Batch-to-batch variations of the resin paste can lead to SMC inconsistencies.
- Additional manpower is required to make the paste and deliver it to the SMC machine.

The SMC supplier generally can justify a more automated resin-mixing system if large quantities of material are to be produced.
Batch/continuous mixing has these primary advantages over the batch system:

- More reproducible resin paste thickening
- Higher material efficiencies
- Less manpower

This mixing technique normally employs two tanks, A and B, one for holding the thickenable resin bath mix (A) and the other for holding the thickener material or component in a nonthickenable resin mix (B). A metering pump or cylinder is used to proportion each side of the paste system and simultaneously pump the paste through a static or dynamic mixer to the paste doctor (metering) blades. Batch-mixing equipment for each

paste side is still required in this system, but the combined A and B resin paste delivered to the machine has marked improvement in reproducibility.

Continuous mixing eliminates a separate resin paste mixing facility, which is its biggest advantage over the batch/continuous mixing system. Predetermined amounts of the liquid ingredients are individually pumped into a continuous mixer. The dry ingredients can be preblended or fed individually by automatic-metering equipment into the same continuous mixer. The amount of thickened resin paste in the continuous mixer can be kept to a minimum level for delivery to the SMC machine. Better control of the resin mix is accomplished, because reproducible pumping and metering rates are used. The continuous-mixing system also provides higher material efficiencies than either the batch or batch/continuous system. A change of resin formulation of the normal clean-up operation wastes only a small amount of material. Only the head of the mixer requires cleaning (flushing) with a suitable solvent, whereas in the batch/continuous system, all lines must be flushed, which involves more cleaning time and greater material waste. Water jacketing of the continuous-mixing head in an automatic system offers temperature control, thereby maintaining a more reproducible resin paste. The temperature of the resin mix is critical in viscosity control, with 32 °C (90 °F) at the time the thickening ingredient is added considered optimal. The continuous-mixing system (Fig. 3) is best for long runs. The length of set-up time makes short runs of various formulations impractical.

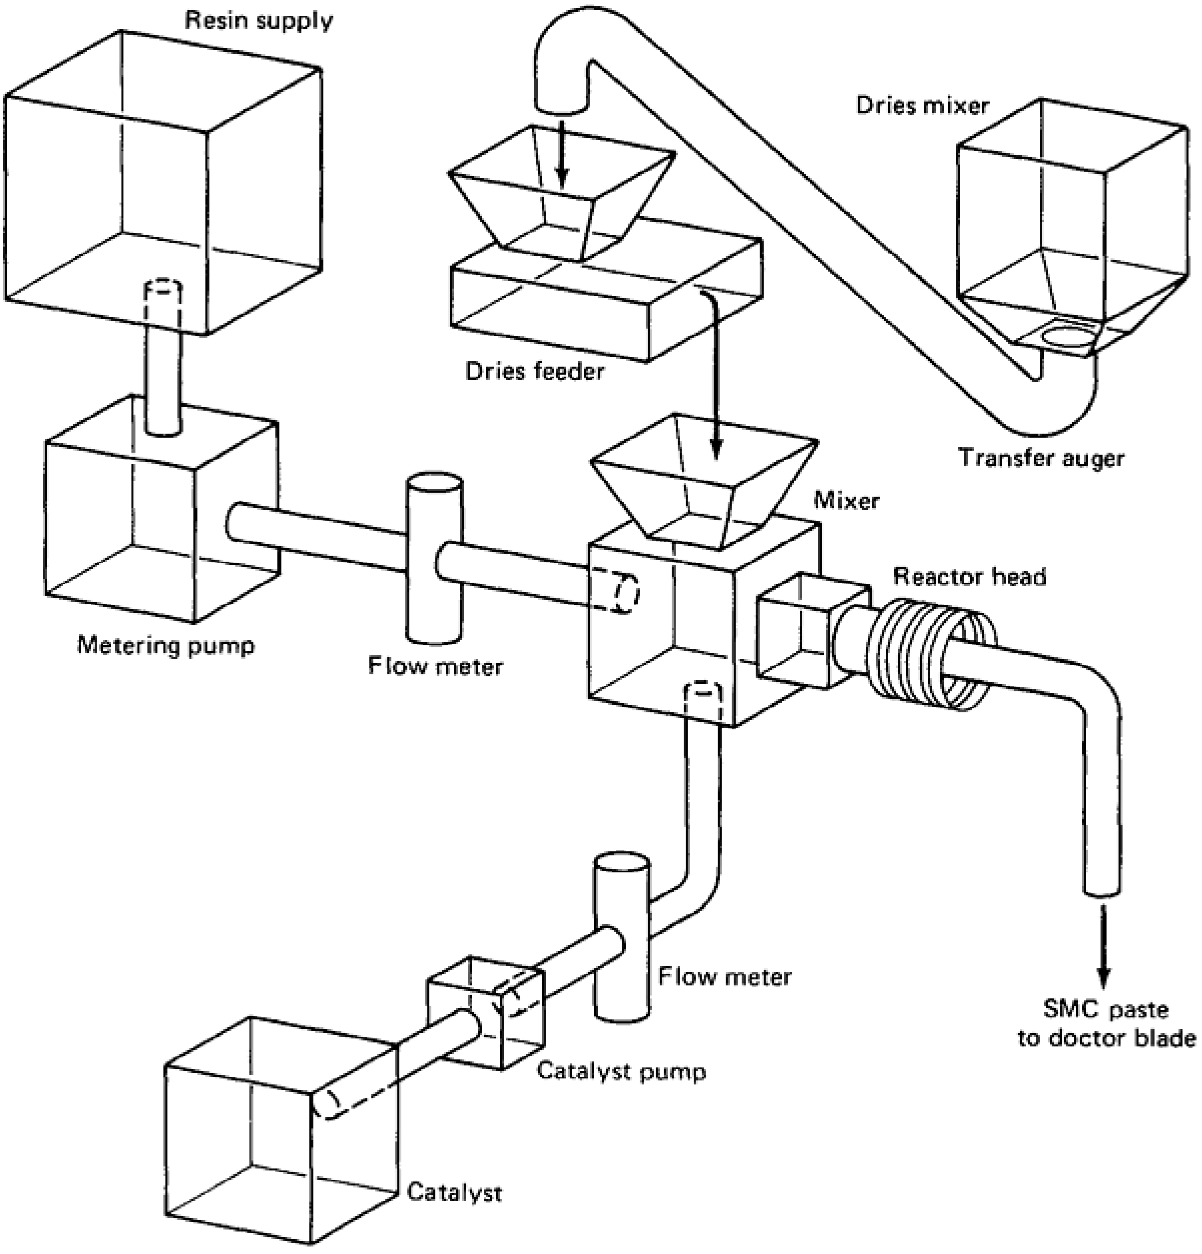

Fig. 3 Continuous SMC paste mixing system

SMC Machines

The two most common types of SMC machines are the continuous-belt and the beltless machines. Each type has unique design features, although the functional operations of both are very similar (see Fig. 1). Both types can handle chopped roving or chopped and continuous strand mat glass reinforcements.

Paste Metering. There are two adjustable paste doctor blades (Fig. 4) on the SMC continuous-belt machine, which meter a predetermined thickness of resin paste onto upper and lower carrier films of (usually untreated) polyethylene that is 0.05 mm (0.002 in.) thick. Paste doctor blades are adjustable for both product width and thickness. They are rigid blades positioned vertically to the belt and are beveled to a fine edge on the side of the belt away from the paste flow. The bevel makes the metering of the paste less sensitive to viscosity and temperature variations.

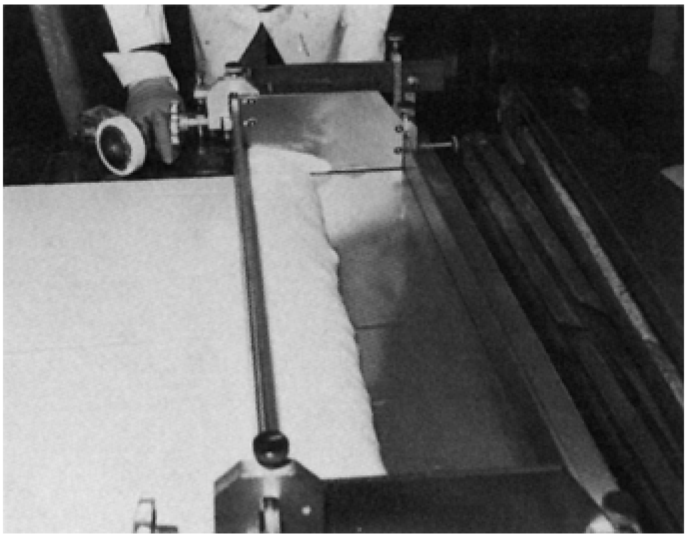

Fig. 4 Adjustable paste metering blades

The amount of resin paste in the final SMC product is determined by the height adjustment of the paste doctor blades. The speed of the machine and viscosity of the resin formulation have been found to have little or no effect on the paste distribution. Figure 5, which shows the relationship of paste weight to paste doctor blade settings, is representative of the settings for each of the two paste doctor blades when a typical SMC resin paste formulation (1.5 to 1 filler ratio) is used.

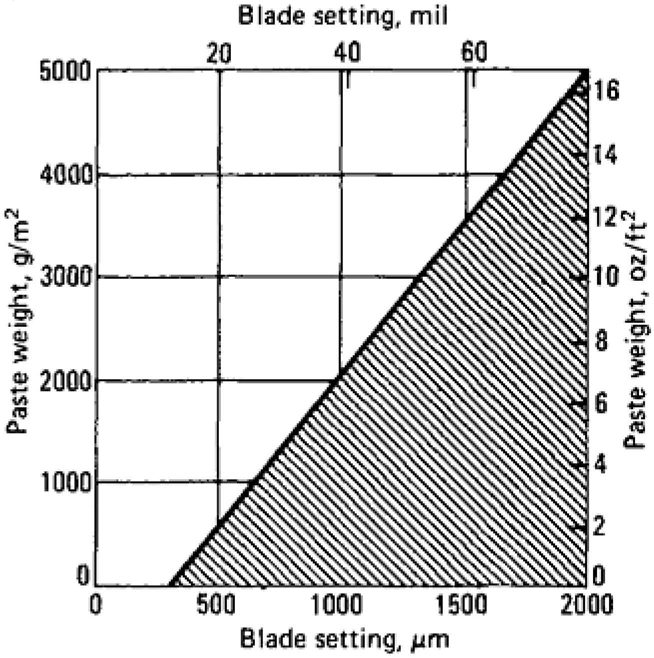

Fig. 5 Paste metering blade setting versus resin paste weight for typical SMC formulation

Compaction. After the materials are brought together, they go through a compaction section to help push the resin paste through the glass to ensure wet-out of the glass. The two designs commonly used for compaction sections are serrated steel rollers and a chain belt.

Serrated Steel Rollers. This type of compaction system consists of three series of serrated steel rollers. The first series initiates the wet-out process, the second more intimately compacts the partially wet-out sheet, and the third completes the wet-out. There are a number of roller designs that do an adequate job of compacting the glass-resin sheet, but one particularly popular design uses grooved, spiral-cut roller flutes to force the resin paste into the glass pack with some lateral movement. Usually the rollers are pneumatically adjustable so that they can be set for maximum pressures (equal at each end) without causing shifting of the fibers or buildup of resin paste.

Chain Belt. New machines can be equipped with one or two dual wire mesh belt compaction modules. The two-dual module unit supports the sheet of SMC on both sides with a flexible wire mesh as it follows a sinusoidal path through the unit. The two modules have different mesh sizes in order to increase the range of materials that can be compounded, with the upstream module having a coarser mesh than the downstream module. The reasoning behind this is that a coarse mesh forces the resin paste to the center of the glass layer, and the fine mesh spreads the paste evenly through the layers. The compaction modules can also impart an oscillating motion to the movement of the upper belt to aid wet-out.

Take-up. SMC production machines are normally equipped with a dual turret take-up system for continuous operation, although festooning into 1350 to 1800 kg (3000 to 4000 lb) boxes is becoming more popular. The speed of the turrets is controlled by a weighted dancer roll that automatically adjusts to the correct tension as the SMC roll diameter increases. Electronic devices can be used to provide torque control on the wind-up mandrel.

When a full roll of SMC is ready, the sheet is cut and transferred to the second wind-up turret. The full roll is taped to prevent unwinding, and a vapor barrier sleeve is applied. The sleeve film can be any material, such as aluminum foil or monomer resistant film, that can contain the styrene monomer in the SMC and prevent UV light or moisture contamination. SMC rolls may vary in weight, but for shelf life stability and/or shipping in cardboard boxes, a weight of about 450 kg (1000 lb) per roll is considered the maximum. Sheet molding compound rolls for in-house storage and subsequent molding are suspended on racks that are mounted on wheels or designed for transporting by forklift vehicles.

Maturation Room Environments. A common practice among SMC processors is to condition their products in a temperature-controlled environment, known as a maturation room, to provide a uniform, reproducible viscosity for sheet molding. Maturation rooms are usually maintained at temperatures in the range of 29 to 32 °C (85 to 90 °F). Storage times may vary from 1 to 7 days, depending on the resin formulations. Maturation of most SMC formulations requires approximately 3 days.

Output and Feed Requirements. A single SMC machine can satisfy the material requirements of many molding presses. At 100% efficiency and continuous operation, one 1.2 m (4 ft) SMC machine can produce 11×10^9 g (25×10^6 lb) of molding compound per year.

Bulk Molding Compounds

Bulk molding compounds, or fiber-reinforced thermoset molding compounds, represent the original engineering plastic materials. Phenolic molding compounds reinforced with cellulose fibers were developed by L. Baekeland early in the twentieth century. Fiberglass reinforcement and polyester, melamine, and epoxy resin

systems extended the range of thermoset material capabilities. More recent developments of carbon and aramid fibers and of polyimide and silicone matrices offer further enhancements of the engineering properties that are available in thermoset molding compounds.
Thermoset materials reinforced with long fibers offer excellent engineering properties in a moldable material. Bulk molding compounds can be molded into a variety of complex shapes by methods that can be readily automated for high-volume production. At the same time, their engineering properties can approach those attainable with continuous fiber-reinforced composites.

Formulation

There is a general similarity in the many formulations of bulk molding compounds. However, because of the wide variety of reinforcements, thermoset resins, and additives available, a multitude of compounds can be tailored for a variety of uses. Most compounds consist of:

- Resin matrix, with the necessary hardeners, catalysts, and plasticizers to make a moldable composition capable of curing
- Fiber reinforcement
- Additives, such as colorants, lubricants for mold release, and others for special properties, such as flame retardancy, dimensional stability, and crack resistance

Processing

Just as there are many formulations, there are many ways to compound and process the requisite raw materials into a bulk molding compound. These methods influence the final physical properties. Minimizing damage to the fiber reinforcement during processing is a key factor in maintaining optimal-strength properties.
Compound Preparation. One of the most common processing methods is the use of the sigma blade mixer. With this method, fiber reinforcement is charged to the mixer in prechopped form. Resin matrices are added in liquid form, such as polyester resins dissolved in styrene, or a varnish solution of resin (such as a phenolic) dissolved in methanol. With polyester bulk molding compound, the material is ready to mold when it is discharged from the mixer. With material made from a varnish, the solvent has to be volatilized and the resin advanced to a moldable viscosity.
Other methods of manufacture are used to obtain a longer chop length or a higher loading of reinforcement. One method is to pull reinforcement from a roving form through a dip tank of resin varnish, evaporate the solvent, and chop to length. Prepreg fabric can also be diced or chopped, with fabric used as the reinforcement. The resultant fabric is in a macerated form.
Molding Methods. Bulk molding compounds are processed by compression, transfer, and injection molding. Compression molding is used for large parts and wherever strength is critical to a molded part. This molding method causes the least amount of damage to reinforcing fibers, and in some cases, the orientation of the fibers can be predetermined.
A particular use of transfer molding is to mold inserts into the part, by prepositioning them in the mold prior to the transfer operation. Transfer molding is also used to ensure accurate dimensions in the end part and reduce cleanup of molded flash.
Injection molding is capable of the highest degree of automation and lowest processing cost. Special techniques are needed to feed the bulky materials into the injection machine. This process is not widely used for bulk molding compounds because of the poor flow characteristics of many compounds.
Properties A discussion of the effects of fiber type and length and matrix type on thermoset bulk molding compounds follows.
Effect of Fiber Type. The translation of fiber properties to bulk molding compounds that use the same matrix, fiber length, and percentage of fiber but different types of fiberglass, carbon, and aramid fibers, is shown in Table 2. Specific gravity, as might be expected, translates well with the fiber properties. Tensile and flexural strengths, and flexural modulus especially, also closely follow fiber properties. However, compressive-strength properties show a distinct pattern of higher values produced by fiberglass reinforcement, followed by polyacrylonitrile- (PAN-) based carbon-fiber materials. Aramid- fiber compounds have lower compressive-strength values. PAN-based carbon fibers, being brittle, demonstrate the lowest Izod impact strength. Glass

fibers have higher elongation values than aramid fibers, but are notch sensitive. The toughness of aramid fibers is demonstrated by their higher impact values; the difficulty encountered in cutting aramid fibers is demonstrated by this property.

Table 2 Properties of composite materials molded from bulk molding compounds

Material			Typical values

Aramid	Kevlar 29	Epoxy	1.33	53	49	110	16	270	39	19	2.8	130	19	2.1	40

Effect of Fiber Length. Generally, the longer the fiber reinforcement, the higher the physical properties. Typical lengths range from 3.2 to 50 mm ($\frac{1}{8}$ to 2 in.), with 3.2 mm ($\frac{1}{8}$ in.), 6.4 mm ($\frac{1}{4}$ in.), and 12.7 mm ($\frac{1}{2}$ in.) predominating. The tensile, flexural, and particularly the impact strength properties show great improvement with increasing fiber length. Modulus values also show improvement with increasing length, but to a lesser degree than strength values.

The values for strength and modulus properties listed in Table 3 were obtained from compression molded test specimens. Partial orientation of the fiber reinforcement is obtained by mold geometry and resin flow. Orientation of the fiber reinforcement can be used with long fiber- reinforced bulk molding compounds to enhance performance in molded parts.

Effect of Matrix. Epoxy is used whenever the best structural performance is required, and polyimide is used when higher temperature performance is a criterion. Phenolics are used for their good heat-resistant and flame-retardant properties. Polyester is used in electrical applications that require high arc track resistance. Silicone does not offer good structural properties, but is used in applications where temperatures requiring continuous exposure up to 300 °C (570 °F) are needed.

The comparison in Table 4 of properties of bulk molding compounds reinforced with 12.7 mm (1/2 in.) chopped fiberglass measured at room temperature shows that an epoxy matrix yields the best structural properties. Polyimide and phenolics are close in their performance at room temperature. The slight advantage of polyimide improves with increasing temperature. Polyester offers good performance in electrical applications. Silicones, although unimpressive at room temperature, maintain their mechanical properties at temperatures up to 300 °C (570 °F).

Injection Molding Compounds

Injection molding compounds are thermoplastic or thermosetting materials and their composites, which are specifically formulated for the injection molding process. This process requires materials capable of being fed into a molding machine, transported to accumulate pressure, injected through channels, and made to flow into a small opening in the mold. The process may cause major changes in both the physical and chemical properties of the molding compound. Because of their resistance to flow, neither high- molecular-weight resins nor long reinforcing fibers, or flakes, can be effectively manipulated through the molding process. Consequently, parts produced from molding compounds represent a compromise between optimal physical properties and the essential ability to flow under pressure. This compromise is offset by the ability to produce three-dimensional products with holes, ribs, and bosses, often without secondary operations or direct labor.

While the flow process has the potential to physically change the molding compound, these changes are not always negative. Improved homogeneity, better reinforcement wetting, and higher physical properties may be achieved if the response of the molding compound to the injection process conditions is well understood. Where this understanding is absent, reinforcements may be broken, and polymers may be either degraded or prematurely cured. This article focuses on enhancing the general understanding of the forces that these compounds encounter in the injection molding process, rather than on the thousands of commercially available molding compounds. Table 5 itemizes the more common thermoplastic and thermosetting molding compounds and indicates where, within the four subprocesses of injection molding, specific formulations demand special care or attention.

Table 5 Common thermoplastic and thermoset molding compounds

Base polymer	Principal applications	Potential subprocess problem areas			
		Feeding	**Transporting**	**Injecting**	**Flowing**
Thermoplastics					
ABS	Furniture, cabinets, containers, trim	(b)	(h)(i)	(k)(l)(n)(o)	(q)
Acetal	Clock gears, miniature engineered parts	(b)	(f)(h)(i)(j)	(o)	(p)(s)
Acrylic	Automobile light lenses, plastic glazing	(b)	(h)(i)	(k)(l)(n)(o)	(q)
Cellulose	Esters trim, moldings, screwdrivers	(b)	(h)(i)	(k)(l)(n)(o)	(q)(r)
Polycarbonate	Auto bumpers, traffic lights, lenses	(b)(c)	(f)(h)(i)(j)	(k)(l)(n)(o)	(q)
Polyester	Appliance parts, pump and electrical housings	(b)(c)	(h)(i)(j)	(o)	(p)(s)
Polyethylene	Houseware, food storage, dunnage	(b)	(i)	(o)	(p)
Fluoroplastics	Corrosion/solvent-resistant parts	(b)(c)	(f)(i)(g)	(k))(l)(n)(o)	(q)
Polyimide	Aerospace items, electrical insulators	(b)(c)	(h)(i)(j)	(k)(l)(n)(o)	(q)
Ionomer	Bumper rub strips, golf ball covers	(b)	(h)(i)	(k)(l)(n)(o)	(p)
Nylon	Auto parts, bearing retainers, appliances	(b)(c)	(h)(i)(j)	(o)	(p)(s)
Polyphenylene oxide and alloys	Auto instrument panels	(b)	(h)(i)(j)	(k)(l)(n)(o)	(q)(r)
Polypropylene	Battery cases, auto parts,	(b)	(h)(i)	(o)	(p)(s)

	containers				
Polystyrene	Toys, advertising displays, picture frames	(b)	h)(i)	(k)	
Polysulphone	Camera cases, aircraft parts, connectors	(b)(c)	(h)(i)(j)	(k)(l)(n)(o)	(q)
Polyvinyl chloride	Soft steering wheels, trim items	(b)	(f)(h)(i)(j)	(k)(l)(n)(o)	(q)(r)
Thermosets					
Alkyd	Switches, motor housings, pot/pan handles	(a)(b)	(g)(h)(i)(j)	(k)(l)(m)(n)(o)	(q)(r)(s)(t)
Allyl	Electrical connectors, circuit boards	(a)(b)	(g)(h)(i)(j)	(k)(m)(n)(o)	(q)(r)(s)(t)
Epoxy	Electrical insulators, electronic cases	(b)(e)	(g)(h)(i)(j)	(k)(l)(m)(n)(o)	(q)(r)(s)(t)
Polyester	Automotive structural parts	(d)(e)	(g)(i)(j)	(k)(l)(m)(n)(o)	(p)(q)(r)(s)(t)
Polyimide	Aircraft components, aerospace parts	(a)(d)(e)	(g)(h)(i)(j)	(k)(l)(m)(n)(o)	(p)(q)(r)(s)(t)
Melamine	Dinnerware, microwave cookward	(b)	(g)(h)(i)(j)	(k)(l)(m)(n)(o)	(q)(r)(s)(t)
Phenolic	Distributor caps, plastic ash trays	(a)(b)	(g)(h)(i)(j)	(k)(l)(m)(n)(o)	(q)(r)(s)(t)
Urethane	Automotive body panels, bumpers	(a)(d)(e)	(g)(i)	(l)(m)(o)	(q)(r)(t)
Vinyl ester	Composite car/truck springs, wheels	(b)(d)(e)	(g)(i)(j)	(k)(l)(m)(n)(o)	(p)(q)(r)(s)(t)

(a) Moisture may chemically react to degrade the polymer base.
(b) Drying is recommended to avoid splay in molded product.
(c) Drying is essential to prevent molecular weight attrition.
(d) Drying may volatilize monomers essential to the curing reaction.
(e) Fiber reinforcement breakage may occur during force feeding.
(f) Overheating may cause explosive depolymerization.
(g) Overheating may cause premature curing of (thermoset) compound.
(h) Venting is recommended to remove volatiles and reduce splay.
(i) Fiber reinforcement lengths may be severely reduced.
(j) Overheating may produce chemical changes in the base polymer.
(k) Fast injection of the molding compound can lead to serious overheating.
(l) Filled or reinforced compounds will exhibit much higher viscosity.
(m) Open runners required because material can cure in closed channels.
(n) Melt fracture may occur with high injection speed.
(o) Fiber-filler orientation will occur if molding compound is reinforced.
(p) Major sink marks may develop if part sections are thick, not uniform.
(q) Weak knitlines may develop if compound packing pressure is low.
(r) Large mold vents recommended to allow volatiles to escape.
(s) Hot molds required to promote cure, crystalline growth.
(t) Curing reaction may produce peak exotherm, leading to degradation.

The injection process (Fig. 6) may be divided into four specific zones in which the molding compound properties may be changed. These zones, which correspond to the four injection molding subprocesses, are:

- Feeding the molding compound into the molding machine
- Transporting and melting the compound, while developing pressure
- Injecting the molding compound through runners and gates
- Flowing the molding compound material into the mold cavity

Within each of these areas, several forces may combine to affect one molding compound in a manner entirely different from the way they affect another. The uniformity of a thermoplastic may be improved by the combination of shearing forces and heat, while the fibrous reinforcement of a thermoset molding compound

may be broken, or the polymers may be prematurely cured. An extremely high shear rate may be beneficial to an unfilled polymer blend or alloy, but similar conditions might cause another molding compound to flow unevenly.

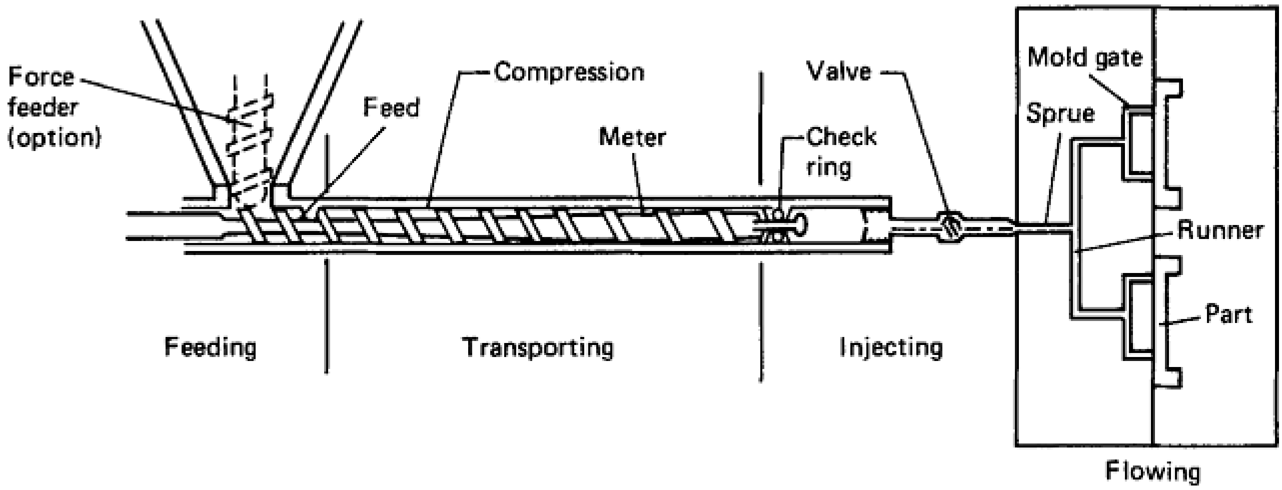

Fig. 6 The tortuous path of injection molding compounds

Plastic resins obtained directly from a chemical reaction rarely exhibit the properties that are essential to meet the flow requirements for feeding into injection machines. Therefore, a separate compounding operation is used to convert the form of a resin while also introducing the stabilizers, lubricants, reinforcements, filters, and even the pigments that will constitute the final injection molding compound formulation. During this operation, the molding compound resin may be exposed to heat, shearing forces, and ambient moisture. Most "virgin" molding compounds carry a history of these events. The nominal molecular weight distribution, length of the reinforcement (if one is used), and moisture content may vary as a result.

In most cases, the chemical effects are slight and would require precision analytical instruments to detect. It is wise, however, to monitor the consistency of the average molecular weight of the "as received" molding compound, using ASTM D 1238 (Ref 2), ASTM D 3123 (Ref 3), or gel-permeation chromatography.

Because fiber length may be dramatically reduced during compounding (Ref 4) some compounders of glass- or carbon-fiber composites coat the strands of fibers with coupling agents or molten/fluid ingredients and chop them into pellets of the desired length to ensure a specific fiber length in the "after compounding" product.

Moisture will usually interfere with thermoset curing reactions. Compounding, unless done in controlled environments, may introduce extreme moisture content variations between the extremes of dry winter periods and humid summer days. Thermoplastic molding compounds are often produced as extruded strands and quenched in water. The moisture content of thermoplastics produced in this manner may vary, based on the efficiency of the compounder's driers and the moisture-sealing effectiveness of the shipping containers. Thermoplastic molding compounds should be dried before feeding. At the very least, moisture can affect surface quality, cause steam erosion of the mold, or interfere with the curing reaction. At worst, moisture can actually interfere with polymerization, and hence diminish the molecular weight of certain condensation thermoplastics, such as nylon, polycarbonate, or polyester, or consume vital cross-linking sites in thermoset compounds, such as urethanes. Hopper driers and routine quality assurance tests are usually all that is required to ensure that compounding has not already changed the chemistry of the plastic.

Feeding thermoplastic, thermoset, or composite molding compounds is greatly facilitated when they are in the form of dry, free-flowing pellets. However, if this is not the case, the feeding process may cause variations in both the base polymer and any reinforcements. Typically, the molder will elect to integrate some or all of the compounding operations into the feeding and transport processes. The injection of liquid pigments, cointroduction of glass fibers and thermoplastic pellets, and building of a bulk molding compound at the press are examples of this dual- process integration. While economically feasible, compounding integration during the molding process should not be attempted without a solid understanding of the underlying effects on a molding compound.

Molding compounds that are sticky, rubbery, or powdery present feeding problems that often require specialized prefeeders. Force-feeding units may be employed, although the potential improvement in mixing may be outweighed by fiber-length attrition in reinforced molding compounds. There are mechanical auger-

feeder devices and so-called strap feeders that are designed to introduce a ribbon of molding compound (usually rubber) directly into the feed throat of the injection molding machine. Auxiliary feeders generally add no heat to the molding compound.

Transporting the molding compound forward from the feed section to the injection section often provides high shearing forces, heat, and extensive mixing, which can be good or bad depending on the polymer. In normal processing of thermosets, the transport zone is designed only to densify the molding compound by removing entrapped gases. For thermoplastics, the densification process requires heat. A pressure gradient, required to degas both thermoplastics and thermosets, is produced by use of variable flight depth (tapered) screws to provide pumping, compression, decompression, and mixing functions. The design of these screws will vary greatly from thermoplastic to thermoset, from crystalline to amorphous polymers, and from inherently solid to potentially volatile materials (see Fig. 7). The description of an injection molding screw is complex and involves two key factors: the length and the compression ratio.

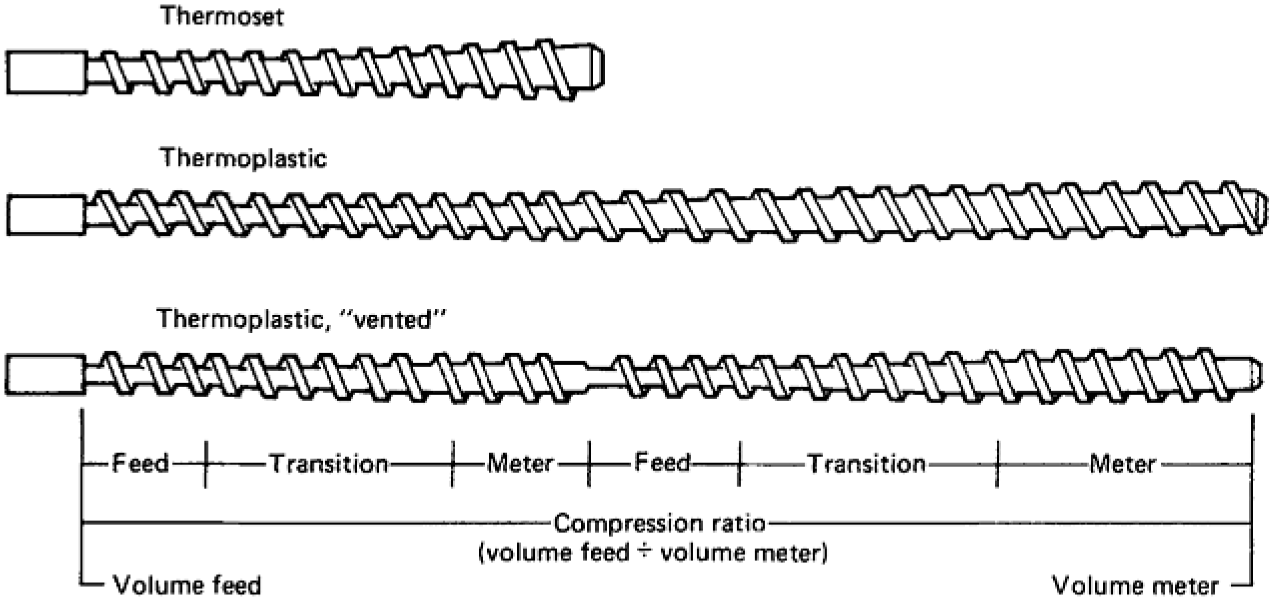

Fig. 7 Injection molding compound screws

Short screws are recommended for heat-sensitive thermosetting injection molding compounds. Longer screws are needed for thermoplastic molding compounds that must be both compressed and melted. The compression ratio is determined by dividing the "open volume" in the feed zone of the screw by the volume at the end of the screw. Thermoplastic molding compounds require compression ratios in the range of 2.0 to 3.0 or more. Thermoset molding compounds rarely require compression ratios above 1.5. Exactly how the compression is achieved is also of great importance to the ultimate properties of the molding compound. A heat-sensitive thermoset should not be compressed quickly during the transport process, because reinforcing fiber lengths will be broken and/or excessive heat will be created. Similarly, a thermoplastic molding compound should not be compressed quickly, unless the intent is to create a hot spot of extremely high work energy. The specification of the screw profile of the injection molding machine is just as vital as the specification of its compression ratio and length.

Thermoplastic molding compounds must be gradually melted, compressed, degassed (if volatile), sheared (if crystalline and amorphous), and accumulated before injection. This must be accomplished with minimal thermal gradient, at the lowest possible temperature, and with minimal heat history. Otherwise, the part cooling time will be extended, part shrinkage may vary, and the potential for polymer degradation may be increased, although degradation is not always the result. Reinforced thermoplastic molding compounds of improved strength may be obtained if sufficient time is allowed for the polymer to wet the reinforcement surface (Ref 5). The proper compression ratio for an injection molding screw will be slightly greater than the bulk density of the as-received molding compound divided by the density of the molten metal (melt).

Crystalline thermoplastics, such as acetal, nylon, polypropylene, and polyester, should be processed with screws containing a meter zone (no further compression) at the end of the profile. The meter zone is really a high shear zone where the crystalline regions can be more effectively melted or fluxed. Amorphous thermoplastics, such as acrylonitrile-butadiene-styrene, styrene, polycarbonate, and acrylic, require little, if any,

meter zone (Ref 6), because it would create useless shear and heat that could reduce molecular weight, which in turn could reduce impact strength.

Volatile materials must be removed from any molding compound to prevent either internal voids or splay (a fanlike surface defect near the gate) on the part. With thermoplastic molding compounds, a two-stage “vented” screw may be employed, as shown in Fig. 7. Only thermally stable molding compounds can safely employ two-stage injection molding screws. The orderly transport of molding compound is interrupted where the second screw stage begins. Thermally unstable molding compounds may accumulate, and the increased residence of time and heat will degrade them at this vent point. Attaching a vacuum pump to this vent point will further reduce the volatile content of the molding compound.

Thermoset molding compounds are rarely vented, because their formulations usually include a proportion of potentially volatile, low- molecular-weight monomers that are needed later in the molding process to cross link the resin. Venting could seriously deplete these vital ingredients. The objective of the transport process in the injection molding of thermosets is to preserve both the physical and chemical integrity of the compound, while providing mixing and densification. Low compression ratios are required to prevent the reduction of reinforcing fiber length and to avoid the mechanical heat. Any hot spots could prematurely initiate the curing reaction. For this reason, it is standard operating procedure to cool the barrel of an injection molding machine that is used for thermosets, whereas the barrel is always heated for use with thermoplastics.

In either thermoplastic or thermoset injection molding, the end of the transport process is the accumulation of a volumetrically predetermined amount (shot) of compound, under pressure, somewhere in front of the screw. In some thermoplastic molding techniques, such as molding of structural foam, this shot is held in an accumulator. Normally, however, the shot is accumulated between the end of the screw and the end of the barrel. The screw must be allowed to slide back out of the barrel, under some controlled back pressure, to allow for this accumulation. In the subsequent injection subprocess, the travel of the screw is reversed, because the shot is forced forward.

A check ring, ball check, or some other mechanical valve must be placed at the tip of the screw to prevent the molding compound from flowing back down the screw during the subsequent injection. The resistance to flow through these devices can be so difficult that the polymer and any reinforcement will be degraded. The development of the free-flow check ring concept minimizes this difficulty (Ref 7). Another mechanical device, the nozzle valve, is needed to contain the molding compound within the barrel of the injection machine as the shot is being accumulated. As with the check ring, nozzle valves can be areas of extremely high shear, work energy, and heat. In some cases, nozzle valves can be eliminated by assuming that the tail end of the prior shot acts as a mechanical plug. This is effective only if the back pressure is low and the viscosity of the molding compound is high. Otherwise, the nozzle will “drool” after the molded part is removed.

Injecting thermoset molding compounds is done directly into the mold cavity through a single hole known as a sprue. The potential thermal instability of thermoset molding compounds usually precludes the use of “close” manifold systems used to support multicavity thermoplastic injection molding. When molding thermoplastics, however, the molding compounds will flow from the sprue into a system of “runners” leading to the gate of the mold. Injection pressures of up to 100 MPa (15 ksi) are employed to cause the molding compound to flow, although higher pressures are available on special injection machines equipped with boosters. The compound must flow if the mold is to be filled, and molding compounds are formulated specifically for this moment. If the flow is inadequate under the available conditions, an internal lubricant or processing aid may be used by the molding compound formulators to ensure that the molding compound flows smoothly without melt fracture or jetting (Ref 8), that is, the formation of disorderly ropelike patterns.

Jetting can occur as a result of fill rate in materials without these additives; it is a process phenomenon rather than a material condition. As the molding compound is injected from the nozzle through the sprue and then forward toward the mold, the narrowness of the runners exerts high shearing forces. In some cases, the presence of additional shear is beneficial, because it lowers the apparent viscosity in those molding compounds that exhibit shear thinning. Under these high-shear conditions, fibrous and flake reinforcements will align parallel to the runner walls. Random orientation will become flow orientation. As the compound reaches the entrance, or gate, of the mold, it will begin to flow into the cavity unless there is a gate valve restriction. Gate valves may be used in thermoplastic molding compound applications to avoid the scrap loss associated with the runner system. In some cases, however, these restrictions may create conditions of high shear and heat.

Flowing from the gate into the mold cavity proceeds as in the runner system. If the molding compound is reinforced and the gates are smaller than the fiber lengths, the reinforcements will break (Ref 5). If the

formulator, compounder, and molder have all done their jobs, the molding compound should flow in an even front, or curtain. Experimenting with short shots, shown in Fig. 8, is a valuable analytical tool. Successively increasing the size of a short shot should produce a progressively more complete product with good surface finish. The presence of splay, bubbles, pits, or roughness indicates that something is wrong in the preceding feed, transport, and injection subprocesses. There are two notable exceptions to this rule. Rib sink, or a reverse vein appearance over a rib, is normal in a short shot. The molding compound has not been “packed out.” If the molding compound is a structural foam, the front will not be smooth, as in a properly delivered unfoamed short shot, because under the tremendous injection pressure it will tend to explode into the unpressurized mold.

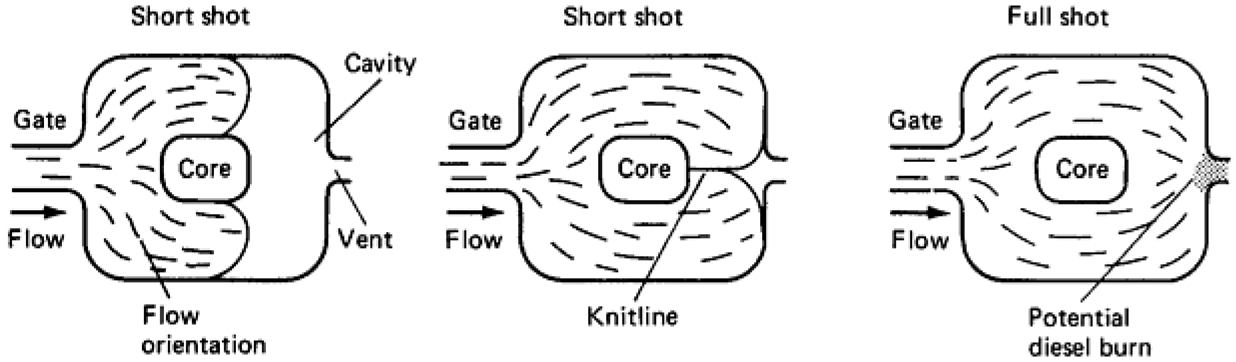

Fig. 8 Flowing molding compounds into molds

In order to inject the molding compound into a mold, the air within the mold must be adequately vented. Usually this is accomplished by determining the last area to be filled and providing a narrow vent slot from this point to the outside edge of the mold. When the mold fills to a point that is inaccessible to the parting line plane, an undersized ejector pin or flatsided pin may be used. If either of these actions is not taken or if the vents clog with processing oils or volatile additives, the force of injection may locally ignite the molding compound. Known as diesel burn, the ignition is caused by compressing the combustible oxygen in the mold. The molding compound within a burn area is chemically destroyed, and adjacent areas also may be affected.

Knitlines occur in any part that is molded in a cavity with more than one gate, or in any part where the molding compound is forced to flow around a pin or core. In cases of high shear stress, reinforcements such as talc, mica, and glass may physically protrude from the molding compound front. If knitlines are formed under these conditions, they will have greatly reduced strength. Although knitlines may be nearly invisible to the eye, they are areas of very high stress, fiber orientation, and potential weakness. To maximize the strength of a knitline, it is necessary to arrange the mold gating such that the melt fronts join before the completion of the shot. The molding compound fronts may thereby “scuff” together with sufficient force to achieve a higher-strength knit.

At the end of the flow process, the mold cavity will be filled. Depending upon whether the molding compound is thermoplastic or thermoset, it will begin to cool or cure. The cold molds used for crystalline thermoplastics must be held above the minimum crystalline growth temperature of the molding compound. Crystallinity initiators and so-called nucleated resins accelerate the rate of crystal growth but generally do not effectively lower the minimum crystal growth temperature. When thermoplastics crystallize, they shrink. If the mold is too cold to permit crystallization, the molded part will crystallize at some later time/temperature schedule, which may cause warpage or distortion. Thermoset molding compounds must cure. To initiate their chemical cross-linking reactions, it is necessary to heat the mold above the initiation temperature of the curing reaction. Once initiated, thermoset reactions liberate exothermic heat. At its peak, the heat produced in this manner may raise the molded temperature above the polymer degradation threshold. Thick thermoset molding compound products may present extreme difficulties both in the ability to uniformly initiate the curing process and, once initiated, to control the heat generated during the curing process.

Metallic Matrices

Awadh B. Pandey, Pratt & Whitney

Introduction

METALLIC MATRICES are essential constituents for fabrication of metal-matrix composites (MMCs). Research and development on MMCs have increased considerably in the last decade due to their improved modulus, strength, wear resistance, thermal resistance, and fatigue resistance—and improved consistency in properties and performance in general—compared to the unreinforced matrix alloys. The concept of MMCs is based on using the best characteristics of two different materials, such as ductility and toughness of metallic matrices and the modulus and strength of ceramic reinforcements, to make a material with superior properties compared to the unreinforced metals. The reinforcements are added extrinsically or formed internally by chemical reaction. The properties of MMCs depend on the properties of matrix material, reinforcements, and the matrix-reinforcement interface. While a variety of matrix materials has been used for making MMCs, the major emphasis has been on the development of lighter MMCs using aluminum and titanium alloys, due to the significant potential of improvement in the thrust-to-weight ratio for the aerospace, space, and automotive engines.

The reinforcements are either in the form of continuous fibers or discontinuous reinforcements, such as chopped fibers, whiskers, particulates, or platelets. Metal-matrix composites can contain either continuous or discontinuous or a combination of both these reinforcements. The main advantage of discontinuously reinforced composites over continuous ones is that they can be fabricated using processing techniques similar to those commonly used for unreinforced matrix materials, which makes them more cost-effective. In addition, discontinuously reinforced composites have relatively more isotropic properties than continuously reinforced composites, due to the lower aspect ratio and more random orientation of the reinforcements.

The use of MMCs as ventral fins on F-16 aircraft and as fan exit guide vanes in commercial aerospace engines has attracted the attention of several researchers in the recent past. The life of the ventral fin has been increased significantly by the use of discontinuously reinforced aluminum (DRA). The role of matrix properties becomes

more important in discontinuously reinforced composites compared to the continuous composite, due to a difference in the strengthening mechanisms for both these systems. The strength of continuously reinforced composites is mainly determined by the ability of load transfer from the matrix to the continuous fiber. Thus, the properties of fiber and the matrix-fiber interface become more important than the matrix property itself. This is evident in room temperature properties. For higher temperature, the role of matrix material becomes more important, because the high-temperature properties are controlled by diffusion in the matrix alloys. In discontinuously reinforced composites, the matrix material has a crucial role, because the strength of discontinuous composite depends on many other mechanisms in addition to the load transfer to the reinforcements. The other mechanisms responsible for strengthening in the discontinuous composites are the finer grain size, finer subgrain size, increased dislocation density, increased kinetics for precipitation hardening, and some degree of Orowan strengthening. The mechanical properties of discontinuously reinforced composites are dominated by the behavior of matrix alloys.

The choice of matrix material depends mainly on the strength, temperature, density, and cost requirements for the intended applications. For example, titanium appears to be an obvious candidate for very high-strength and moderate-temperature applications. However, aluminum may compete with titanium on the basis of specific properties, because of its significantly lower density, even though the strength and temperature capability of aluminum is lower than that of titanium. Also, the lower cost of aluminum compared to titanium provides an additional benefit for aluminum. Other factors, such as ductility, fracture toughness, and fatigue resistance, become more important once a particular metal is selected.

One of the most important factors is the compatibility of the matrix material with the reinforcement. Compatibility in this case means that there is no undesirable chemical reaction at the interface of the matrix and reinforcement. This reaction can sometimes lead to the formation of intermetallic compounds at the interface that may have the deleterious effect of transferring load to the reinforcements. Also, the reaction products may act as sites for crack nucleation.

The maximum mechanical property benefits MMCs often provide due to the presence of reinforcement are increased modulus, strength, and fatigue strength. However, the ductility and fracture toughness of MMCs are known to be inferior to those of the unreinforced matrix alloys, because the ductility and toughness of most ceramic reinforcements are very low. These properties are very important for any load-bearing structural applications. Therefore, it is apparent that the matrix alloys having higher ductility and fracture toughness are desirable for MMC applications.

Research in the area of aluminum-matrix composites has been concentrated mainly toward development of DRA composite, because of the ease of processing. Pure metal is usually not considered as a matrix material for MMCs, because the properties of pure metals are not attractive. Three classes of aluminum alloys have been chosen in the past for fabrication of MMCs:

- Wrought commercial aluminum alloys, such as 6061, 2124, and 7075, and cast aluminum alloys, such as aluminum-silicon and aluminum-magnesium
- The lighter aluminum-lithium alloys, such as 8090
- High-temperature aluminum alloys, such as aluminum-iron- and aluminum-scandium- base alloys

Most of the earlier studies have focused on understanding of the composite behavior rather than developing newer aluminum alloys. Work on developing a newer matrix alloy suitable for MMCs has focused on the modification of existing aluminum alloy compositions. Among these three alloy systems, maximum efforts have been put into developing MMCs with commercially available aluminum alloys (Ref 1, 2). These alloys were selected for MMCs because they offer good properties, are well understood, and are commercially available. While aluminum-lithium has considerable potential in terms of lowering density and improving modulus, only a few studies are available with regard to MMCs (Ref 3, 4). This may be partly related to the fact that aluminum-lithium itself is in the early development stage. Because commercially available aluminum alloys cannot be used at higher temperatures, the high-temperature aluminum alloys based on Al-Fe-V-Si and aluminum-scandium have been used to improve the high-temperature capability of MMCs. While significant potential exists for developing a newer aluminum alloy with improved properties for a wide range of temperatures, limited studies are available in this area (Ref 5, 6, and 7).

Titanium-matrix composites with continuous fibers have received considerable attention in the past for improving strength and modulus of titanium alloys at ambient and high temperatures (Ref 8, 9, and 10). Initially

the efforts were concentrated on Ti-6Al-4V, which is the workhorse titanium alloy, with major emphasis on understanding the interfacial behavior. The studies were also focused on evaluating fiber strength, because the strengthening in the composite depends on the strength of the fiber and the quality of the interface. The understanding of interface characteristics is very important, because the transverse strength of continuous fiber composite is usually inferior. Different types of fibers were used to manufacture titanium composites with different fiber strengths. Subsequently, considerable studies have been conducted to exploit ordered intermetallics Ti_3Al and TiAl (γ), which offer improved high-temperature properties for MMCs applications. These ordered intermetallics have excellent high-temperature strengths, but lower room-temperature ductility. More recently, significant interest has been generated on discontinuously reinforced titanium (DRTi) composite to take advantage of isotropic properties. While both ingot and powder metallurgy (P/M) routes have been used, more emphasis was on the powder technique to reduce reaction between the matrix and reinforcement and also to provide more uniform distribution of reinforcement.

Aluminum Alloys

Aluminum alloys can be categorized in three different classes: commercial aluminum alloys, low-density and high-modulus alloys, and high- temperature alloys. The details of these alloys are given subsequently.

Commercial Aluminum Alloys

Commercial aluminum alloys can be classified in the following categories:

- *Wrought heat treatable alloys,* such as Al- Mg-Si (6000), Al-Cu-Mg (2000), and Al-Zn- Mg (7000), which require heat treatment to develop high strength through precipitation hardening. These alloys offer a wide range of strength and ductility. They have been used extensively in aerospace and other structural applications and have also been used for MMC development.
- *Wrought non-heat-treatable alloys,* such as aluminum-magnesium and aluminum-manganese, which provide strengthening through solid solution and dislocation structure introduced by cold work. The strengths of these alloys are not suitable for aerospace applications. These alloys have found applications in the automotive industries. These alloy systems have found limited use in MMC fabrications, due to their lower strengths.
- *Casting alloys,* which are based principally on the aluminum-silicon, aluminum-copper and aluminum-magnesium alloy systems. These alloys usually have a medium level of strength and ductility and are used in applications with complicated component geometries. Casting alloys have been used extensively for MMC applications.

Wrought heat treatable aluminum alloys are the most common alloys in the aluminum family. Among the three common series of alloys, 6000, 2000, and 7000, Al-Mg-Si (6000-series) alloys are very attractive for MMCs due to their high ductility and toughness, although strengths of this series are lower than the other two series. Table 1 lists the compositions and tensile properties of some selected 6000-series alloys. The Al-Mg-Si alloys are widely used in medium-strength applications due to their very good ductility, weldability, corrosion resistance, and immunity to stress-corrosion cracking. Magnesium and silicon are added in the 6000 series either in balanced amounts to form quasi-binary Al-Mg_2Si or with an excess of silicon needed to form Mg_2Si precipitate. Alloy 6061 is one of the most common alloys in the 6000 series, which has balanced compositions of magnesium and silicon. This also contains 0.2% Cr, which provides improved corrosion resistance. While the presence of excess silicon improves age hardening response, it may reduce the ductility and cause intergranular embrittlement, due to segregation of excess silicon to grain boundaries. This alloy also contains titanium for controlling recrystallization, because most of the aluminum alloys usually contain chromium, manganese, zirconium, or titanium for grain refinement purpose. Alloy 6092 (Al-1.0Mg-0.6Si-0.85Cu- 0.15Ti-0.3Fe), a modification of 6061 alloy, is a P/M alloy developed by DWA Composites, Inc. (Ref 11). The ventral fin and the fan exit guide vane were manufactured using a wrought powder metallurgy 6092/SiC/17.5p composite. The 6000-series alloys are suitable for MMC applications requiring medium strength and high ductility.

Table 1 Typical tensile properties and fracture toughness of selected heat treatable aluminum alloys

Alloy	Composition	Temper	Yield strength in 0.2%		Ultimate tensile strength		Elongation, %	Fracture toughness (K_{Ic})	
			MPa	**ksi**	**MPa**	**ksi**		**MPa $\sqrt{m}$**	**ksi $\sqrt{in.}$**
6061	Al-1Mg-0.6Si-0.25Cu-0.19Cr-0.1Ti-0.7Fe	T6	275	39.9	310	45.0	12	27	25
6063	Al-0.7Mg-0.4Si-0.1Cu-0.1Cr-0.1Ti-0.35Fe	T6	215	31.2	240	34.8	12	…	…
2014	Al-4.5Cu-0.5Mg-0.26Mn-0.7Fe-0.8Si	T6	410	59.5	480	69.6	13	31	28
2024	Al-4.3Cu-1.5Mg-0.6Mn-0.5Fe-0.5Si	T8	450	65.3	480	69.6	6	26	24
2124	Al-3.9Cu-1.5Mg-	T8	440	63.8	490	71.1	8	32	29

(a) Alloys prepared by powder metallurgy processing

The 2000-series alloys have been used in several aerospace applications, due to their higher strengths compared to the 6000-series alloys. Table 1 shows the properties of some common 2000-series alloys used for aerospace and also for MMC applications. This series of alloys contain copper and magnesium to provide precipitation strengthening through formation of metastable precipitate of S′ (Al_2CuMg) for higher-magnesium-containing alloys and precipitation of θ′ (Al_2Cu) for higher copper-to- magnesium ratio alloys upon heat treatment. They also contain some other elements, such as chromium, zirconium, manganese, or titanium, to control the grain size. Alloy 2124, a purer version of 2024, is the most common alloy with lower amounts of iron and silicon contents. Iron and silicon are usually present in all the aluminum alloys as impurities. These elements can have a detrimental effect on ductility and fracture toughness of aluminum alloys. The toughness of 2124 alloy is improved significantly by reducing the iron and silicon content in the alloy (Ref 12). It is almost always desired to keep the amount of iron and silicon as low as possible in most of the aluminum alloys to preserve ductility and toughness, because these elements form large intermetallic particles, which can cause the nucleation of voids by debonding or cracking. This concern is particularly important for MMC applications, because the ductility and toughness of MMCs are lower than those of the matrix alloys due to the presence of the reinforcements.

Other 2000-series alloys that are of interest are 2014, 2219, and 2618. These alloys have been used for slightly higher-temperature applications. The higher copper-to-magnesium ratio provides improved properties at elevated temperatures, due to formation of θ′ (Al_2Cu) precipitate. Alloys 2014 and 2219 have high copper- to-magnesium ratios (Table 1). On the other hand, 2618 contains additional elements, such as manganese, iron, and nickel with low diffusivity, which provides improved strengthening at elevated temperatures due to the formation of thermally stable dispersoids, such as Al_6Mn, Al_3Fe, Al_3Ni, and Al_9FeNi, respectively. Alloy 2219 is being used in cryogenic liquid tank for space application due to its higher strength and fracture toughness at cryogenic temperatures. In addition, 2219 has good creep strength at elevated temperatures. While 2014, 2219, and 2618 can be used at slightly higher temperatures compared to the conventional aluminum alloys, they cannot be used above 150 to 170 °C (300 to 340 °F). A modified version of 2219 with composition Al-6.3Cu-0.45Mg-0.3Ag-0.3Mn-0.15Zr is very attractive for MMC applications. The role of silver is to promote uniform precipitation of Ω- phase as very thin plates on {111} matrix planes, as shown in Fig. 1 (Ref 12). This Ω-phase has close relationship with θ (Al_2Cu), which forms as equilibrium precipitate. The Ω-phase is stable up to 200 °C (390 °F). The room-temperature strength and creep strength of this alloy are superior to that of 2219 alloy. The yield strength of this silver-containing alloy is 520 MPa (75 ksi) in the T6 condition, compared to 390 MPa (57 ksi) for 2219 alloy. The 2000-series alloys exhibit superior fatigue resistance compared to the 7000-series alloys, as shown by the fatigue crack growth rate (*da/dN)* versus the stress-intensity factor range (Δ*K*) in Fig. 2 (Ref 13). The higher threshold stress intensity and lower rate of crack growth in the 2000 series may be attributed to the higher ductility of 2000-series alloys compared to 7000 alloys.

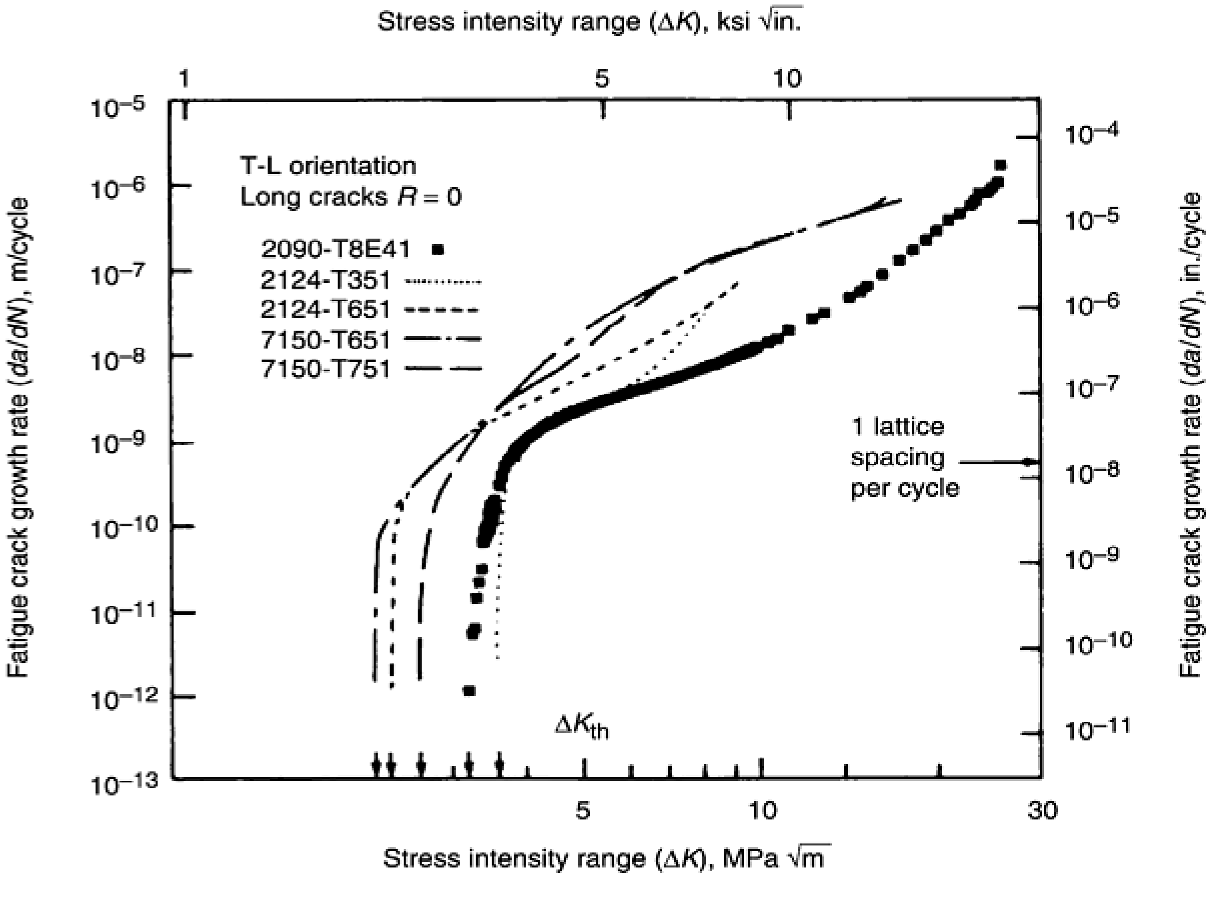

Fig. 2 Variation of fatigue crack growth rate (*da*/*dN*) versus stress-intensity factor range (Δ*K*) for various aluminum alloys, showing higher crack growth resistance for aluminum-

lithium alloy. ΔK_{th}, change in threshold stress- intensity factor. Stress ratio (R) is 0. T-L is transverse or longitudinal. Source: Ref 13

The 7000-series alloys have received special attention in aerospace industries, because they provide the highest strength among all aluminum alloys. Table 1 shows the composition and properties of some common 7000 alloys. This series of alloys contain zinc and magnesium to provide precipitation hardening through formation of η′ (Zn_2Mg) phase. The role of copper is to improve stress-corrosion cracking resistance of these alloys. In addition, small amounts of chromium, zirconium, titanium, or manganese are also present for controlling recrystallization. The presence of zirconium also provides improved strength and toughness and reduced quench sensitivity of the alloys, in addition to the grain-size control. Alloy 7075, the most common alloy in this series, provides a good combination of strength, ductility, and toughness. The 7000-series alloys exhibit inferior stress-corrosion cracking resistance in the peak-aged condition; therefore, these alloys are used mostly in the T73 condition. The T73 condition is a duplex aging treatment employing higher-temperature aging (170 °C, or 340 °F) followed by peak aging at 120 °C (250 °F). Strength in the T73 condition is reduced, compared to the peak-aged condition.

Significant advances have taken place in the development of newer 7000 alloys such as 7090, 7091, and CW 67, using a P/M approach in order to improve the strength, toughness, and stress- corrosion cracking resistance by using the benefits of rapid solidification. This approach uses rapidly solidified powder produced by gas atomization, followed by compaction and extrusion of the powder. As shown in Table 1, the properties of all the P/M alloys are improved significantly over ingot metallurgy 7075 alloy. These alloys contain cobalt, nickel, or zirconium, which form very fine dispersoids of Al_9Co_2, Al_3Ni, and Al_3Zr, respectively, depending on the composition. These dispersoids effectively pin the grain boundaries, providing considerable strengthening through Hall-Petch relation. The grain size of P/M alloys is much finer than that of the ingot-based alloys (as shown in Fig. 3), which helps in achieving improved strengthening. The CW 67 has the best combination of strength and toughness, indicating significant potential for MMC applications to derive maximum benefit from matrix properties. As evident from Table 2, the strength of DRA depends significantly on the strength of the matrix alloy for a fixed volume fraction of reinforcement (Ref 14). These DRA materials are made by P/M approach to provide a uniform distribution of reinforcement particles in the matrix. Powder metallurgy is a preferred approach for making DRA today, because this can provide higher strength, ductility, and toughness than that of cast DRA materials. The strength of DRA containing 7091 alloy is higher than that of DRA containing 6061 and 2124, indicating that the 7000 alloys are more attractive for high-strength applications. It should also be noted that the effect of matrix alloys on the properties of DRA is more pronounced than that of volume fraction of reinforcement. The effect of matrix heat treatment on the properties of a powder metallurgy 7093/15 vol% SiC discontinuously reinforced aluminum is shown in Table 3 (Ref 15, 16). The yield strength of this DRA material is very high (640 MPa, or 93 ksi) in the peak-aged condition. This table also indicates that the strength, ductility, and fracture toughness of DRA depend significantly on the heat treatment.

Overaged 2	93.0	13.5	447	64.8	514	74.5	7.0	22.1	20.1
Overaged 3	89.2	12.9	369	53.5	451	65.4	7.6	25.3	23.0
Solution treated + 5% deformation	91.9	13.3	507	73.5	592	85.9	5.4	19.6	17.8

(a) Solution treated: 490 °C (915 °F)/4 h + water quenched (WQ). Underaged: 490 °C (915 °F)/4 h + WQ + 120 °C (255 °F)/25 min. Peak aged: 490 °C (915 °F)/4 h + WQ + 120 °C (255 °F)/24 h + air cooled (AC). Overaged 1: 490 °C (915 °F)/4 h + WQ + 120 °C (255 °F)/24 h + AC + 150 °C (300 °F)/8 h + AC. Overaged 2: 490 °C (915 °F)/4 h + WQ + 120 °C (255 °F)/24 h + AC + 170 °C (340 °F)/36 h + AC. Overaged 3: 490 °C (915 °F)/4 h + WQ + 120 °C (255 °F)/24 h + AC + 170 °C (340 °F)/97 h + AC.

(b) K_{Ic} values were obtained from valid J_{Ic} data.

(c) Fracture toughness values are based on the maximum load, because the specimens failed following elastic loading.

Wrought non-heat-treatable aluminum alloys include manganese and magnesium where strengthening is derived from solid-solution and strain hardening. Strain hardening is associated with the increase in dislocation density from cold deformation. Table 4 shows the tensile properties of some selected non-heat-treatable alloys. As can be noted from the table, the strengths of these alloys are lower than heat treatable aluminum alloys, because precipitation hardening cannot be imparted in these alloys. The ductility of these alloys in the strain-hardened condition (H) is not very high, due to increased dislocation density present in this material. Because magnesium is known to be a good solid-solution strengthener, the strength of higher-magnesium-content alloys, such as 5456, is superior to aluminum-manganese-based alloys. It also suggests that the strength of aluminum-magnesium alloys increases with magnesium content. These alloys have not been used much for MMC applications, due to their lower strengths. The solid-solution strengthening alone is not sufficient to provide required strengthening. A combination of solid-solution and dispersion hardening in the presence of fine dispersoid particles may provide sufficient strengthening. In addition, P/M would be required for making these alloys, because more magnesium can be taken into solution by extending the solid solubility by rapid solidification, and also, fine dispersoids can be formed.

Table 4 Typical tensile properties of selected non-heat-treatable aluminum alloys

Alloy	Composition	Temper	Yield strength in 0.2%		Ultimate tensile strength		Elongation, %
			MPa	ksi	MPa	ksi	
1100	Al-0.12Cu-0.1Zn-1Si + Fe (CP Al)	O	35	5.1	90	13.1	35
		H18	150	21.8	165	23.9	5

		H34	255	37.0	325	47.1	10

Cast Aluminum Alloys

Cast aluminum alloys consist of two groups: one with copper and the other with silicon. Alloys with silicon as the major alloying addition are the most important ones, because silicon imparts high fluidity by the presence of a larger volume of aluminum-silicon eutectic. The eutectic is formed between aluminum solid solution and silicon, with about 12.7% Si content. The eutectic is composed of individual cells within which the silicon particles appear to be interconnected. Table 5 shows the tensile properties of some selected cast aluminum alloys. The strength and ductility of aluminum-copper alloys, especially 201, are very attractive. However, the castability of aluminum-copper is not as good as aluminum-silicon alloys, due to the greater tendency for hot tearing and hot shortness in aluminum-copper alloys. Hypoeutectic and hypereutectic aluminum-silicon alloys are commercially available; hypoeutectic is more common, because these alloys can provide slightly higher ductility. Finer eutectic via rapid cooling is preferred to impart more ductility in the alloys. The refinement of eutectic can also be achieved by small additions of sodium or strontium. Figure 4 shows the microstructures of Al-12 wt% Si in the unmodified and modified conditions. Finer microstructures in aluminum- silicon alloys result from sodium additions, because sodium depresses the eutectic temperature by almost 12 °C (22 °F) and thereby reduces the potency of nucleating sites for the eutectic phase, silicon. The fracture toughness of modified aluminum-silicon alloys improves significantly over unmodified alloy, due to the finer structure of the former alloy.

Table 5 Typical tensile properties of selected cast aluminum alloys

Alloy	Composition	Temper	Yield strength in 0.2%		Ultimate tensile strength		Elongation, %
			MPa	**ksi**	**MPa**	**ksi**	
201	Al-4.6Cu-0.35Mg-0.35Mn-0.2Ti	T6	345	50.0	415	60.2	5
213	Al-7.0Cu-2Si-2.5Zn-0.6Mn-0.1Mg	T533	185	26.8	220	31.9	0.5
355	Al-5Si-0.5Mg-0.5Mn-1.2Cu-0.35Zn-0.25Ti	T6	235	34.1	280	40.6	1
356	Al-7.0Si-0.25Cu-0.3Mg-0.35Mn-0.35Zn-0.25Ti-0.6Fe	T6	205	29.7	230	33.4	4
357	Al-7.0Si-0.55Mg-0.12Ti-0.055Be	T6	221	32.1	283	41.0	3

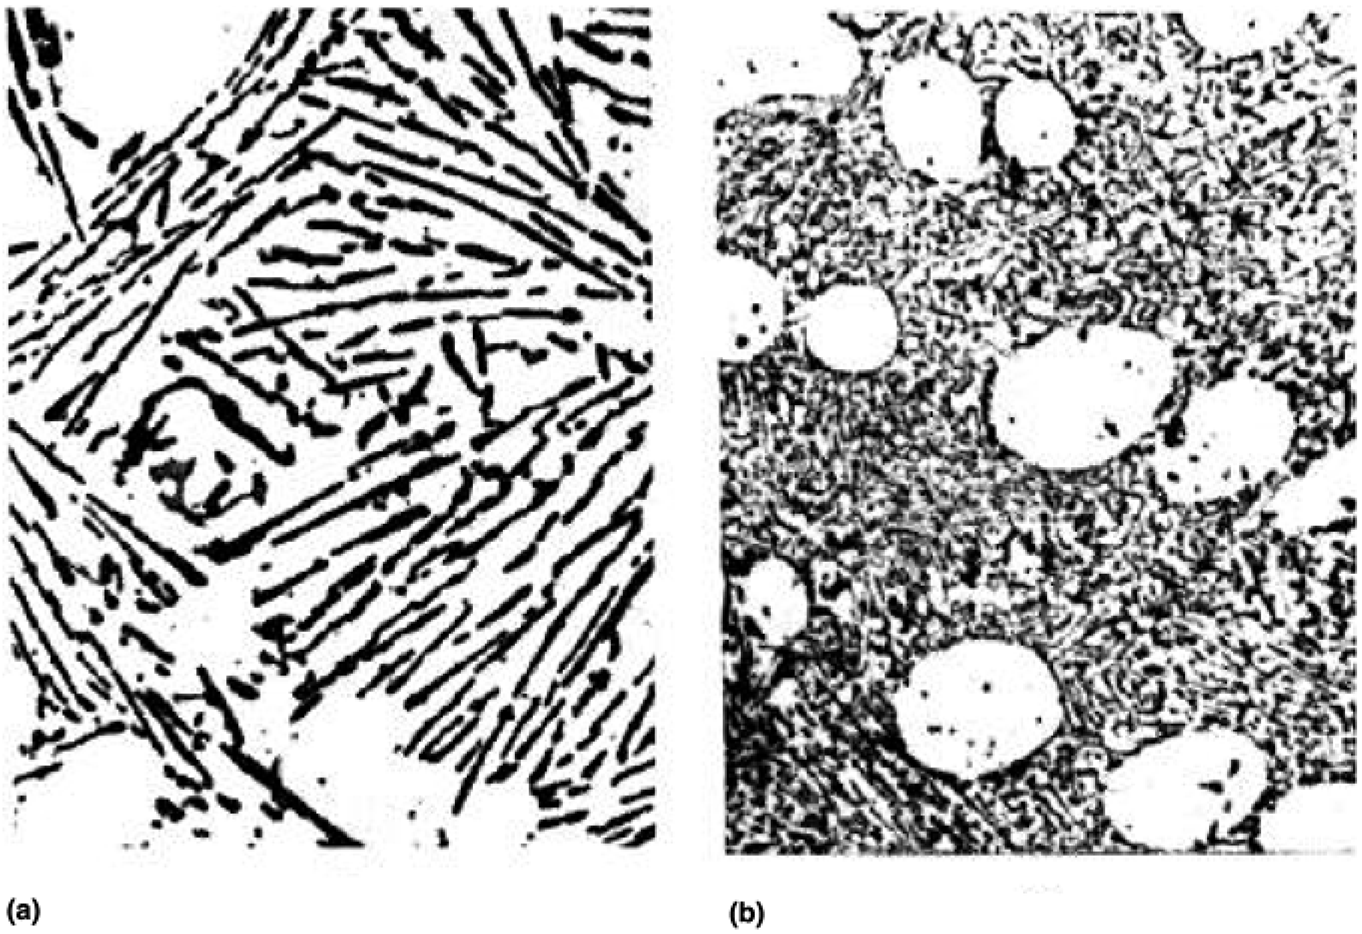

Fig. 4 Microstructures of aluminum-silicon alloy in the (a) unmodified and (b) modified conditions. Source: Ref 12. Courtesy of J.A. Cheng

Aluminum-silicon alloys have been used extensively for making MMCs via various casting techniques. Unlike P/M in casting there is a reaction between molten aluminum alloys and the reinforcements, particularly with SiC forming the deleterious product Al_4C_3 at the interface. The reaction between aluminum and SiC can be written as (Ref 17):

$$Al\ (l) + 3SiC\ (s) = Al_4C_3\ (s) + 3Si \qquad \text{(Eq 1)}$$

where Si represents silicon in solution of aluminum. The stepwise reaction leading to the formation of Al_4C_3 can be given by

$$SiC\ (s) = Si + C \qquad \text{(Eq 2)}$$

$$3C + 4Al\ (l) = Al_4C_3\ (s) \qquad \text{(Eq 3)}$$

The previous equations show that SiC has to go into solution in order to form Al_4C_3 by reaction with aluminum from the matrix. One of the factors that controls the extent to which SiC would go into solution is the activity of silicon in aluminum. If the activity of silicon in the alloy were sufficiently high, then the dissolution of SiC would be reduced significantly. Therefore, aluminum-silicon alloys with silicon contents over 8 to 9 wt% are required to avoid reaction with SiC. Alloys without sufficient silicon cannot be used for making MMCs with SiC reinforcement in casting. However, non-silicon-containing alloys can be used with Al_2O_3, TiB_2, and B_4C for making MMCs. Alloys containing magnesium react with Al_2O_3, forming $MgAl_2O_4$ (spinel) at the interface. The spinel is not detrimental to the properties of MMCs. Therefore, it is important to select matrix alloys and reinforcements in such a way that the formation of detrimental reaction products is prevented.

There is a continued interest in the development of cast DRA, with the objective of achieving good strength, ductility, and fracture toughness at lower cost. Alcan has conducted a considerable amount of work on DRA materials with two alloy systems: aluminum-silicon alloys with SiC as the reinforcement and 2014 alloy with Al_2O_3 as the reinforcement (Ref 2). Silicon carbide and Al_2O_3 reinforcements are both slightly denser than the matrix alloys, so particulate settling is an issue that requires attention. Alcan has used a proprietary stirring process for wetting and dispersion of reinforcements in the melt and has produced composite material with

good properties. The advantage with this technique is that reinforcement contents up to 30 vol% can be added easily.

MMCC Inc. and Triton Systems Inc. have been involved in pressure infiltration casting (PIC) of DRA. MMCC Inc. has used an aluminum-silicon alloy and 2014 alloy as matrices, whereas Triton Systems Inc. has used 2219 as a matrix for DRA applications. Aluminum-silicon alloys have been used with SiC, and 2014 has been used with Al_2O_3 reinforcements. As mentioned previously, 2219 has good strength and toughness at cryogenic temperatures suitable for space applications. The PIC process requires a high-quality preform for infiltration. Although reasonably high strengths can be achieved using the PIC process, the ductility is very low (less than 1%), as shown in Table 6. This is partly because of the very high volume fraction (40 to 60%) of reinforcements present in the DRA materials produced using the PIC process. Brake calipers for potential automotive application have been made by MMCC Inc. using the PIC process. Current technology is not able to produce high quality preforms with reinforcement volume fractions below about 40%, thus limiting material produced by the PIC process.

Table 6 Typical tensile properties and fracture toughness of cast DRA materials

Alloy	Reinforcement	Temper	Young's modulus		Yield strength		Ultimate tensile strength		Elongation, %	Fracture toughness		Reference

Lanxide Corporation has patented techniques known as Primex and Primex Cast, which have been used to make DRA materials via pressureless infiltration at a lower cost compared to PIC processes. These techniques are based on the unique capability to infiltrate ceramic reinforcements with molten aluminum without application of pressure or vacuum. To produce DRA materials, magnesium is added to the alloy and the infiltration is carried out in a nitrogenous atmosphere at a temperature above the melting point of the aluminum alloy. Using this technique, reasonably good properties in DRA have been obtained, as shown in Table 6. The brake discs made out of cast DRA using the Primex pressureless infiltration technique have been used successfully on all four wheels of the Lotus Elise. Several other automotive components for potential applications have been made from cast DRA using the pressureless infiltration technique.

Low-Density, High-Modulus Alloys

Lithium is a unique alloying element for aluminum because it reduces density and improves the modulus of the aluminum alloy considerably. It has high solid solubility (4 wt% at 610 °C, or 1120 °F) in aluminum and responds to age hardening, due to precipitation of an ordered, metastable phase δ′(Al_3Li) that is coherent and has small misfit with the matrix (Fig. 5). Due to these characteristics, aluminum-lithium alloys have attracted considerable attention in the past for the development of new-generation low-density, high-modulus alloys for aerospace and space structures. Specifically, aluminum-lithium alloys have been considered for cryogenic propellant tank applications.

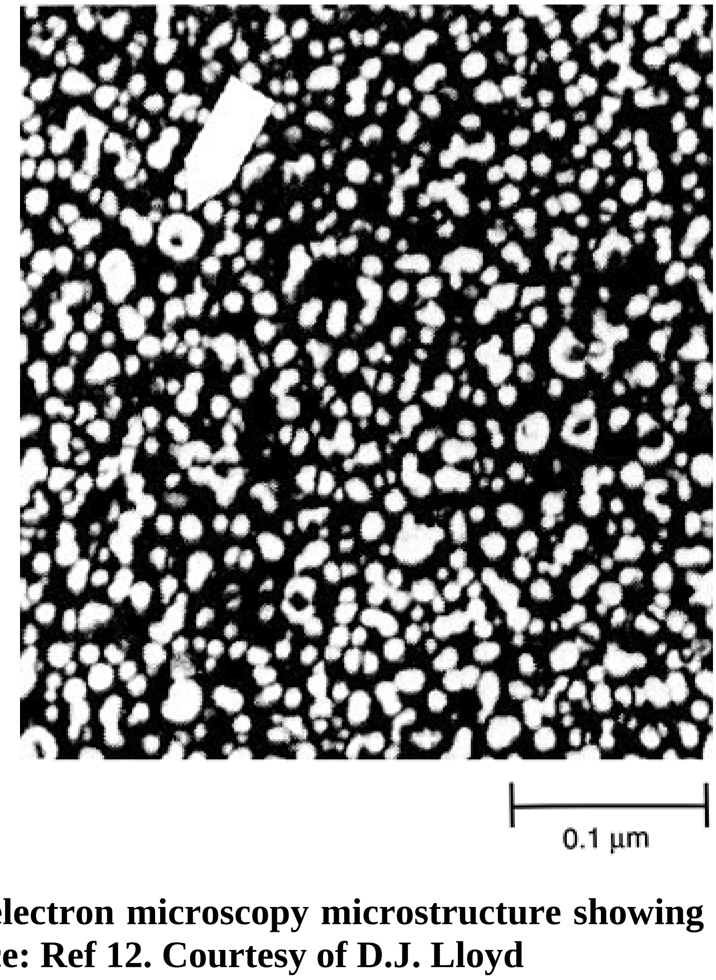

Fig. 5 Transmission electron microscopy microstructure showing δ′ precipitate in an Al-Li-Mg-Zr alloy. Source: Ref 12. Courtesy of D.J. Lloyd

Binary aluminum-lithium alloys suffer from low ductility and fracture toughness, due to severe strain localization resulting from the shearing of coherent δ′ precipitates by moving dislocations. Therefore, significant work has been done to develop ternary and quaternary alloys with dispersoids capable of dispersing dislocations more homogeneously. Table 7 lists the compositions and properties for some selected aluminum-lithium-based alloys. There are two categories of aluminum-lithium-based alloys: modified aluminum-copper alloys (such as Weldalite, Martin Marietta Corporation) that have small lithium additions to enhance strength and alloys (such as 8090 and 2091) with higher lithium contents to maximize density reduction. The quaternary alloys based on Al-Li-Cu-Mg (such as 8090) are the most common, due to a good combination of strength, ductility, and toughness. The Al-Li-Cu-Mg alloys are strengthened by three types of precipitates: δ′ (Al_3Li), T1

(Al_2CuLi), and S′ (Al_2CuMg). Most of the aluminum-lithium alloys contain a small amount of zirconium, similar to other aluminum alloys. The role of zirconium here is twofold: Al_3Zr controls recrystallization and grain growth, and Al_3Zr particles have similar $L1_2$ structure as δ′ substituting to the Al_3Li precipitate forming Al_3 (Li_xZr_{1-x}) (Ref 18). The presence of zirconium improves strength and toughness in aluminum- lithium based alloys.

Table 7 Typical tensile properties of selected lithium-containing aluminum alloys

Alloy	Composition	Temper	Yield strength in 0.2%		Ultimate tensile strength		Elongation, %	Fracture toughness (K_{Ic})	
			MPa	**ksi**	**MPa**	**ksi**		**MPa** $\sqrt{m}$	**ksi** $\sqrt{in.}$
2091	Al-2Li-2.1Cu-1.5Mg-0.1Zr	T8X (UA)	370	53.7	460	66.7	15	40	36
		T851	475	68.9	525	76.1	9	25	23
8090	Al-2.4Li-1.3Cu-0.9Mg-0.16Zr	T81(UA)	360	52.2	445	64.5	11	45	41
		T6	400	58.0	470	68.2	6	35	32
		T851	455	66.0	510	74.0	7	30	27
2090	Al-2.3Li-2.7Cu-0.3Mg-0.5Zr	T83	510	74.0	565	81.9	5	…	…
8091	Al-2.6Li-2Cu-0.85Mg-0.16Zr	T851	515	74.7	555	80.5	6	22	20

Weldalite 049	Al-6.3Cu-1.3Li-0.4Mg-0.4Ag-0.18Zr	T8	725	105.1	797	115.6	9.8	…	…

UA, underaged

The 2090 alloy containing Al-Li-Cu is hardened by δ′ and the hexagonal T1 phase (Al_2CuLi) that forms as thin plates on {111} planes. Plates of θ′ (Al_2Cu) may also be present in this alloy. Because nucleation of T1 and θ′ are difficult, cold working is required prior to aging to promote uniform precipitation on dislocations (T8 condition). The 2091, 8090, and 8091 alloys contain S′ precipitate, which is resistant to shearing by dislocations, promoting more homogeneous deformation. These alloys provide improved precipitation in the T8 condition. Figure 2 indicates that aluminum-lithium alloy has superior crack growth resistance to 2000- and 7000-series alloys. The Russian alloy 1421 (Al- Li-Mg-Sc-Zr) also shows good strength and ductility (Table 7). These alloys—which have good mechanical properties and are light, weldable, and corrosion resistant—are used for fuel tanks, fuselage stringers, cockpits, and other aircraft parts. The Weldalite, with a small addition of silver in the Al-Li-Cu-Mg-Zr alloy, has very high strength (700 MPa, or 100 ksi), good weldability (Ref 19), and was developed by Martin Marietta Corporation.

While some of the aluminum-lithium alloys show a very good combination of strength, ductility, and toughness in addition to lower density and higher modulus, the use of aluminum-lithium alloys has been very limited as matrices for DRA applications (Ref 3, 4). This is mainly due to the fact that that P/M version of aluminum-lithium is not attractive because of severe oxidation of aluminum-lithium powder, and these alloys cannot be used easily for making cast DRA with SiC.

High-Temperature Aluminum Alloys

The commercial aluminum alloys and aluminum-lithium alloys cannot be used at temperatures above 150 °C (300 °F), due to rapid coarsening of strengthening precipitates and loss of mechanical properties in these alloys and loss of mechanical properties. There is an increasing demand for high-temperature aluminum alloys for aerospace and space applications to substitute for titanium alloys at temperatures up to 315 °C (600 °F) (Ref 20, 21, , 22, 23, and 24). A considerable amount of work was done in the 1990s to develop high-temperature alloys

via a rapid solidification process (Ref 5, 6, and 7). However, the use of these alloys for MMCs has been limited, mainly due to lower ductility and fracture toughness of these alloys. Also, processing of MMCs with high-temperature alloys as matrices requires careful control of temperature during processing to prevent coarsening of dispersoids.

Aluminum-scandium-based alloys provide a unique opportunity for developing improved ambient- and high-temperature properties. Scandium is known to be a potent strengthener in aluminum alloys (Ref 25). While aluminum- scandium alloys have potential for making MMCs using casting techniques, studies on MMCs do not exist. The higher-scandium-containing aluminum alloys have been investigated for MMC applications using P/M technique (Ref 26, 27). The aluminum-scandium-based alloys have the potential to provide a new class of MMCs, due to the balanced strength, ductility, and toughness in this system.

Another class of aluminum alloys that has attracted the attention of researchers in the recent past is the amorphous aluminum alloys for elevated-temperature applications (Ref 28, 29, and 30). While significant research on amorphous structure has been carried out in the past, the present emphasis is toward development of bulk amorphous structure in alloys using conventional processing techniques. Recently, a large initiative in the area of amorphous alloys has been started by the Defense Advanced Research Projects Agency in the United States. Although these alloys have not been used as matrices in MMCs, they may be used in the future, with further advancement in understanding.

Titanium Alloys

Titanium alloys are very attractive for MMC applications, due to their higher strength and temperature capability compared to aluminum alloys. Despite significant potential for discontinuously reinforced titanium MMCs in various applications, much less emphasis has been given for development of this class of materials until recently. A significant amount of work has been carried out for developing continuously reinforced MMCs to derive substantial strengthening and stiffening at ambient and elevated temperatures (Ref 8, 9, and 10). While Ti-6Al-4V and Ti-15V- 3Cr-3Sn-3Al have been used commonly for MMC applications, other alloys, such as titanium aluminides, were also considered with specific objectives. The alloy Ti-6Al-4V is the most common alloy in the titanium family and has been used in many applications.

The alloying in titanium largely depends on the ability of elements to stabilize either the low- temperature α- or high-temperature β-phase, which is related to the number of bonding electrons (Ref 31). Alloying elements with electron- to-atom ratios of less than four stabilize the α- phase, and elements with electron-to-atom ratios greater than four stabilize the β-phase in titanium. Elements with a ratio of four are neutral. All of the transition elements stabilize the β- phase in titanium, except some rare earth elements. Also, titanium has a high solubility for most of the elements, except a few rare earth elements. The phase diagram of titanium can be categorized as α- and β-stabilizers. The α-stabilizers are the elements that provide complete solubility, with a peritectic reaction such as titanium-oxygen and titanium-nitrogen, and those that have limited α-stability, with a peritectoid reaction into β plus a compound, such as titanium-boron, titanium-carbon, and titanium-aluminum. The β-stabilizers consist of two categories: β-isomorphous and β-eutectoid. In the β-isomorphous systems, an extra β-solubility range exists with only a restricted α-solubility range, such as titanium-molybdenum, titanium-tantalum, and titanium-vanadium. In the β-eutectoid systems, for example, titanium-chromium and titanium-copper, the β-phase has a limited solubility range and decomposes into α and a compound. It is customary to classify titanium alloys into three main groups, designated as α, α+β, and β.

The alloys Ti-6Al-4V and Ti-15V-3Cr-3Sn- 3Al have been used with SCS-6 silicon carbide monofilament reinforcements for MMC applications with reasonable success (Ref 32). These alloys have good ductility at room temperature, which helps achieve rule-of-mixture tensile properties in MMCs. The need for materials that possess superior specific strength and specific modulus at high temperatures has focused attention on a different class of alloys, titanium aluminides. There has been considerable interest in niobium-rich Ti_3Al alloys for continuous fiber- reinforced MMC applications, due to the presence of an orthorhombic (O) phase based on the compound Ti_3AlNb. This O-phase was first found in a Ti-25Al-12.5 Nb (at.%) alloy. The O- phase is similar in nature to α2 (Ti_3Al, DO_{19} structure), however it differs in the lattice arrangement of niobium with respect to titanium. The O-phase has been identified in titanium alloys containing 20 to 30 at.% Al and 11 to 30 at.% Nb, and such alloys are known as O-alloys. Orthorhombic alloys such as Ti-22Al-23Nb (at.%) have good creep resistance, tensile strength, ductility, and thermomechanical fatigue behavior (Ref 33). Improvements in properties such as tensile strength and toughness also have been observed in Ti-25Al-17Nb (at.%) alloy (Ref 34). Because of the attractive combination of room-temperature ductility and elevated-temperature strength, O-alloys have been considered as matrix alloys for continuously reinforced MMCs. Additional advantages of O-based alloys are reduced reaction with SiC fibers and improved environmental resistance compared to most other titanium aluminide alloys. The matrix alloy plays a key role on the properties of continuously reinforced titanium MMCs (Ref 8).

Table 8 shows the tensile properties of an O- alloy in different heat treatment conditions (Ref 35). The table indicates that the strength of the Ti-25Al-17Nb (at.%) alloy is very high and ductility is low after supertransus treatments, whereas for subtransus treatments, it shows much higher ductility with not much reduction in strength. Ductility for subtransus heat treatment ranges from 7 to 14%, which is excellent for MMC matrices. The higher ductility of this alloy helped in efficient use of fiber strength during longitudinal loading of MMCs, as shown by the properties of SiC fiber-reinforced orthorhombic MMCs in Table 9 (Ref 35). The table also includes the properties of the monolithic O-alloy to provide a comparison with MMCs. In the case of a $[0]_4$ MMC, heat treatment has significantly improved the ultimate tensile strength (UTS) and ductility; whereas in the case of $[90]_4$, the heat treatment did not produce as significant improvement in the UTS and ductility. It is known that fiber-matrix debonding under transverse loading can produce a high stress concentration around the fibers. Such stresses can initiate matrix cracks, which can rapidly grow to failure if the fracture toughness of the matrix is low. The low ductility observed for $[90]_4$ MMCs is related to the low toughness of the titanium aluminide matrix. When the matrix possesses sufficient toughness, as in the case of SCS-6/Ti-15V-3Cr- 3Al-3Sn metal-matrix composites, room-temperature ductility of about 1.4% was observed (Ref 36). Table 9 also includes the data for single-ply niobium-coated SCS-fiber-based MMCs in the transverse loading condition that show some improvement in the UTS and ductility.

Significant residual stresses brought about by the mismatch in coefficient of thermal expansion (CTE) between the fiber and the matrix, in combination with limited matrix ductility has caused a major concern with regard to the thermal cycling capability of the titanium aluminide composite system. In earlier studies, chemical interactions in the interfacial region led to the formation of a β-depleted zone, within which cracks often formed from thermal stresses. However, subsequent studies on matrix alloys with higher levels of niobium, from 22 to 27 at.%, showed that the β-depleted zone was eliminated. In fact, a β-enriched zone in the interfacial region led to significantly improved properties under thermal cycling conditions. Studies of MMCs based on other intermetallics with limited ductility, such as titanium aluminide alloys, further emphasize the importance of matching the matrix and fiber CTEs. Significant damage is often observed in TiAl/SiC metal-matrix composites, while TiAl/Al_2O_3 metal-matrix composites exhibit far less damage as a result of a much closer match in CTE between the matrix and the reinforcement.

The progress made in the development of fiber-reinforced titanium MMCs since the 1980s is underscored by the successful military applications now in use (see the article "Aeronautical Applications of Metal-Matrix Composites" in this Volume). While many of the matrix-related issues for O-matrix alloys were adequately addressed in the 1990s, expanded applications of fiber-reinforced titanium MMCs await the development of more-reliable composite processing and lower-cost reinforcements.

Discontinuously reinforced titanium composites have received significant attention in the recent past, with the aim of developing materials having a good combination of strength, ductility, fatigue resistance, and fracture toughness. The major benefit of DRTi over continuous fiber MMCs is that relatively more isotropic properties can be achieved in DRTi. Discontinuously reinforced titanium can be processed using conventional techniques. Due to the reaction between SiC and titanium alloys, SiC is not a preferred reinforcement for titanium alloys. Particles of TiB and TiC have been considered commonly as reinforcements for making DRTi, due to their attractive properties, including compatibility with the matrix alloys. Titanium diboride (TiB_2) is not thermally stable in conventional titanium alloys and therefore, cannot be used as a stable reinforcement. However, TiB_2 can be used to make TiB reinforcement dispersed in titanium alloys by conversion at higher temperatures. While casting can be used to make DRTi (Ref 37), more emphasis has been given to the P/M approach to achieve improved properties through controlled microstructure in the material.

A significant amount of work has been done in Japan (Ref 38, 39, and 40) to develop DRTi for automotive applications. An elemental powder approach using titanium sponge fines was used to reduce the cost of MMCs. This approach also provided a high degree of freedom in the selection of alloy compositions suitable for processing. The processing approach consists of mixing elemental powder of the desired composition, compacting by using cold isostatic pressing (CIP), and then sintering at high temperature in vacuum. This process eliminated the use of hot isostatic pressing (HIP), thereby reducing the cost of the composite. In order to develop an alloy suitable for elemental blending, many alloys were considered for MMC evaluation using elemental powder blending, including Ti-6Al- 4V (Ref 38). Boron powder was used to produce TiB by reaction with titanium during high-temperature sintering of the powder. Except for gamma alloy, where TiB_2 is the stable compound, TiB in the form of plates or needles was found to be a stable reinforcement in α, α-β, and β alloys. A clean interface at TiB/Ti was observed in these MMCs.

The effect of matrix alloys such as α, α-β, and β on the modulus of DRTi is shown in Fig. 6. The modulus value depends on the type of matrix alloys. The aluminum-rich alpha alloy shows the highest modulus for a given TiB fraction, indicating the potential of this alloy for high- modulus applications. Figure 7 shows the comparison of yield strength and creep deflection of the as-sintered DRTi with different matrix alloys. The wrought alloy IMI 834 and 21-4N steel are also used in the plots for comparison purposes. The yield strength of MMC with Ti-Al-Sn-Zr- Nb-Mo-Si is the highest at 800 °C (1470 °F). The creep resistance of this MMC is also better than MMCs with other titanium alloys, except gamma-based MMCs. These plots indicate that by careful selection of a matrix alloy, one can design DRTi with superior thermal resistance relative to typical heat-resistant steel (Ref 38).

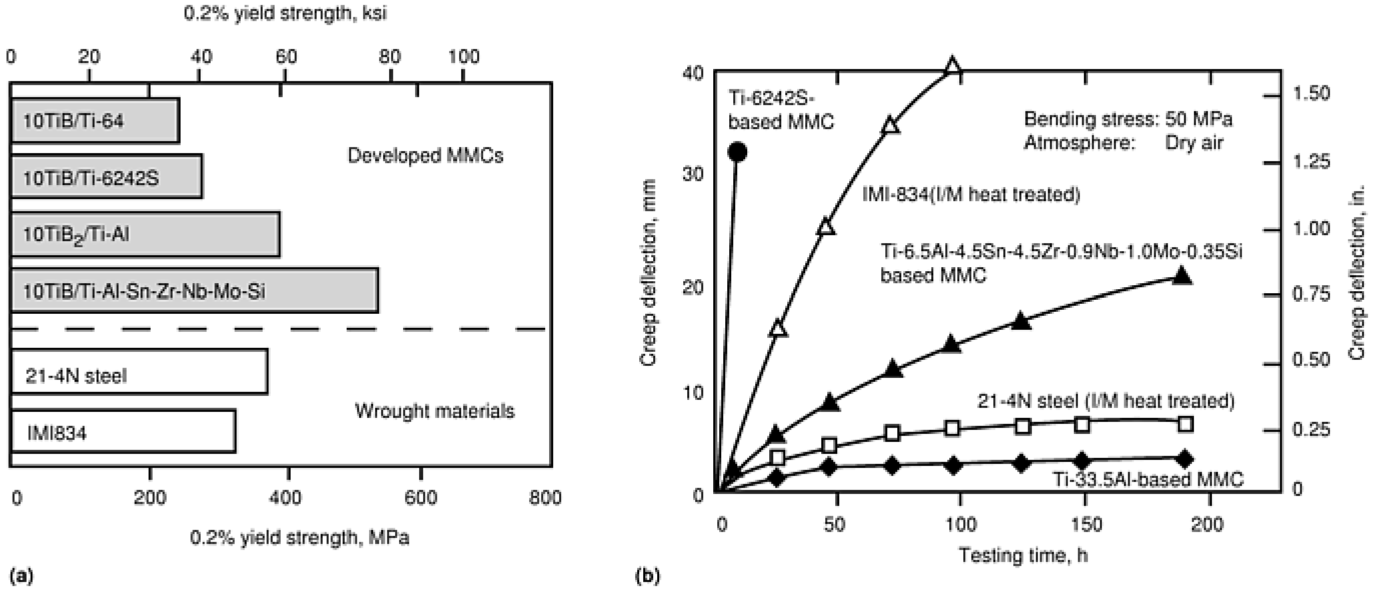

Fig. 7 Effect of matrix alloys on (a) strength and (b) creep of titanium composite at 800 °C (1470 °F). I/M, ingot metallurgy. Courtesy of T. Saito, Toyota Corp.

In order to make MMCs suitable for hot working, a new β-alloy, Ti-4.3Fe-7.Mo-1.4Al-1.4V, has been developed that is compatible with the elemental blending approach (Ref 38). Figure 8 compares hot workability of the developed β- matrix MMC and Ti-6Al-4V-based MMC. The data for commercial medium-carbon steel is also included for a comparison. The β-matrix MMC shows better hot workability than both Ti-6Al- 4V-based MMC and medium-carbon steel. This suggests that β-matrix MMC can be processed successfully using a high-temperature forging operation. Figure 9 shows the tensile properties of the β-matrix MMC in the sinter-swaged and annealed condition. Compared with the as-sintered Ti-6Al-4V-based MMC, the β-matrix MMC shows significantly higher strength and ductility. This suggests that the β-Ti-4.3Fe- 7.0Mo-1.4Al-1.4V alloy is a very effective matrix alloy for MMC applications The high performance was achieved from cheap sponge fine powder using CIP and sintering processes only. The material yield was as high as 100% allowing postprocessing after sintering to a minimum level. Metal-matrix composites of Ti-6Al-4V/ TiB are being used for intake valves, and a high- temperature Ti-Al-Zr-Sn-Nb-Mo-Si/TiB metal- matrix composite is being used for exhaust valves in the Altezza car made by Toyota Motor Manufacturing (Ref 39, 40). Over 500,000 valves have been produced, with no failures, underscoring the maturity of this technology in the automotive market. Additional details of this application are provided in the article "Automotive Applications of Metal-Matrix Composites" in this Volume.

Alloy Ti-6Al-4V has been used with TiC reinforcement to make MMC using a cold and hot isostatic pressing (CHIP) process developed by Dynamet Technology Inc. (Ref 41). The CHIP process consists of CIP of blended elemental matrix alloy powders and reinforcement particles, followed by vacuum sintering and HIP to provide completely densified products with near-net shape. The MMC developed using the CHIP process is commercially known as CermetTi-X, where “X” denotes the volume fraction of reinforcement. CermetTi-10 consists of Ti-6Al-4V with 10 vol% of TiC particles. The Young's modulus of CermetTi-10 is significantly improved over Ti-6Al-4V from room temperature to 650 °C (1200 °F). The room-temperature yield and tensile strengths are retained up to higher temperatures. Ductility of the MMC is lower than that of the matrix alloy at all temperatures. However, the difference between the MMC and matrix alloy ductility gets smaller at higher temperature (650 °C, or 1200 °F). The creep stress rupture property of the MMC is higher by an order of magnitude relative to the matrix alloy at 540 °C (1000 °F). The fracture toughness of the MMC is reasonably high, 28 MPa $\sqrt{\text{m}}$(25 ksi $\sqrt{\text{in.}}$), even though the ductility is low. The fatigue properties of the MMC are comparable to those of the cast Ti-6Al-4V alloy. The improvements in high-temperature strength and modulus of the MMC increase the use-temperature limit relative to unreinforced Ti-6Al-4V by approximately 110 °C (200 °F). Prototype parts made using CermetTi MMC include domed rocket cases, missile fins, and aircraft engine component preforms (Ref 43).

While casting has also been used in many studies (Ref 37, 38), rapid solidification can provide improved properties, due to the finer and uniform distribution of reinforcement in the matrix (Ref 42, 43). Fine dispersions of borides and carbides in the powder have been produced by inert gas atomization. The rapidly solidified powder was consolidated using HIP and/or extrusion. Discontinuously reinforced titanium with Ti-6Al-4V/TiB, Ti-6Al-4V/TiC, and Ti- 6Al-4V/TiB+TiC were produced using this technique. A significant improvement in properties was observed in DRTi containing TiB reinforcements (Ref 43), compared to the Ti-6Al- 4V matrix. Most of these studies concentrated on developing MMCs using different processing techniques

with Ti-6Al-4V alloy as a matrix. Little effort has been put into developing newer matrix alloys for DRTi applications.

Conclusions

Both DRA and DRTi are well-established materials with significant commercial markets. Generally, the matrix alloys are based upon alloys developed for use as monolithic materials. Small modifications in chemistry and processing have provided alloy characteristics more suitable for a matrix alloy, while simultaneously producing notable improvements in materials performance. Additional evolution in discontinuously reinforced MMCs may be achieved by further matrix alloy development.
There is a significant potential of DRA and DRTi materials for several applications. Future work should be directed in the following areas in order to widen the existing applications of discontinuously reinforced aluminum and titanium composites:

- Improvement in the ductility and fracture toughness of DRA materials by developing more fracture-resistant matrix alloys
- Improvement in the high-temperature capability of DRA materials through development of newer heat-resistant matrix alloys
- Improvement in the fracture properties of DRTi through better understanding of processing effects and failure mechanisms in matrix alloys

Ceramic Matrices

Daniel R. Petrak

Introduction

FIBER-REINFORCED CERAMIC-MATRIX COMPOSITES (CMCs) have received a great deal of interest since the 1980s for their potential as high-temperature structural materials. This new class of composites has been the subject of many research programs aimed at ultimately producing components for turbine engines for aerospace and power generation and components for space applications and a variety of industrial uses. Currently, these materials are considered to be expensive relative to available alternatives. Progress on development of design methods and evaluation of full-scale components has been slow. This may be due to the wide variety of chemistries for both matrices and reinforcements and also the process methods used for fabrication. Other factors limiting CMCs use are cost and the poor oxidation resistance of interfacial coatings. This discussion is directed at the matrices for the composites; therefore, attention is focused on the process methods and matrix chemistries. Issues related to reinforcements and interfaces are discussed in other articles in this Volume. In general, the processes of interest include:

- Pressure-assisted glass-matrix densification
- Chemical vapor infiltration (CVI)
- Melt infiltration (MI)
- Polymer infiltration and pyrolysis (PIP)
- Sol-gel processing

In essence, all of the previously mentioned methods involve use of a ceramic, preceramic, or metal phase as a fluid or vapor phase reactant to form the matrix. Each processing technique and specific matrix chemistry types of interest are discussed subsequently. Emphasis is placed on microstructural features that influence ultimate composite properties.

Daniel R. Petrak

Pressure-Assisted Densification

Some of the first successful efforts to produce tough ceramic-matrix composites involved hot pressing of glass or glass ceramics (Ref 1, 2). This work was done with graphite fibers (various vendors), large-filament SiC fibers (Textron Specialty Materials), and ceramic grade (CG) Nicalon fibers (Nippon Carbon Co.). The composites were prepared by slurry coating the fibers with glass frit. Layers or plies of fiber were stacked in a graphite die and then heated under pressure to consolidate the composite above the fusion point of the glass. Typically, the matrices produced in these studies had low porosity and were impermeable to liquids.
The use of glass-ceramic matrices such as $MgO-Al_2O_3-SiO_2$ systems produced crystallized matrices that could be tailored to control matrix thermal expansion and therefore, control the differential stress between the matrix and the fiber. Perhaps most importantly, these studies permitted an understanding of the role of fiber-matrix interfacial layers to be developed. Although many of these composites have useful properties, they are inherently expensive, because the process is size- and shape-limited.

Ceramic Matrices

Daniel R. Petrak

Chemical Vapor Infiltration

Chemical vapor deposition has been recognized as an important process to produce solid materials. It has been used to produce materials for semiconductors and also for structural ceramics (Ref 3). Chemical vapor deposition methods have been useful in producing all of the individual components of ceramic-matrix composites, that is, fibers, interface coatings, and matrices. The term CVI has been used to refer to the process for deposition of interphase and matrix in fiber-reinforced composites. Although the CVI process has been used to produce many carbides, nitrides, borides, and oxides, its use to prepare SiC is most widely known (Ref 4, 5, and 6).

Silicon carbide CVI matrices are often produced by heating methyltrichlorosilane or dichlorosilane and hydrogen to a temperature of 900 to 1100 °C (1600 to 2000 °F) at a pressure of 10 to 100 kPa (1.5 to 15 psi). These deposition conditions permit the use of reinforcements such as graphite, crystalline SiC, Si-C-O fibers (such as CG Nicalon), and Si-C-O-Ti fibers (such as Tyranno, Ube Industries Inc., New York, NY).

The SiC phase produced by this method is beta-SiC. Depending upon the actual deposition time, temperature, and other variables, CVI deposition tends to close off matrix pores. Machining the surface of the composite can open the pores to permit additional matrix densification. Depending upon the thickness of the composite, that process can be repeated until the desired density and porosity are achieved. The CVI process is normally considered complete when the overall porosity is 10 to 15%. Most CVI materials are prepared under isothermal and isobaric conditions. However, thermal gradients and pressure gradients can be used to minimize porosity and to manufacture certain geometrical shapes more efficiently.

The typical microstructure of two-dimensional fabric laminates produced by the CVI process is characterized by dense matrix regions near the fibers tows and by rather coarse pores (10 to 200 μm) in the regions between plies or within the tows (Fig. 1). The SiC-matrix phase is essentially continuous but does not necessarily protect the fibers and the fiber-matrix interface coating from the environment. The ability of the SiC matrix to protect the interface coating is often dependent on the thickness of the coating, its chemistry, and actual environmental conditions. Porosity and matrix stress cracking will allow the ingress of oxygen, which will degrade the interface coating.

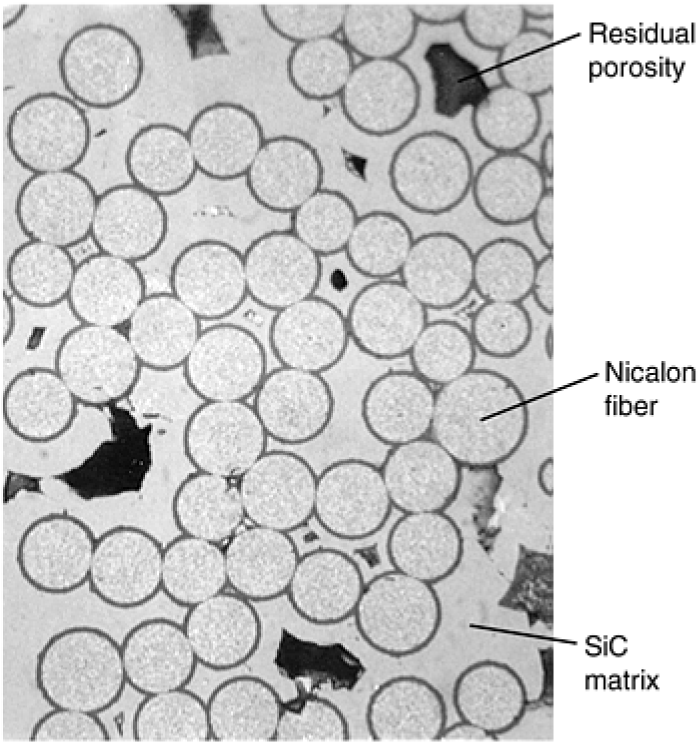

Fig. 1 Typical microstructure of a fabric laminate produced by the chemical vapor infiltration process. The micrograph shows fibers in only one direction in one tow.

Ceramic Matrices

Daniel R. Petrak

Melt Infiltration

The MI method to produce ceramic composites involves producing a reaction-bonded SiC- Si matrix by infiltrating a porous SiC preform with silicon metal. An excellent review of this process and material was given by Corman et al. (Ref 7, 8). The MI technology has evolved over more than 30 years and is covered by a number of patents. Early versions of the technology were called “Silcomp” (General Electric Co.). Silcomp is prepared by infiltrating molten silicon into a porous preform containing carbon in a fibrous form.

More recent versions of the technology include the use of SiC fibers with a BN-based interface coating. Preforms of the coated fiber can be prepared by laminating with a carbon-producing resin or by using CVI methods to produce a porous preform, followed by slurry casting SiC particles into the open porosity of the preform. Densification of the porous preform is accomplished by silicon infiltration. The infiltration step is done in vacuum, at a temperature above the melting point of the silicon alloy. This process results in a nearly fully dense composite. Figures 2 and 3 show examples of MI composites from General Electric Company.

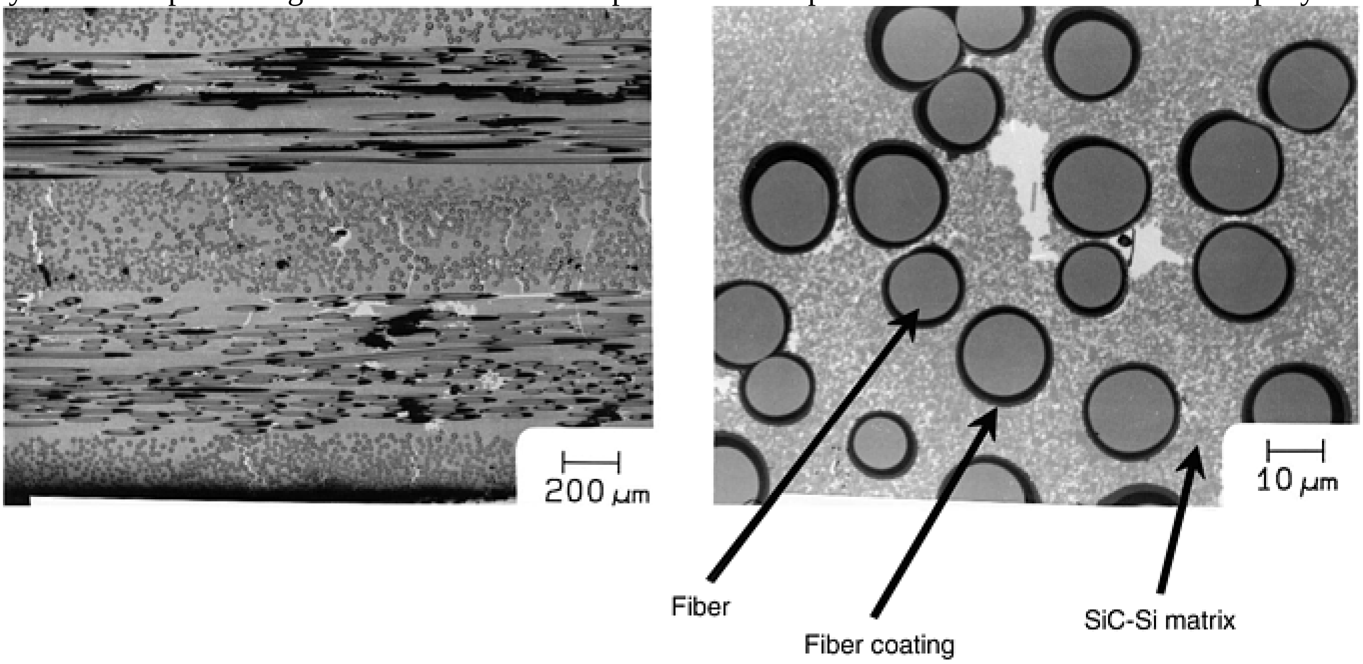

Fig. 2 Micrographs of a melt infiltrated composite prepared from Hi-Nicalon fiber and the tow-winding method to create a tape that is then laminated with a resin. The resin is pyrolyzed to produce carbon in the preform. The silicon infiltration is then done to produce a low-porosity SiC-Si matrix.

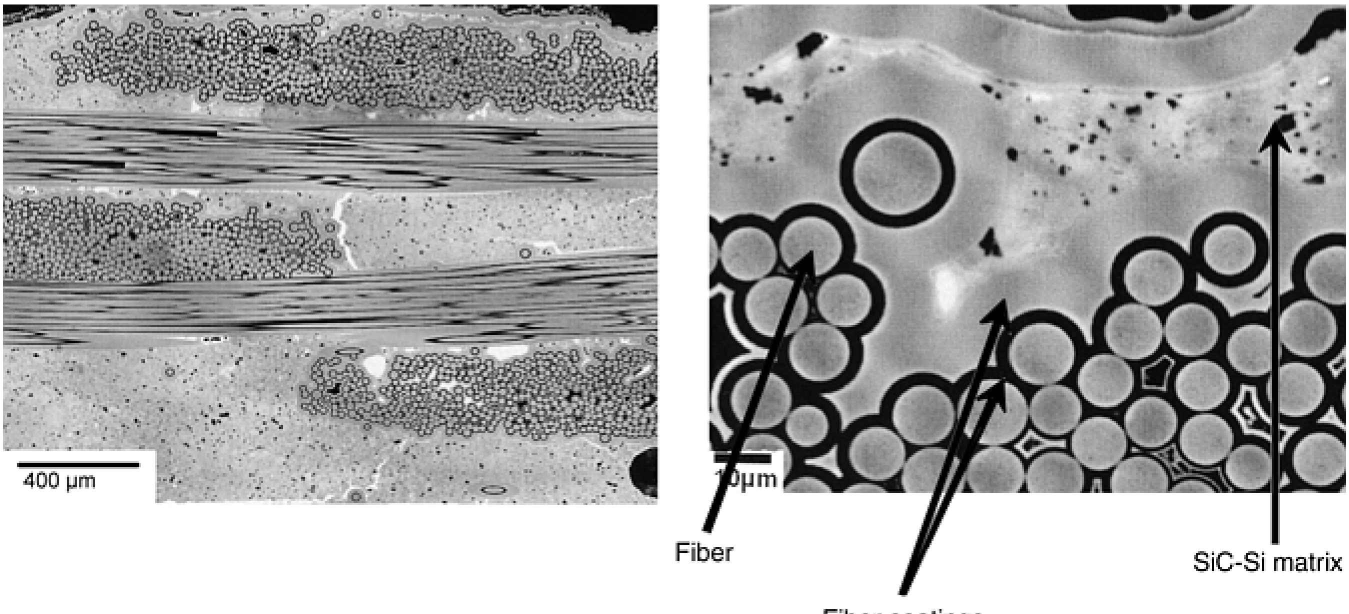

Fig. 3 Micrographs of a melt infiltrated composite reinforced with Sylramic SiC fiber. The preform was made from two-dimensional cloth and was prepared by using a CVI method, followed by slurry casting and silicon melt infiltration.

Figure 2 is a micrograph of an MI composite prepared from Hi-Nicalon fiber and the tow- winding method to prepare a tape, followed by laminating with a resin. The resin is then pyrolyzed to produce carbon in the

preform, followed by silicon infiltration to yield a low-porosity SiC-Si matrix. Figure 3 shows a similar structure, but with Sylramic SiC fiber from Dow Corning, Midland, MI. The preform in Fig. 3 was made from two-dimensional cloth and was prepared by using a CVI method, followed by slurry casting and silicon melt infiltration. The “white” phase in Fig. 2 and 3 is silicon metal; the dark rings around the fibers are interface coatings.

The SiC-Si MI matrix nearly matches the thermal expansion of the high-temperature SiC fibers. It is also a higher thermal conductivity material than the CVI SiC matrix due to its low porosity and the presence of silicon. The MI matrix, along with improved interface coatings and environmental barrier coatings, makes the MI matrix composites candidates for high-temperature structural applications, such as components for power-generating turbines.

Ceramic Matrices

Daniel R. Petrak

Polymer Infiltration and Pyrolysis

The PIP method for producing ceramic matrices makes use of preceramic polymers to form the composite shapes and also to densify the composite matrix. A number of preceramic polymers were developed in the 1970s and 1980s that led to the fabrication of silicon-based fibers and other ceramic applications. Those polymers included polycarbosilanes, polysilanes, polysilazanes, and polysiloxanes. The early efforts to fabricate CMCs by the PIP method (Ref 9) were only marginally successful, because as they were made before the role of interface coatings was known. For that reason, they most often resulted in low strength and brittle materials. That work did, however, suggest lower-cost routes for producing large and complex parts with ceramic composites. In addition to the autoclave molding or compression molding methods discussed subsequently, other techniques, such as filament winding, injection molding, and pultrusion, can be used to manufacture CMCs by the PIP method.

Later, with the availability of carbon-coated CG Nicalon fiber and then commercial sources of BN coatings on Nicalon and higher-temperature fibers, a number of PIP-based CMCs were promoted (Ref 10, 11 12, 13 14, 15 16). Basically, all of the PIP composites were prepared by variants of the methods shown in Fig. 4. The process steps through the polymer cure step are essentially the same as for the preparation of organic-matrix composites. The matrix precursors are often ceramic powder-filled preceramic polymers, mixed by ball milling to make a slurry. The slurry is used to infiltrate the space between the interface- coated fibers in a woven fabric or tape. If solvent is used, it is removed by evaporation. The prepreg is then ready for laminating in a press or autoclave. The stack of prepreg layers is heated under moderate pressure to debulk and then cure the laminate. After the cured part is trimmed and inspected, the composite is converted to a ceramic by heating in a nonreactive atmosphere to pyrolyze the matrix. Pyrolysis removes volatiles such as hydrogen, methane, and sometimes ammonia from the polymer, leaving a ceramic char. Different polymers produce different char chemistries. They include Si-C-O, Si-N-C, and SiC or Si_3N_4 under different conditions of atmosphere and temperature. Depending upon char yield (percentage of original weight of polymer retained after pyrolysis), the

char density, and the amount of powder filler used in the matrix, porosity will be created in the matrix. The level of that porosity can be up to 35% of the volume of the composite.

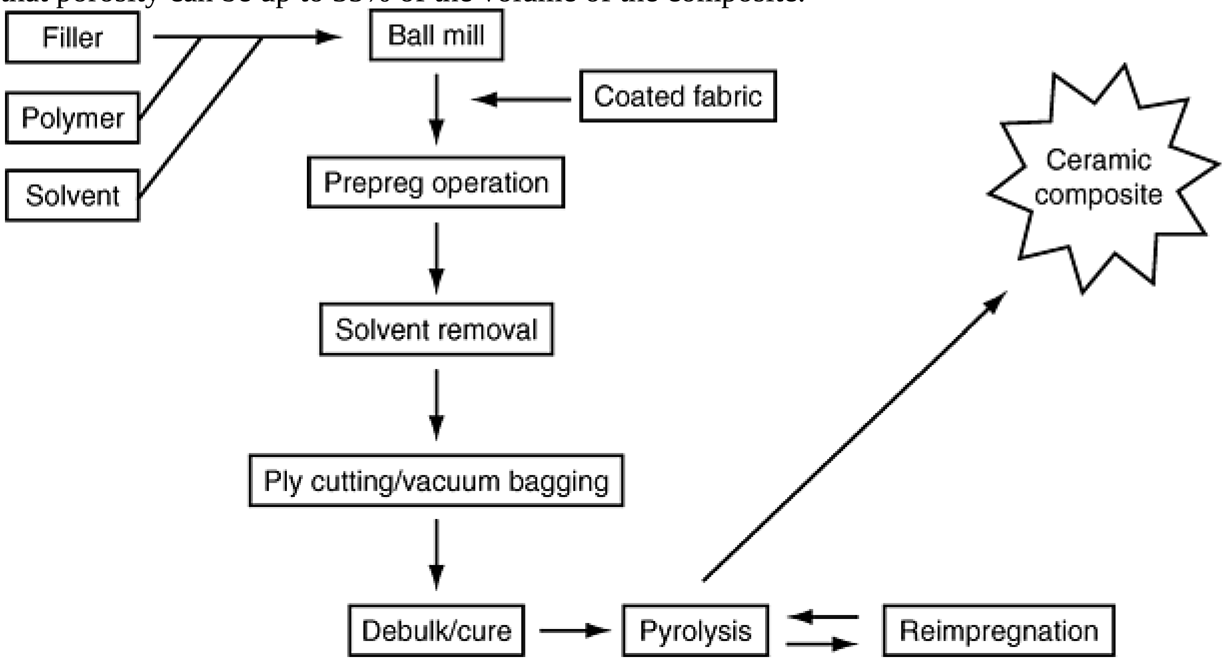

Fig. 4 Polymer infiltration process

If the porosity left in the composite is higher than desired, the polymer used to prepare the prepreg can be used to reinfiltrate the pores, followed by pyrolysis to form additional matrix. This procedure of reinfiltrating the porosity and heating to a pyrolysis temperature can be repeated until the porosity is reduced to an acceptable level. As few as 4 and as many as 15 or 16 pyrolysis cycles are typically required to complete the process. Fully processed PIP composites can have as little as 3 to 5% open porosity, although total porosity is usually approximately 10%.

Figure 5 shows a microstructure of a CG Nicalon fiber composite prepared with a polysilazane-derived matrix (Ref 17). The matrix includes a Si_3N_4 powder filler. The measured open porosity in the composite was less than 5%. Inspection of the micrograph shows that cracks occur in the matrix during the first pyrolysis, and that most of the porosity generated by those cracks has been filled with matrix from subsequent reinfiltrations. Although the PIP composites tend to have some residual open porosity, the formulation of the polysilazane-derived matrix described previously retains good tensile and fatigue properties at 1100 °C (2000 °F) in air for hundreds of hours. That effect occurs because surface oxidation seals porosity to protect the interface and the fiber.

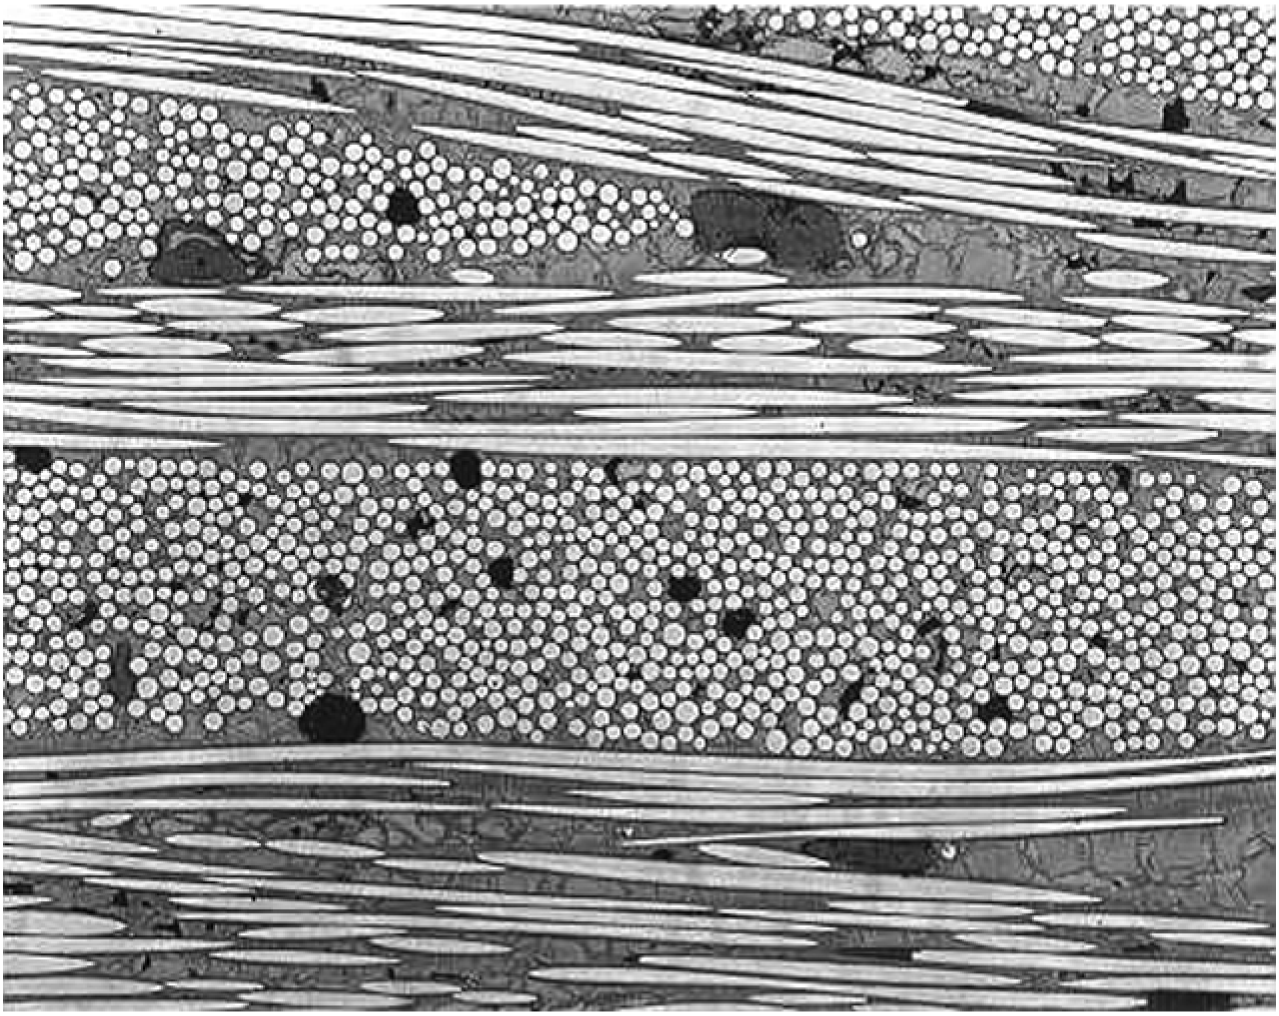

Fig. 5 Microstructure of a CG Nicalon fiber composite prepared from a polysilazane-derived matrix

Silicon-based polymer-derived matrices typically produce amorphous silicon containing glasses when pyrolyzed at temperatures at which CG Nicalon fiber is stable, that is, less than 1200 °C (2200 °F). The use of higher-temperature fibers, such as Hi-Nicalon, Hi-Nicalon S, and Sylramic SiC, permits higher-temperature processing. It is possible to produce crystalline SiC and Si_3N_4 by heating to appropriate temperatures. Depending on the level of oxygen in the char, crystalline phases can be produced in the 1400 to 1600 °C (2550 to 2900 °F) temperature range. However, the volume char yield of the polymer will decrease to levels of less than 20% in some cases, due to the higher density of crystalline phases. The specific gravity of amorphous chars ranges from 2.2 to 2.5, whereas the specific gravity of crystalline SiC is 3.2.

Although many PIP composites have nonoxide chemistries, Szweda et al. (Ref 18) from General Electric Company have used silicon- based preceramic polymers to produce oxide matrices. This permits the polymer to provide the same shape-forming advantages of known organic-matrix composites technologies, similar to the nonoxide precursor capabilities. By processing in air, the SiO_2-containing matrix chemistries can be produced. According to Szweda et al., the processing can be done from 600 °C (1100 °F) to as high as 1400 °C (2550 °F) to produce various solid reactions with ceramic filler particles to form lathlike grains in the matrix. This type of structure minimizes matrix shrinkage and preserves porosity in the matrix to avoid the bonding of matrix to fibers. Fibers useful in producing this type of composite must be stable in the processing and use environment, typically air. Examples include sapphire filaments and weavable oxide tows. One advantage of this process is that only one high-temperature process step is required to make a composite. However, reinfiltration with the polymer can be done to tailor the amount and nature of the porosity.

Sol-Gel Processing

Sol-gel processing (Ref 19) has been used to prepare many oxide compositions in the form of powders, fibers, coatings, and ceramic matrices in CMCs. Sol-gel processing is a chemical solution method to produce ceramic oxides. Two methods are normally used: metal salts or alkoxide precursors. An example of a metal salt is ZrOCl, and an example of an alkoxide precursor is tetraethylorthosilicate. Alkoxides are often preferred, because higher yields and better purity can be achieved with their use.

Combinations of a sol along with solid ceramic powders are often used to prepare a matrix precursor. The sol can act as a carrier and also the binder for the powder in forming a prepreg with the ceramic reinforcing fiber. Once a composite is formed from the preform, the sol can be gelled to make the composite rigid. The composite fabrication process can be filament winding, laminating of two-dimensional prepreg, or injection molding of two- or three-dimensional preforms. Gelling of the sol often can be done by heating, by slight drying, or by a chemical reaction such as exposure to ammonia.

The use of reactive and/or inert filler particles is often very important to reduce matrix shrinkage and cracking during drying and conversion to the final ceramic-matrix chemistry and structure. The typical sol-gel-derived ceramic matrix contains 25 to 40% open porosity after heating to a final process temperature and is of low strength. There are two approaches to selecting the level of desired porosity in these matrices. If the reinforcing fiber does not have an interface coating, then a moderately high level of porosity is generally required to control fiber-to-interface bonding. However, high levels of matrix porosity also typically correspond to low interlaminar strength properties. The introduction of oxidatively stable interface coatings on oxide reinforcements has been studied (Ref 20). Interface coatings, such as $LaPO_4$, are being developed to permit the use of higher-density matrices that should lead to better matrix-dominated properties, higher thermal conductivity, and better erosion resistance.

Figure 6 is a micrograph of a sol-gel-derived Nextel 610 (3M Corporation, St. Paul, MN) fiber-reinforced aluminum-oxide-matrix composite. The composite has nominally 30% porosity and was produced using a two-dimensional cloth lay-up method. The material exhibits a tensile strength of 190 MPa (28 ksi) and an interlaminar shear strength of 11.3 MPa (1.6 ksi).

Carbon Matrices

James Gary Pruett, Hitco Carbon Composites

Introduction

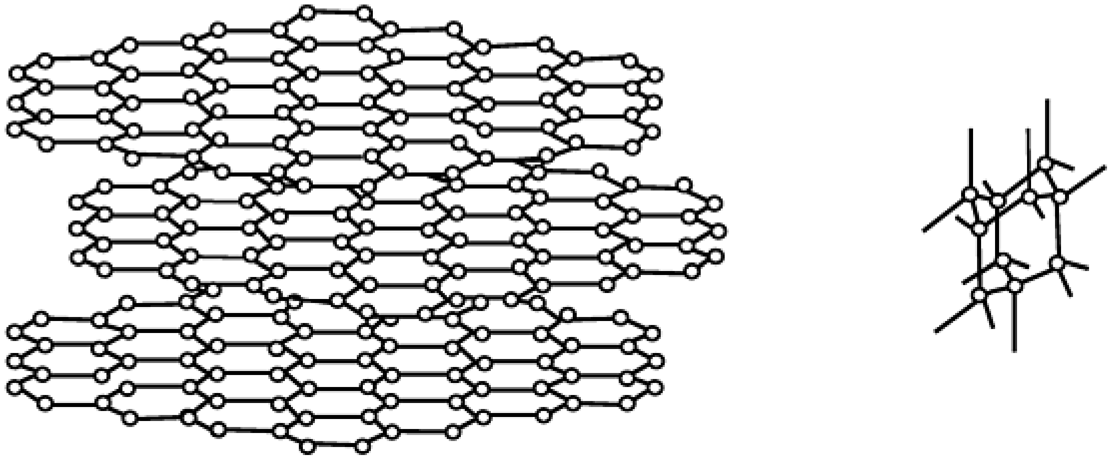
APPLICATIONS involving very high temperature or highly corrosive environments often have requirements that exceed the capabilities of plastic or epoxy matrix composites. Even metal matrices frequently are unable to meet the requirements of the applications. Carbon, which is often included in a discussion of ceramic materials, can sometimes mimic the properties of ceramic matrix composites, but the wide range of processing options and final matrix properties justifies the separation of this material into its own category of matrix materials.

Carbon Matrices

James Gary Pruett, Hitco Carbon Composites

Pure Carbon Forms

Graphite and Diamond. Elemental carbon owes its variety and versatility to the nearly equivalent energy between its two primary forms: (1) diamond, where carbon atoms bond equally to four other carbon atoms, and (2) graphite, where carbon atoms bond equally to three other carbon atoms and weakly to many other carbon atoms. The diamond structure (Fig. 1b) extends uniformly in all three directions to form a very hard crystalline material. The graphite structure (Fig. 1a) is normally pictured as a planar assembly of atoms arranged in hexagonal patterns, much like "chicken" wire. Multiple planes of the basic sheet structure are stacked in a regular pattern, such that alternating planes are exactly matched and aligned. Both the diamond and graphite structures create long-range interconnectivity (theoretically infinite crystal lattices), resulting in large macroscopic crystals in nature (diamonds and natural graphite flakes).



(a) (b)

Fig. 1 Primary forms of elemental carbon. (a) Graphite structure with extended sheets of hexagonal units. (b) Diamond structure with each carbon atom having four equivalent bonds in an interconnected network

The net thermodynamic energy required to transform between diamond and graphite is very small (less than one kilocalorie per mole, with graphite the more stable), yet diamond is very stable even at elevated temperatures. The stability is due to a large energy barrier necessary to convert between the two. The energy barrier is associated with a concerted simultaneous change in bonding of many atoms and the resulting large atomic displacements required. Very high temperatures and pressures are necessary to overcome the barrier. This explains why natural diamonds are found deep in ancient volcano pipes and why synthetic diamond production requires specialized ultrahigh pressure, high-temperature reactor systems.

Since the 1980s, additional methods of making artificial diamonds have been developed that do not require such high temperatures and pressures. With precise control of the gas mixtures, diamond films have been grown with an ordinary acetylene torch. Plasma torches, microwave discharges, and hot filament reactors have also been used with success, as described by Bachman (Ref 1). These approaches avoid the energy barrier between graphite and diamond by constructing the diamond material a few carbon atoms at a time from a carbon-containing gas such as methane or acetylene, rather than trying to transform a bulk graphite form.

The combination of nearness in energy and propensity for large interconnectivity gives rise to many intermediate mixed structures between diamond and graphite that are also metastable. On the graphite end of this spectrum are near- graphites, which exhibit long-range order in a given plane of carbon atoms (so-called graphene sheets), but whose planes are stacked somewhat randomly and exhibit a range of angles of in- plane rotation between adjacent sheets. Moving toward more disorder, the graphene sheets can be contorted, split, twisted, and reconnected with a resulting high level of defects and void structures. The logical end to this sequence would be a totally random and very hard, glassy network of carbon atoms with an amorphous morphology. As these amorphous structures contain more three-dimensional diamondlike structures, the material begins to resemble a diamond lattice.

These intermediate structures have wide property ranges that are exploited in carbon matrix composites. They are all highly metastable, especially the glassy forms, and, for all practical purposes, are stable and useful over wide temperature ranges. Under normally accessed temperatures and pressures, the graphite form is the most stable.

Fullerenes and Nanotubes. A third "new" form of carbon recently discovered, the fullerenes, is qualitatively different from the traditional forms of carbon. The fullerenes are actually molecular forms of pure carbon. The connectivity between the atoms is "closed," in that all bonds are satisfied within a short distance. For example, C_{60} is a stable carbon molecule whose structure was worked out by Kroto, Curl, and Smalley (Ref 2) to be that of a soccer ball (mixture of hexagons and pentagons of carbon atoms connected in a closed structure). This is also the structure presented by Buckminster Fuller's geodesic dome, from which the common name of the material is derived. If additional six- carbon atom rings are added around the circumference of C_{60}, it becomes cigar shaped and, eventually, a closed-end tube, referred to as single wall nanotubes.

All of these new forms of carbon should be thought of as molecular forms of carbon that condense into various phases. For example, crystals of C_{60} have been separated and examined by x-ray diffraction, and "condensed"

ropes of single wall nanotubes are the most commonly observed structures of nanotubes in the laboratory. These carbons are less metastable than the graphite or diamond forms, due primarily to the higher energy related to the carbon pentagons. As a result they tend to convert to graphitic or glassy forms of carbon when heated to moderately high temperatures. As a molecular form of pure carbon, there are some potential advantages of this material as a matrix precursor, if not as the actual matrix. Since there is no other element present except carbon, it could have a unique role as a zero-mass loss precursor to other forms of carbon. Laboratory examples of composites made by using some of these materials began to emerge in the late 1990s.

The commercial importance of each of these forms as matrix materials varies widely. A graphitic carbon matrix is a desired goal for composites whose primary function is heat transfer. Large quantities of aircraft brake materials are made with the specification of having a highly ordered graphite structure in the matrix. The graphite structure is also desirable when a better resistance to oxidation at high temperature is advantageous. These matrices are readily made either by choosing the right conditions for pyrocarbon deposition, or by using highly graphitic pitch-precursor materials for liquid impregnation. For purely structural applications, a less-graphitic and more-glassy carbon matrix material is often used, which requires less high-temperature processing. Diamond as a matrix material is not commercially available due to the difficulty of achieving the diamond structure within the bulk of a composite. The new fullerene materials have been used in the laboratory as matrix materials and matrix precursors, but suffer from the high cost and low availability of the starting materials.

Carbon Matrices

James Gary Pruett, Hitco Carbon Composites

Matrix Formation Methods

General Considerations. Carbon, since it does not melt or flow even at quite high temperatures, must be introduced into a matrix in a precarbon or presolid form, similar to any refractory matrix material. Inclusion in a matrix can be done in a variety of ways. The earliest method employed was by the introduction of a precarbon liquid followed by solidification and carbonization of the carbon precursor. Later, the matrix was formed by the introduction of a carbon-containing gas into a hot porous part, with subsequent chemical decomposition of the gas to elemental solid carbon within the porous part. In the case of liquid infiltration, the liquid flow properties can also be used to introduce finely divided solid carbon or modifying materials into the matrix as fillers or modifiers for a variety of end-use properties. The whole process can be catalyzed or uncatalyzed, and it can be aided with a variety of energy-enhanced processes such as plasmas or electrical discharges.

Table 1 illustrates the variety of carbon types and the corresponding general methods used to create them or incorporate them into a matrix of a composite.

Table 1 Carbon forms and methods used to incorporate them into a composite matrix

Carbon form	Liquid	Particulate	Pyrolytic	Catalyzed	Enhanced
Graphite	X	X	X	X	
Turbostratic graphite	X	X	X		
Glassy carbon	X	X	X		
Diamond		X			X

Fullerene	X		X
Nanotube		X	X

X, applicable method

Liquid Precursors. Liquid precursors are generally one of three types: thermoplastic (viscosity decreasing with temperature), thermosetting (transforming to nonfluid state at increased temperature), and evaporative or solvent carriers (disappearing entirely during later processing).

Thermoplastic varieties are relatively easy to process to a noncarbon composite state, but present significant challenges to convert to pure carbon. Their thermoplastic behavior requires that they either be confined within the object by external means, or be chemically treated (stabilized) prior to heating to carbonization temperatures. Petroleum- or coal-based pitch materials are a good example of this type. Most pitches are solids at room temperature. They can be dissolved in a volatile solvent or heated to reduce their viscosity to the point that they can infiltrate a porous object or preform. Since the pitch material melts prior to carbonization, the object to be filled must be held within a closed container that, at the fluid temperature of the pitch, subjects the object to complete immersion in the fluid. The fluid can enter the porous part by capillary action or by using external pressure. As the material continues to be heated, the pitch will begin to solidify through condensation reactions, a process that releases gaseous products. Unless held at high pressure, these gaseous products tend to cause the pitch fluid to foam, displacing pitch from the preform. Prior to reaching the foaming reaction, the pitch material can be exposed to an oxidizing environment at an elevated temperature over a period of time. This treatment induces an oxidative cross-linking among the constituents of the pitch, causing it to permanently harden. Further increase in temperature causes decomposition to form solid carbon, but no fluid phase occurs and the carbon is retained in the object. The net result is that a process using this type of carbon precursor requires the steps of fluidization (by heat or solvent), infiltration, confinement and stabilization, final carbonization, and removal of the object from waste- carbonized precursor. Other thermoplastic forms can be treated similarly.

Thermosetting Fluids. At an elevated temperature and without the introduction of additional materials, thermosetting fluids possess the property of curing to a solid that will not melt at a higher temperature. Some of these materials cure with an exothermic reaction that releases water. Others cure without the release of any volatile materials. From a fabrication process perspective, this is a very useful behavior because reinforcing material can be preimpregnated with the precursor material, compression and heat molded, and cured to a near-net shape in one step. The resulting near-net shape part can then be carbonized and further processed to finish the composite structure with no further fixtures or confinement. This process is at least the first step in the fabrication of a large number of aircraft brake materials made of carbon matrix composites.

Evaporative Precursors. Some more-recently developed methods use a carrier fluid, which is evaporated prior to carbonization, to carry powdered materials into the reinforcement structure; the powders themselves have no or much- reduced fluidity even at very high temperatures. In this technique, a solids-loaded carrier fluid is introduced to the reinforcement through a preimpregnation process or by multiple soaking and evaporation steps. The purpose is to obtain a very high carbon content in the matrix prior to carbonization. Subsequent carbonization then results in a high carbon yield within the composite while reducing the number of processing cycles. Variations of this technique have long been used with standard precursor fluids to introduce fillers into the composite. Either pure carbon (carbon black or advanced pitch-derived carbon particles) or active fillers, such as boron-containing compounds or silicon carbide, can be added for the purpose of modifying the performance properties of the composite.

Processing Characteristics and Properties. All liquid precursor methods for producing a carbon matrix suffer from one problem: the precursor materials always have a lower carbon content per unit volume than does the desired carbon matrix. Therefore, there is always a reduction in volume of the precursor when going to the final matrix. In addition, most of the liquid precursor materials lose some of their carbon content and all of their noncarbon content during the carbonization process. The most commonly used phenolic heat-set resins, for example, lose up to 50% of their mass when being carbonized. This mass loss also produces waste products in the process that must be handled carefully as potential health risks (polyaromatic and phenolic species). This mass and volume loss results in a fully dense, precarbonized composite that becomes porous and weak after carbonization. This situation is usually remedied by multiple reimpregnation and carbonization steps, reaching a diminishing return at around 5 to 10% porosity. As a result, a high premium is placed on carbon yield in the process. Poor carbon yields are obtained from polyesters and epoxides (<20%). Useful yields are obtained from epoxy-novalac, furan, and phenol formaldehyde resins (>50%). Some difficult-to-obtain materials, such as

polyphenylene, have been shown to give over 80% carbon yields. Pitch materials, when processed at high pressure, can give yields in the 80% range. In general, the more aromatic structure in the precursor, the higher the carbon yield. Carbon yield can be increased by selection of precursor, by use of fillers, or by carrying out the carbonization at high pressure to inhibit the loss of volatile carbon species during carbonization. The high pressure impregnation and carbonization method was developed specifically to overcome this mass loss issue in pitch materials.

The matrix shrinkage of liquid precursors can have a profound effect on the composite properties as well. Carbon and noncarbon loss during carbonization is often a source of damage in the structure, especially during the early stages when there are no passages for the material to escape. When the evolved species collect in isolated voids and exert pressures that exceed the local material strength, larger voids can open and create damaged regions (primarily delaminations). During later stages when a network of connected cracks has developed, this danger is largely over. As a result, careful attention is often paid to the carbonization process temperature versus time profile to avoid these dangers in manufacturing.

The nature, location, and size of the shrinkage cracks is also a subtle but important issue in the processing of these matrix materials. If the crack structure is to be used as the conduit for later infiltration steps, it is important to have a structure that is compatible with the next processing step. When a region of resin surrounded by reinforcement begins to shrink, stress occurs in any direction that the reinforcement is constrained and unable to move with the shrinking matrix. When the stress extends to the area of lowest material strength, a crack opens in that area to relieve the stress. As the material continues to shrink, stress builds up again until another weak area is found, thereby creating a new crack or extending the size of an old crack. While some of the shrinkage can occur as net dimensional shrinkage of the composite, the fiber or other reinforcement often holds the part shrinkage to a small value, resulting in substantial porosity within the part. The shrinkage can result in either a few large cracks or a large number of smaller cracks within the part. This behavior is often dictated by a combination of resin strength at various stages during carbonization, stress induced by shrinkage at those stages, and the interfacial strength between the carbonizing matrix precursor and the reinforcing network.

For example, in traditional two-dimensional fabric composites, it is relatively easy for the part to shrink in a direction perpendicular to the fabric planes. There are no fibers oriented in that direction to maintain the dimensional stability of the article. Stress buildup in the direction normal to the plane is rare, and few, if any, cracks are found in that direction in the composite. In the two orthogonal directions, however, the composite dimensions are constrained, and quite large stresses build up during matrix shrinkage. Two general cases can occur, as illustrated in Fig. 2. If the reinforcement-matrix interface is strong, the stress will build up until the material strength of the matrix itself is matched, causing a crack to occur within the matrix material. For a strong matrix material, this most often results in the formation of a few large cracks within the composite structure. These appear as ribbonlike cracks when viewing the fiber bundle cross section (Fig. 2a). These cracks are often nearly equally spaced, indicating a classic stress field in one direction that results in cracks at even intervals. The second case (Fig. 2b) is if the matrix-reinforcement interface is very weak, or if the matrix itself has little strength. In this case, cracks begin to occur at very low stress levels, and the final structure has many very fine cracks with few large cracks. A fine-cracking structure is usually obtained when there is a very weak surface bonding between the matrix and the reinforcement or any fillers present. This creates a large number of weak crack sites during matrix shrinkage.

Fig. 2 Effects of shrinkage. (a) Shrinkage cracks in matrix carbon when matrix is strongly bonded to reinforcement. (b) Debonding and shrinkage in matrix when matrix is weakly bonded to reinforcement

Chemical Vapor Infiltration. Pyrolytic carbon deposition from hydrocarbon gases has been known and used for many years. The process was first developed to provide carbon overcoats on nuclear fuel pellets. Relatively early in the development of carbon matrix composites, the method was adapted to infiltrate a porous preform with pyrolytic carbon. In this process a porous carbon or other refractory material reinforcing structure is placed inside a closed furnace vessel and heated in the presence of a carbon- containing gas, usually natural gas. The process is normally run at a reduced pressure, about 20 mbar (2 kPa), and with sufficient hydrocarbon gas flow to reduce residence time in the furnace to less than a few seconds. This type of process is referred to as isothermal chemical vapor infiltration (CVI). Hydrogen gas is often added as a side reaction moderator. The temperature is usually between 800 and 1100 ^{o}C (1470 and 2010 °F) in order to slow the deposition rate down such that deposition occurs throughout the part rather than just at the surface. The process is a very complex multi-step reaction in which the initial gas components decompose to more reactive gases, while all the time diffusing into the porous parts and converting to solid carbon as it contacts surfaces. It is not surprising then that variations in both chemistry and deposition rate can and do occur in large furnaces where the diffusion length of the gas is much smaller than the furnace during the transit time through the furnace. A large part of the commercial success of this process is due to the artful control of such variables.

The highly complex nature of the process has led to some misunderstanding of the limitations of the isothermal CVI. The presence of the gas phase side reactions that leads to ever-increasing reactivity of the molecules produced gives rise to furnace limitation effects on the kind of processing that can be done. If the gas flow is too low and residence time is too long in the furnace, reactive species build up that eventually (and non-linearly) lead to soot formation. Long before soot is formed, species are generated that are so reactive they deposit carbon on the first surface they encounter, leading to surface coatings on the parts and necessitating costly and time-consuming unloading and machining. Such sooting also is most apparent in regions of restricted flow within a furnace. These same species, if generated within the pores of the part, are rapidly depleted due to the high surface area-volume ratio within the part, contributing to the desired internal deposition but never advancing to the sooting stage. This soaking up of soot-forming precursors leads to the observation that soot

plumes are usually associated with regions of the furnace away from reacting parts. The surface coating is often blamed on the intrinsic limitations of isothermal CVI as being an "outside-in" process. In reality, the reactivity of the initial species introduced into the furnace is low enough that such limitations are not realized. In small furnaces where it is easy to avoid side reactions, successful infiltration of parts can proceed at many times the speed of the process practiced in large furnaces. A recent series of demonstrations and measurements by Huttinger (Ref 3) clarifies this process and has the potential of modernizing the isothermal CVI process practice, or at least clarifying most of the issues in its commercial use. Huttinger has even demonstrated that proper attention to the issues of this complex process can actually succeed in adding carbon to the matrix from the inside-out rather than the reverse.

In other efforts to overcome the issues of isothermal CVI processing, two other vapor deposition concepts have been developed. One method, which was developed to overcome the diffusional mass transport limitations, is known as forced flow CVI. In this process, the part to be infiltrated is fixtured in such a way that gases flowing in the reactor are forced to move through the part by pressure gradients, rather than being limited to diffusion due to concentration gradients. This process has indeed been demonstrated to allow much faster infiltration times. Its commercial acceptance is probably limited by the prior installation of an ample amount of isothermal CVI capacity, and by the fact that in large production, it is often impractical to arrange the fixtures and gas flow patterns to accommodate multiple parts and complex part geometries.

Another method that has been developed is known as thermal gradient CVI. In this process a thermal gradient is developed across the object to be infiltrated, such that the reaction proceeds slowly on the outside of the part that is relatively cool while proceeding rapidly on the inside of the part where it is hot. In some examples, the gradient is obtained by natural radiative cooling of the hot exterior of the parts exposed to cold reactor walls, and in other examples by the boiling of a hydrocarbon source liquid in contact with the outside surfaces of the part. As the reaction proceeds, the hot zone migrates to the outside, resulting in very high filling efficiencies in notably short periods of time. This method, while very successful, also suffers in some commercial applications where complex part geometries are not amenable to this type of processing. In addition, this method suffers from the consideration that the thermal gradient requires considerable power per unit being processed, resulting in high power costs to establish a large volume production based on the technique.

For all of the CVI processing options, there are two very significant advantages of CVI processing over liquid precursor processing. First, when infiltration is complete, the matrix is all carbon with no processing shrinkage to damage the composite. Second, the type of pyrocarbon in the matrix can be tailored to range from highly graphitic to very isotropic.

Since all CVI processing is a surface deposition rather than a volume deposition process, carbon is deposited layer by layer until the pore is either inaccessible through a closed neck, or it is completely filled. As long as the pores being filled are small in size, this layer-by-layer process is economical and relatively fast. Typical surface thickness growth rates in commercial isothermal CVI processing are on the order of 0.02 μm per hour, requiring about 50 hours of processing time to fill all pores below 2 μm in diameter. Larger pores are clearly an important issue, and successful commercial applications of isothermal CVI have paid close attention to the pore size distribution in the parts to be infiltrated. When preceded by a liquid infiltration step, the issues associated with crack size during carbonization are of clear importance. The resulting relatively crack-free composite structures tend to be of the highest strength class of composites using the same reinforcements.

Pyrocarbon has been known for many years to be produced in a wide range of microstructures. Some rough processing maps have been produced to indicate the types of conditions necessary to create the different carbon types. In general, slower deposition rates using precursor species that contain acetylenic, if not aromatic, bond units tend to give more graphitic structures. Such pyrocarbons can have as-grown densities above 2.0 g/cm^3 and can be converted to nearly pure graphite at reasonably achievable temperatures. On the other hand, using either high deposition rates or precursor species with little or no aromatic content can lead to pyrocarbons that have densities below 1.4 g/cm^3, almost no graphitic character, and unresponsiveness to heat treatment. The desired type of carbon can therefore be controlled to fit the performance requirements of the final composite.

James Gary Pruett, Hitco Carbon Composites

Matrix Contribution to Composite Properties

All carbon matrix forms exhibit the characteristic thermal and chemical stability of carbon, but they do not all result in the same final properties of the composite. Although composite properties are often dominated by the reinforcement properties, some properties, such as interlaminar shear and interlaminar tensile, are matrix dominated. In addition, properties such as thermal and electrical conductivity can be strongly affected by the matrix material type. Even the more traditional structural properties are affected by the density and/or porosity of the composite, which are almost entirely due to the matrix or to the process of forming the matrix. Finally, some performance properties of composites, such as friction coefficient and wear in brakes and clutches, are such complex functions of the composite constituents that the matrix material and its processing can never be disregarded.

High thermal and electrical conductivity are best obtained by having as high a graphitic content in the matrix as possible. This is moderated by the fact that both electrical and thermal conductivity of graphite are highly anisotropic, so the alignment of the graphitic planes in the final composite is as important as the presence of the graphite itself, if thermal conductivity is desired in a particular direction. If the composite is produced using isothermal CVI or related techniques, the graphitic planes usually align with the surface they are grown on. Thus, if a fiber reinforcement is used, the direction of highest thermal conductivity is aligned along the fiber direction. Liquid impregnation processing has less of a templating effect on the graphitic plane orientation in the matrix, so the matrix contribution is more uniform in direction, but is less dramatic in any one direction.

The effects of crack size and porosity on the strength of the material is well established, so to minimize these effects, careful attention must be paid to the matrix and the process of making it. Since part density is such an easy property to measure and is directly correlated with part porosity for a composite of a given structure, density is often used as a property to correlate with strength. Caution should be exercised, however, since such a wide range of matrix densities can be realized that a fully dense, near-zero porosity part of high strength could be made with a density below that of a weak and still-porous composite.

Alteration of Properties by Heat Treatment. Since graphite is the most stable form of carbon under normal conditions, nongraphitic forms of carbon can be converted to more graphitic forms by applying heat to the composite after matrix formation. In cases where the object will be used at very high temperature, the preheating of the composite is also beneficial for stabilizing the properties during use. As mentioned previously, the transformation of the metastable forms of carbon to graphite requires a high temperature to overcome barriers to the transformation. For the wide variety of imperfections that are possible in a nongraphitic carbon, it is not surprising that some of those imperfections would become annealed at lower temperatures, while others would require very high temperatures. A great deal of differentiation in carbon materials comes from whether they can be heat treated to achieve graphitic character, and the temperature required to achieve that character. For easily heat-treated materials (mesophase pitch-derived carbon and anisotropic pyrocarbons), it may only be necessary to heat to temperatures of 1930 to 2200 °C (3500 to 4000 °F), while other materials (isotropic pitch-derived carbons, isotropic pyrocarbons, and phenolic resin chars) may require up to 2760 °C (5000 °F) to achieve the same structure. Some materials resist becoming graphite at even those extreme conditions.

James Gary Pruett, Hitco Carbon Composites

Future Directions and Needs

Future changes in the practice of carbon matrix composites most likely will be driven by the cost requirements necessary to transform the material from a military and aerospace specialty to a commercially viable substitute for monolithic graphites or specialty metals and coatings. Lower-cost production methods are required, which primarily means continuous, hands-off processing and more sophisticated control of process variables. On the materials side, low cost, ultrahigh-yield carbon precursors are required. It will also be helpful when a balance is struck between the performance required and the level of processing of the composite. Many of the new rapid densification techniques being developed will need to find a new market-pull application. This will allow them to move around the momentum established by the brakes market for carbon matrix composites, which has driven and frozen the technology due to long qualification times and incorporation of the technology into a vertically integrated manufacturing process.

Introduction

FIBER-MATRIX ADHESION is a variable to be optimized in order to get the best properties and performance in composite materials. The contemporary view of adhesion rests on an *interphase* model in which not only the actual chemical and physical interactions between fiber and matrix are considered, but also the structure and properties of both the fiber and the matrix in the region near the interface. While not a "phase" in the true sense of the word (that is, an identifiable volume with uniform properties), the term has come to be used to describe a region of finite dimensions where the local properties vary from those of the bulk phases. Although our understanding of this interphase is far from complete, the studies completed to date provide some insight into selection of surface treatments and finishes for certain classes of fiber and matrix constituents. An optimal design methodology starts with the specification of the fiber and matrix from a structural consideration. Once the constituents are selected, the focus is on the creation of a beneficial fiber-matrix interphase. This interphase region where the fiber and matrix interact has to be designed for both processing and performance. Although no quantitative models are available for interphase optimization, various thermodynamic and materials science principles coupled with a growing body of experimental data allow us to understand the interphase as well as to qualitatively design the interphase. The tools available for analysis and design include selection of surface treatments for surface structural and chemical modification; the use of surface finishes and/or sizes to ensure thorough wetting and protection of the fiber; creation of interphases with desirable stiffness, toughness, and failure modes; and quantitative and qualitative characterization tests for measuring fiber- matrix adhesion levels compatible with the structural environment and constituent materials.

Interfaces and Interphases

Interface and Interphase

A composite material is the combination of any two or more constituents, one of which has superior mechanical properties but is in a difficult-to-use form (e.g., fiber, powder, etc.). This superior constituent is usually the reinforcement, while the other constituent (the matrix) serves as the medium in which the reinforcement is dispersed and serves to transmit external loads from reinforcing fiber to fiber. The resultant composite is a material whose properties are close to those of the reinforcement constituent, but in a form that can be easily fabricated into a structural component. Included in this definition of the reinforcing materials are particulate, fiber, flake, and sheet reinforcements. Matrices may be ceramic, metallic, polymeric, and cementitious.

Interface. Since their inception, composite materials behavior has been predicated on the use of structure-property relationships accounting for the fiber and matrix constituents. Factors such as constituent composition, physical morphology, and geometrical arrangement have been incorporated in models that can predict composite mechanical behavior. Since the 1980s, however, the realization that "acceptable" properties of the interface between reinforcement and matrix are necessary for coupling of the reinforcement to the matrix and behavior that agrees with the structure-property models, for example, rule- of-mixtures. An optimized interface is necessary for the composite to achieve maximum static and dynamic mechanical properties and environmental resistance. Indeed, interfacial adhesion between fiber and matrix is based on empirical methods for optimization in most commercial composites marketed today. In optimized commercial materials, the interface functions as an efficient transmitter of forces between fiber and matrix. As such, as long as the interface is intact, composite materials behavior can be adequately described by models that assume ideal adhesion between fiber and matrix and consider the interface to be a two-dimensional boundary.

Interphase. Fiber-matrix adhesion is viewed as a necessary criterion for achieving acceptable composite properties. The patent literature contains numerous chemical formulations, processes, and procedures designed to increase fiber-matrix adhesion levels so that acceptable composite mechanical properties could be achieved. As our understanding of the relationship of fiber-matrix adhesion to composite mechanical properties has increased (Ref 1), it has become apparent that adhesion not only is necessary, but also, if properly designed, can enhance the composite mechanical properties and performance. Although our quantitative understanding of the fiber-matrix interface and the mechanisms of adhesion is not completely developed at this time, it is possible to

optimize the fiber-matrix interphase in much the same manner as composite design methodologies are optimized. The key to success in this endeavor is using the concept of a fiber-matrix interphase as a framework upon which to build this methodology. For the illustration of the concept of "interphase," comments will be directed to and examples will be selected from polymeric matrix composites.

Research since 1990 has expanded the concept of the fiber-matrix interface, which exists as a two-dimensional boundary, into that of a fiber- matrix *interphase* that exists in three dimensions (Ref 2). The complexity of this interphase can best be illustrated with the use of a schematic model, which allows the many different characteristics of this region to be enumerated, as shown in Fig. 1.

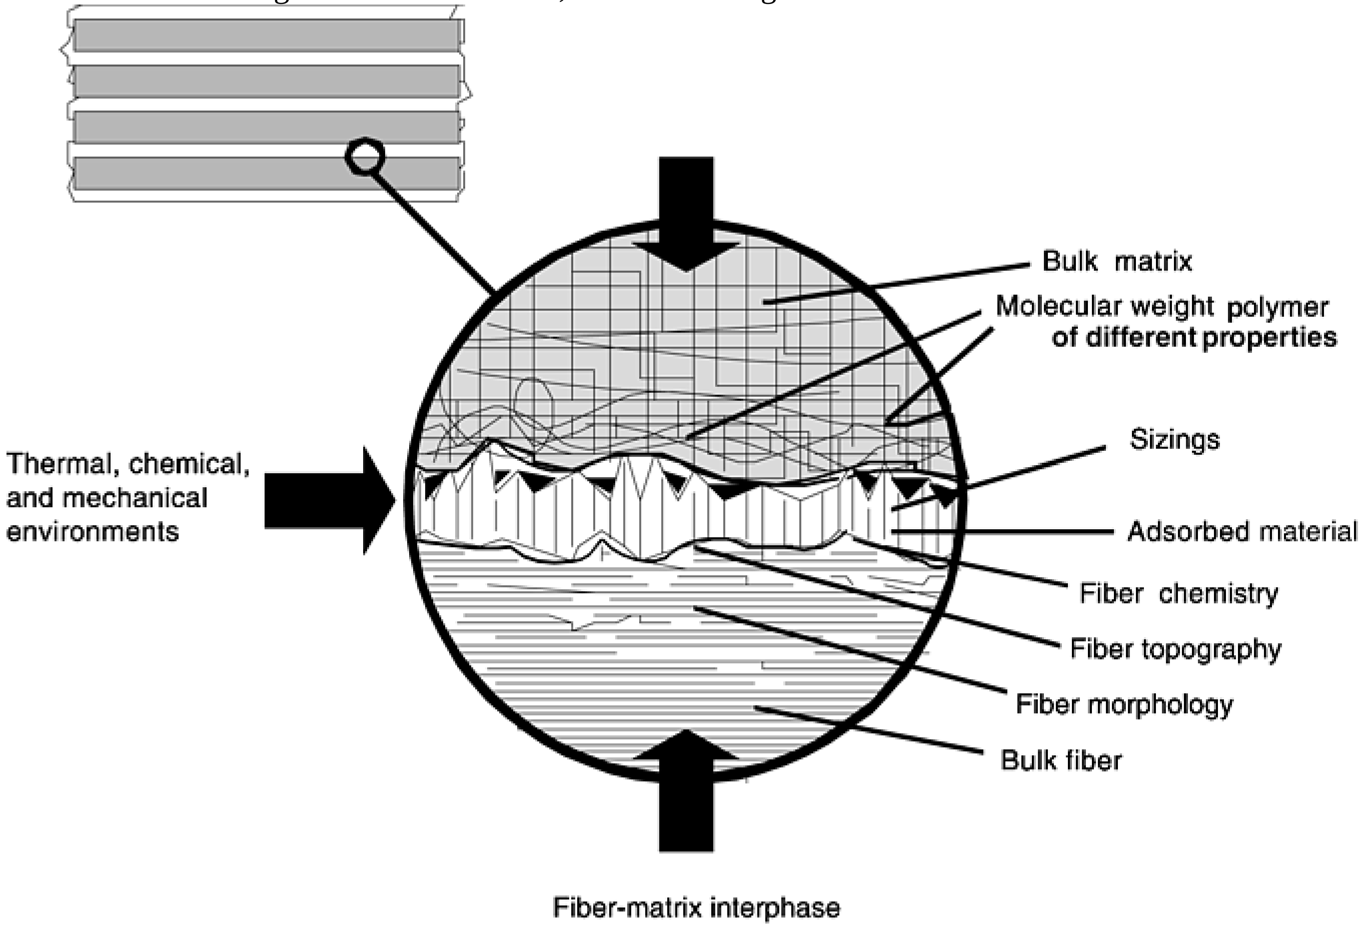

Fig. 1 Schematic diagram of the fiber-matrix interphase and some of the factors that contribute to its formation. Source: Ref 2

By definition, the interphase exists from some point in the fiber where the local properties begin to change from the fiber bulk properties, through the actual fiber-matrix interface, into the matrix where the local properties again equal the bulk properties. Within this region, various components of known and unknown effect on the interphase can be identified. For example, the fiber may have morphological variations near the fiber surface, which are not present in the bulk of the fiber. The surface area of the fiber can be much greater than its geometrical value, because of pores, pits, or cracks present on the surface. The atomic and molecular composition of the fiber surface can be quite different from the bulk of the fiber. Surface treatments can add surface chemical groups or remove the original surface, giving rise to a chemically and structurally different region. Exposure to air before composite processing can result in the adsorption of chemical species, which may alter or eliminate certain beneficial surface reactivity. These adsorbed materials may also desorb at the elevated temperatures seen in composite fabrication and be a source of volatiles, which, if not removed, can be the origin for voids that disrupt the interface. The thermodynamic surface energy of the fiber is a result of these factors. A necessary condition for acceptable interfacial interaction between the reinforcement and the matrix is determined by its surface free energy and that of the matrix. Usually this means that the surface energy of the reinforcement must be greater than that of the matrix.

Once the fiber surface and matrix come into contact, both chemical and physical bonds can form at the interface. Surface chemical groups can react with chemical groups in the matrix, forming chemical bonds. Van der Waals attractive forces, hydrogen bonds, and electrostatic bonds can also form, depending on the system.

The number and type of each strongly influence the interaction (i.e., adhesion) between fiber and matrix. The structure and properties of the matrix in the interphase can also be influenced by proximity to the fiber surface. The presence of the reinforcement and its chemical and physical nature can alter the local morphology of the matrix in the interphase region. Unreacted matrix components and impurities can diffuse to the interphase region, altering the local structure and interfering with intimate contact between fiber and matrix or producing a material with little useful mechanical properties.

Each of these phenomena can vary in magnitude and can occur simultaneously in the interphase region. Depending on the materials system, the interphase itself can be composed of any or all of these components and can extend in thickness from a few to a few thousand nanometers. Furthermore, each interphase is formed during composite processing and, therefore, may not be in its equilibrium configuration as a result of processing constraints. The structure of this region can have profound effects on the performance of the composite in terms of its mechanical strength and chemical and thermal durability. The exact composition and properties of this region must be understood if accurate predictive models of interphase behavior are to be developed and integrated into a model of composite performance. Sufficient knowledge of the interphase and its effect on fiber-matrix adhesion and composite mechanical performance has been achieved so that the fiber-matrix interphase can be engineered through the use of fiber surface treatments, coupling agents, and sizings in a rational manner to optimize composite performance. Even though it is not yet possible to either quantify or predict the formation of this “interphase” from first principles, it can serve as a framework on which the interactions between composite constituents can be studied and the interphase can be designed in an optimal manner.

Interphase Thermodynamics

One of the keys to obtaining effective composite properties is ensuring thorough infiltration of the fiber tow by the matrix. This infiltration process is limited by the interfacial thermodynamics. Wettability of the fiber by the matrix is taken as a necessary prerequisite for the formation of any composite material (Ref 3). Often, microscopic examination of the fracture surfaces of composite materials shows bare reinforcement surfaces, and/or the presence of voids is taken as an indication that “good wetting” has not occurred. Frequently, poor off-axis mechanical properties are attributed to less-than-ideal fiber-matrix adhesion that is related to poor wetting. There is a linkage between fiber surface chemistry, matrix surface free energy, thermodynamic wetting of the fiber by the matrix, and adhesion of the matrix to the fiber. The generation of adhesion during composite processing is a dynamic event that can be affected by processing conditions and that ultimately can affect composite properties.

Thermodynamics provides an excellent framework upon which to study the surface of the fiber and matrix and to quantify the interactions that can occur when they are brought together. For small-molecule liquids where the time constants for the rearrangement of molecules is short, *equilibrium thermodynamic relationships* are available that describe the interactions between the solid surface and the liquid phase and can be used to understand and predict polymer-matrix interaction with the reinforcing fiber (Ref 4). Although care must be taken when applying these relationships to polymer systems, because the viscosity and kinetics may prevent

equilibrium from being attained in the composite fabrication time frame, thermodynamics does provide a useful framework upon which to understand fiber-matrix interactions.

Surface Energy. An atom or molecule on the surface of a liquid or a solid has a net force acting on it, pulling it toward the interior of that phase. The manifestation of this force is commonly called the surface tension (also called “surface energy”). In a liquid where the rearrangement of molecules takes place on the microsecond scale, the surface tension can be observed creating a “skin” on the liquid. Liquids that are composed of molecules that exert dispersion forces alone (e.g., hexane) have low values of surface tension, and liquids with a highly polar nature (e.g., water) have large values of the surface tension. Solids have a surface free energy also, but because the atoms in the surface cannot rearrange spontaneously as in a liquid, its surface appears to be unaffected by any disturbance.

Contact Angle. When a liquid having a surface tension γ_{LV} is placed on a solid surface with surface tension γ_{SV}, the liquid will spontaneously form a droplet or spread out into a film (Fig. 2). If a droplet is formed, a relationship between the solid surface tension and the liquid surface tension can be derived, if the surface tensions are considered to be vectors acting at the edge of the drop. The surface free energy of the solid-liquid interface is labeled γ_{SL} and the equilibrium can be expressed as:

$$\gamma_{SV} = \gamma_{SL} + \gamma_{LV} \cos\theta$$

where θ is the angle formed by the drop surface with the solid surface, measured through the liquid. Various established physical-chemical methods are available for measuring the surface tension of a liquid. Optical methods and gravimetric methods are available for measuring the angle that the droplet makes with the solid surface. Neither the solid surface tension nor the solid-liquid interfacial tension can be measured directly, but the difference between the two is the product of the cosine of the contact angle and the liquid surface tension.

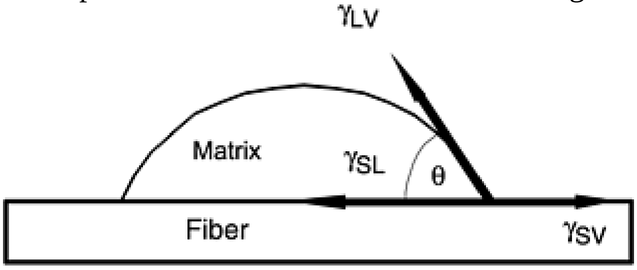

Fig. 2 Schematic diagram of the contact angle and its surface free energy (tension) components

Liquids that form contact angles greater than 90° are called “nonwetting.” Liquids that form a contact angle less than 90° are termed “wetting.” If the liquid does not form a droplet, that is, the contact angle is 0°, the liquid is said to be “spreading,” and the relationship does not hold.

The equilibrium is expressed by an inequality where:

$$\gamma_{sv} - \gamma_{SL} \geq \gamma_{LV}$$

because as the liquid flows, it is decreasing the solid-vapor interface. Closer inspection of this relationship leads to the conclusion that for all cases of wetting and spreading, the surface tension of the wetting liquid must be greater than the solid surface tension.

Work of Adhesion. A term frequently used is “work of adhesion” (W_a), which gives an expression for the thermodynamic work necessary to create a solid-vapor surface and a liquid-vapor surface by:

$$W_a = \gamma_{LV} + \gamma_{SV} - \gamma_{SL}$$

pulling apart the solid-liquid interface. By substituting the equilibrium expression for the droplet forming the contact angle, the work of adhesion is given by:

$$W_a = \gamma_{LV} (1 + \cos\theta)$$

This expression is a thermodynamic work and as such, is a reversible equilibrium value. Likewise, it is not to be confused with the work of disrupting an adhesively bonded interface between reinforcing fiber and matrix that includes many substantial energy-absorbing and dissipative processes. This thermodynamic expression actually states that the maximum value of the work of adhesion occurs when the contact angle is equal to zero, and the work of adhesion is twice the surface tension of the liquid.

Solid Surface Energy. Although these expressions apply to equilibrium situations, they can be used to understand the wetting process in a polymer-reinforcement system as well. Zisman used these concepts to identify a critical solid surface tension for polymers. He noted that if the cosine of the contact angle were plotted against the contacting liquid surface tension, a straight line would result that intersected the 0^o line at some value of the surface tension. By testing a variety of polymer surfaces, he found that there was a characteristic value for γ_O, which was an intrinsic characteristic of the solid. If a liquid had a surface tension greater than γ_O, the liquid would form a droplet on the surface, and if it was less, it would spread on the surface. This concept reinforced the rule that for spreading to occur, the surface tension of the liquid had to be less than that of the solid.

Kaelble (Ref 5) built upon some earlier work of Fowkes and proposed that the surface tension, or more properly, the surface free energy, of a liquid or a solid is composed of dispersion interactions and higher order ones, such as polar interactions. If liquids with known dispersion and polar components of their surface free energy were used as contacting fluids with solid surfaces, the polar and dispersive components of the solid could be determined. This resulted in an expression for the work of adhesion that was related to the contact angle and the liquid surface free energy, which could be measured directly through the following expression, where the surface tensions refer to the dispersive (*D*) and polar (*P*) components of the solid (SV) and liquid (LV) phases.

A plot of the left-hand side of this equation versus the ratio of the square roots of the polar- to-dispersive ratios of the contacting liquids results in a straight line whose slope and intercept determine the dispersive and polar component of the surface free energy of the solid:

$$\frac{\gamma_{LV}(1+\cos\theta)}{2\gamma_{LV}^{D^{1/2}}} = \gamma_{SV}^{D^{1/2}} + \gamma_{SV}^{P^{1/2}} \frac{\gamma_{LV}^{P^{1/2}}}{\gamma_{LV}^{D^{1/2}}}$$

Recently, an alternative to the polar-dispersive approach has been developed in which the surface free energy is divided into a dispersive component in a manner similar to the Kaelble formulation, but the polar component is replaced by acid and base components (Ref 6). This acid- base model has a more solid theoretical foundation and is gaining wider acceptance.

Wetting and Wicking. Although the discussions on wettability have focused on the thermodynamics between the fiber surface and the matrix, real composite systems are very large assemblies of small-diameter fibers. A key to creating good composite properties is infiltration of the matrix into this fiber assembly, or tow, during the processing steps. The small interstices in the tow can create very large capillary forces that aid in the wetting process. This capillary force is commonly characterized as a pressure drop, due to the surface tension acting in the small capillaries. A relation quantifying this driving force for infiltration is:

$$\Delta P = \Delta\rho g h = \frac{\gamma_{LV} - \cos\theta}{2r}$$

where the height of the rise, *h*, of a liquid of density, ρ, is directly related to the liquid surface tension, γ_{LV}, the cosine of the contact angle, θ, and inversely related to the radius, *r*, of the capillary, and where *g* is the gravitational constant. The contact angle controls the capillary forces, because at $\theta = 90^o$, the capillary force vanishes, and at $\theta > 90^o$, infiltration is prevented.

As stated earlier, the thermodynamic analysis of wetting and capillarity is true for equilibrium conditions. Thermoplastic polymer melts or thermoset polymer mixtures are high-viscosity fluids that may never reach true thermodynamic equilibrium during the processing of a composite. Yet the condition predicted by the analysis is valid. That is, the surface tension of the fiber must be greater than that of the matrix. A properly designed interphase should employ surface chemical treatments, finishes, and/or sizings to minimize the contact angle between matrix and reinforcement and to gain the most assistance from capillary forces during composite processing. This will ensure displacement of any moisture and assist the transport of voids from the composite during processing.

Surface Modification Strategies

Because wetting is a necessary prerequisite for optimal processing, thermodynamics tells us that the surface free energy of the matrix should be less than the surface free energy of the solid. Most polymers have low values of surface free energy (tension), that is, 20 to 45 mJ/m^2, which decrease slightly with increasing temperature. Solids, on the other hand, can have surface energies that vary over orders of magnitude if they are in the pristine state. Solid surfaces that have been exposed to the ambient environment want to minimize their surface free energy and, therefore, adsorb material or grow oxides to lower their surface free energy. In some cases, this “native” surface can have a surface free energy lower than that of the polymer matrix. In order to increase the solid surface free energy, surface treatments, finishes, and sizings have been developed to enhance the wettability of a solid surface.

Surface Treatments. The term “surface treatment” usually refers to a chemical treatment that imparts an altered surface chemistry to a material, primarily in the outermost layer, increases the surface energy, and/or creates beneficial microtopographical features without a deliberate coating of the surface. These treatments can be applied from the gas or liquid phase, be acidic or basic, or involve bombardment of the surface with radiation of various types. In most cases, effective surface treatments also remove surface material, that is, etch the surface to some degree. From a composite processing viewpoint, the use of a surface treatment is desirable to promote wettability and intimate contact between the fiber and the matrix.

Surface Finishes. The term “surface finish” is usually applied to describe coatings applied to reinforcement surfaces after or in conjunction with surface treatments. In many commercial examples for thermoset-matrix composites, finishes are the base resin component of the matrix applied from solvent solution or water emulsion to the reinforcement surface without any curing agent, to thicknesses of about 100 nm. The purpose is to protect the reinforcement surface during handling operations. Most reinforcements are very “flaw sensitive,” and even the slightest contact with another hard surface can introduce critical-sized flaws that reduce strength. The 100 nm surface finish layer prevents actual contact between reinforcing entities. Finishes can be used with any reinforcement and have been developed primarily by the textile industry to aid in keeping fiber tows together during the textile steps that are sometimes required in composites manufacture. They find the widest use with carbon- and polymeric-reinforcing fibers. Another use for surface finishes is to protect the surface chemistry from environmental attack or contamination of the surface and consequent reduction in the surface free energy. Because the finish is an unpolymerized layer, exposure to the matrix or essentially the same composition during processing allows the finish to be solubilized and removed from the fiber surface.

From a processing viewpoint, finishes are very helpful in assisting and ensuring that the wetting and infiltration steps are complete. Well-designed surface finishes promote infiltration, disbursement, and wetting of individual reinforcements by their presence. Because the finishes are placed on the reinforcements from solution (both organic solvent and water-based), retention of solvent and volatilization during the early portion of the processing cycle is a potential problem. The high surface area of the fibers, their small size, and their large volume make the generation of voids a potential problem. If the composition of the finish is susceptible to chemical aging during long-term ambient storage, its solubility may be reduced to the point where it becomes confined to the fiber-matrix interface and is detrimental to both processing and adhesion.

Surface Sizings. In the composites industry, the term “sizing” has come to mean any surface coating applied to a reinforcement to protect it from damage during processing, aid in processing, or improve the mechanical properties of the composite. Surface sizings are similar physically to surface finishes, that is, they are applied to the fibers in thicknesses of approximately 0.1 μm, but differ in their chemical composition. They are almost always used with glass fibers and sometimes used with other reinforcements. Surface treatments are sometimes confused with sizings, especially in carbon-fiber reinforcement technology (Ref 7). The distinction between sizing and surface treatment is fairly clear in the case of carbon fibers, but is less clear in the case of boron fibers that are treated chemically to form a boron carbide or boron nitride coating (Ref 8). A useful definition is that a sizing is a deliberate coating of the reinforcement, which may incidentally react chemically with the surface; a surface treatment is a deliberate chemical modification of the reinforcement, which may incidentally result in the formation of a coating. Other terms used synonymously for sizing include finishing agent, which comes from the textile industry and refers to fiber coatings that render flexibility, drape, and special features, such as fire retardance, to fabrics. This term still finds use in fibrous composite nomenclature, especially for woven glass or carbon-fiber products. Sometimes sizing is referred to as a coupling agent when it is designed to enhance composite mechanical properties or durability.

Typical sizings solutions (Ref 9) contain a silane coupling agent or combinations of coupling agents, as well as other ingredients, such as film formers, antistatic agents, and lubricants. Sizings are applied to glass fibers from solution immediately at the point of glass manufacture. They are formulated to protect the glass-fiber surface from corrosive attack by water from the ambient environment. The silanes are hydrolyzed and react with glass-fiber surface hydroxyls to form very stable siloxane bonds. The remaining ingredients in the sizings systems are there to protect the glass surface from mechanical damage and to promote infiltration by the matrix. Titanate and zirconate chemistries are also used in addition to silane chemistries.

Sizings designed to protect the reinforcement during processing must coat the surface uniformly. For this reason, polymers that are widely used in the coating industry because of their good film-forming ability (Ref 10) are also used as sizing agents. Typical examples are starch and starch derivatives, the vinyl polymers, and the phenoxys. The choice is dictated by a number of considerations: compatibility with the matrix polymer, the level of protection required (for example, weaving is more severe on continuous fibers than prepregging of unidirectional tape), pliability or drape of the sized tow or cloth (for example, a stiff, “boardy” fabric is difficult to process), and cost. Sizings are usually applied at a level of 1.0 wt% or less, making it necessary to remove and dispose of large volumes of solvent. Environmental pollution and cost considerations mandate that the sizing be applied from aqueous media, which requires that it be soluble in water or able to be applied as a water-based emulsion.

Ideally, a sizing should be chemically compatible with the matrix polymer and should not adversely affect the mechanical properties of the interphase between reinforcement and matrix. If these requirements cannot be met, the sizing may be removed by washing or heating before processing the reinforcement into the final composite form. However, these manipulations usually either damage the fiber or leave residues that may prevent good bonding between reinforcement and matrix. Nevertheless these fugitive sizings are still used, especially for woven reinforcements.

There are a variety of film-forming polymers that are compatible with the more widely used polyester and epoxy-matrix resins. However, there are very few sizings that can be used with the newer high-temperature matrix polymers, such as the bismaleimides and polyimides, or with the tough thermoplastic matrices, such as polyphenylene sulfide or polyether etherketone. One approach to developing sizing for these newer matrix materials is to use the polymers themselves as the sizing. However, they usually do not have the wetting and spreading behavior necessary to form a uniform coating. Developing sizings for these new matrix polymers, especially for carbon-fiber-reinforced composites, is essential in order to realize their full potential.

Sizing systems are usually proprietary, and the manufacturer's recommendations must be followed, especially the storage conditions. Sizing systems are reactive, and the chemical reactions that can occur during long-term storage can make the sizing insoluble and/or lower in surface free energy, resulting in poor infiltration and wetting. Sizings are an essential factor in fibrous composites technology. They are critical in composites manufacturing and can have both negative and positive effects on composites properties. A sizing may adversely affect the mechanical properties of the composite. For example, a sizing that holds the filaments in a bundle so that the strand (tow) can be chopped for discontinuous fiber composites hinders later efforts to disperse the fibers during injection molding or extrusion.

As stated earlier, in commercial practice, the silanes are often applied with a film-forming polymer. Presumably, the coating polymer becomes entangled in the silane network along with the matrix polymer. The composition of this complex interphase is critical to understanding the moisture durability of composite materials. The possible interpenetration formation of silane and epoxy molecules is a subject of recent study (Ref 11).

Surface Modification Examples

Adhesion between fiber and matrix and its modification for composite structural applications must start with consideration of the stresses that the structural element will experience in its operational environment. In addition, the thermal and chemical (i.e, moisture) environments must be specified. This in turn dictates the fiber and matrix constituents to be used in the composite. The interphase will change depending on the matrix (e.g., thermoset or thermoplastic) as well as the reinforcing fiber (e.g., glass, carbon, or polymeric). Each constituent has different but related requirements for the interphase from both a processing and performance perspective.

Glass Fibers. For example, in glass fibers, the native fiber surface is mainly an inorganic oxide. This surface quickly adsorbs water that creates a hydroxylated surface. If exposure to moisture is continued, the adsorption of water corrodes the fiber surface, creating critical-sized flaws that reduce fiber strength. This corrosion process can vary in intensity, depending on the glass-fiber composition. In all cases, however, the glass surface must be protected from the chemical attack of water. Organofunctional silanes, titanates, and/or zirconates (Ref 12) are produced for this purpose and have been shown to be very effective in reducing or eliminating corrosive attack of the glass surface (Ref 6).

The silanes readily form three-dimensional polysiloxane networks through hydrolysis and condensation of the alkoxy groups. This polymerization is acid-base catalyzed, and the silanes are frequently applied from acid solution. It has been demonstrated experimentally (Ref 13) that these silanes form a polymeric network on solid substrates that, as in the case of glass, has an occasional chemical attachment to the surface. It has been suggested that this is a relatively open network that is easily penetrated by the molecules of the matrix polymer (Ref 14), so that an entanglement of the polymer networks is formed in the interphase region between matrix and reinforcement. This polymer network formation does not, in itself, explain how the silanes protect the boundary from attack by water. It does, however, present a more realistic picture of the adsorbed silane film. However, despite all the studies of silanes on glass (and other) surfaces, the mechanisms involved in their protection of the glass-polymer interface are not well understood.

Most commercial glass-fiber treatments are formulated sizes, which contain a silane or similar molecule, but are blended in a solution with a film-former, antistatic agent, lubricant, or other ingredients in a proprietary formulation. These sizes are applied to the fiber surface in thicknesses of about 0.1 μm. The formulation is empirically designed to be compatible with the matrix used with the glass fiber. In addition to providing corrosion protection to the fiber, the sizing surface treatments provide protection for the fiber surface during handling operations to prevent surface damage, ensure compatibility with the matrix, and aid in the infiltration of the matrix into the fiber tows during processing.

Carbon Fibers. Carbon fibers do not have a reactive surface in the same sense as glass fibers. The basal plane of graphite that forms the majority of the carbon-fiber surface is very stable and unreactive. However, the edges and corners of these planes and of the resulting crystallites are the sites at which chemical reactions can take place. The percentage of reactive edge area varies directly with the fiber modulus and the precursor polymeric fiber. For the intermediate- modulus fibers used in the largest number of applications, only 20% of the fiber surface contains surface chemical groups (mostly oxygen) that can be reacted with other molecules under most conditions (Ref 15). Attempts to increase the surface functional group content usually result in a loss of fiber strength, because the oxidation of carbon fibers invariably creates flaws that are greater than the critical size. Surface chemical treatments used to treat carbon-fiber surfaces also etch away the native fiber surface formed during the carbonization and graphitization of the fiber. This in itself creates a surface that can withstand much higher shear loadings and therefore, is largely responsible for the increase in adhesion seen with chemical surface treatments (Ref 16). Attempts at elucidating the amount of chemical reaction between fiber surface and matrix have shown that only a few percent of these groups react with the matrix (Ref 17). Surface "finishes" are commonly used with surface chemical treatments for carbon fibers. These finishes are much simpler than sizings for glass fibers. Finishes are usually a matrix component applied from solvent to the fiber surface to create a layer about 0.1 μm in thickness. Because the composition is the same as the matrix, wetting and impregnation of the fiber tow is enhanced, the carbon-fiber surface is protected from damage during handling, the fiber chemical reactivity is protected until processing, and the tow can be used with textile processing equipment with a minimum of difficulty (Ref 6).

Polymeric Fibers. Reinforcing fibers made from polymers have surfaces that are low in energy and require some surface treatment to enhance their wettability. The polymeric-fiber surface is, for the most part, unreactive, and the use of coupling agents is generally not effective. Finishes can be used, but are viewed as "processing aids" that enhance the impregnation and infiltration of the tow. Polymeric-fiber surfaces are not as sensitive to abrasion as the surfaces of glass or carbon fibers, and the use of a finish does not add to its protection. Likewise, corrosion is not an issue with polymers, and the absorption of moisture is generally small. The application of a finish could reduce moisture pickup, however. Chemical treatments, corona treatments, radio frequency discharge, microwave plasma, and so on are all used to alter the native polymeric-reinforcing-fiber surface. The resulting reported enhancement in adhesion is almost invariably due to removal of low-energy contaminants from the fiber surface coupled with the addition of surface chemical species that improve the wettability. Indeed, it has been shown that in the case of aramid fibers (and probably for all highly oriented polymeric-reinforcing fibers), the upper limit in fiber-matrix adhesion is related to the intrinsic interfibrillar strength of the fiber itself in its surface layer (Ref 18).

Fiber-Matrix Adhesion Measurements

The effectiveness of a fiber surface modification approach ultimately must be evaluated based on its relationship to fiber-matrix adhesion and the composite mechanical properties. There have been several techniques developed to measure fiber-matrix adhesion levels and the effect of the surface modification on the effective properties of composites. These methods can broadly be classified into three separate categories: direct methods, indirect methods, and composite lamina methods. The *direct* methods include the fiber pullout method, the single-fiber fragmentation method, the embedded fiber compression method, and the microindentation method. The *indirect* methods for fiber-matrix adhesion testing include the variable curvature method, the slice compression test, the ball compression test, dynamic mechanical analysis, and voltage contrast x-ray spectroscopy. The *composite* lamina methods include the 90^o transverse flexural and tensile tests, three- and four-point shear, ±45^o and edge delamination tests, the short beam shear test method, and the mode I and mode II fracture tests.

It should be pointed out that while the indirect methods provide a qualitative method of ranking the adhesion between fiber and matrix, and the composite lamina test methods actually measure fiber-matrix interface-sensitive composite properties, the direct methods not only provide a measure of fiber-matrix adhesion, but can also provide information about fiber-matrix failure mode and a method to measure the energy involved in fracture of the fiber-matrix interface. This last parameter is important in relating fiber- matrix adhesion to composite toughness.

Direct Methods. The direct methods of characterizing the fiber-matrix adhesion and the interphase have relied on the use of single-fiber- matrix test methods for measuring adhesion and failure modes. The first technique proposed was the fiber pullout method (Ref 19), which was developed in the early stages of composites research when the fibers were much larger and easier to handle than they are today. There have been variations in the experimental details pertaining to the fabrication of the test coupon and to the execution of this test, mainly in the matrix portion, but overall, the procedures to fabricate samples, the experimental protocols, and the data analysis remain the same. In the pullout version, the fiber is pulled out of the matrix, which can be a block of resin, a disc, or a droplet. The use of very small droplets reduces the difficulties in preparing thin discs of resin and can reduce the variability in exit geometry (Ref 20). These advantages have made this test very popular since the 1990s. In this test, the load and displacements are monitored continuously, and upon fiber pullout, the load registered at complete debonding of the fiber from the matrix is converted into interfacial shear strength. The advantage of this method is that it allows testing of brittle and/or opaque matrices.

Another popular method is the embedded single-fiber fragmentation test. Here, a single fiber is totally encapsulated in the polymeric matrix that has been formed into a tensile dogbone- shaped coupon, which in turn is loaded in tension. An interfacial shear stress transfer mechanism is relied upon to transfer tensile forces to the encapsulated fiber through the interphase from the polymeric matrix (Ref 21, 22). The fiber tensile strength, σ_f, is exceeded, and the fiber fractures inside the matrix tensile coupon. This process is repeated, producing shorter and shorter fragments until the remaining fragment lengths are no longer sufficient in size to produce further fracture through this stress transfer mechanism. A simple shear-lag analysis is applied to analyze the

experimental data based on the length of the resulting fiber fragments, the fiber diameter, and the fiber tensile strength, in order to calculate the interfacial shear strength.

Another method proposed in the 1960s by Outwater and Murphy (Ref 23) uses a single fiber aligned axially in a rectangular prism of matrix. A small hole is drilled in the center of the specimen through the fiber. The prism is placed under a compressive load, and the propagation of an interfacial crack is followed with increasing load. The mode II fracture toughness of the interface can be calculated from this data based on the strain in the resin (ϵ_r), the tensile modulus of the fiber (E_f), the frictional shear stress (τ), the length of the interfacial crack (x), and the fiber diameter (a).

An in situ microindentation measurement technique has also been proposed for measuring the fiber interfacial shear strength (Ref 24). It involves the preparation of a polished cut surface of a composite in which the fibers are oriented perpendicular to the surface. A small hemispherical indenter is placed on an individual fiber, and the force and displacements are monitored to the point at which the fiber detaches from the matrix.

Indirect Methods. The indirect methods for fiber-matrix-adhesion-level measurement include the variable curvature method, the slice compression test, the ball compression test, the fiber-bundle pullout test, the use of dynamic-mechanical thermal analysis, and voltage contrast x-ray photoelectron spectroscopy (VCXPS).

Narkis et al. (Ref 25) proposed the use of a single-fiber specimen in which the fiber is embedded along the centerline in the neutral plane of a uniform cross-sectional beam. The beam is placed in nonuniform bending according to an elliptical bending geometry with the aid of a template. This causes the shear stress to build up from one end of the fiber according to the gradient of curvature of the specimen. Careful observation of the fiber in the specimen allows location of the point at which the fiber fails as a result of a maximum shear stress criterion. The stress along the fiber is calculated as a function of the matrix tensile modulus, the beam width, the first moment of transformed cross-sectional area, and constants from the equation of the ellipse. Some of the advantages of this technique are that a single fiber or fiber tow can be used, the results do not depend on fiber strength, and sample preparation is relatively easy. Some of the disadvantages are that the debond front is not so easy to detect, and the results are sensitive to the location of the single-fiber layer within the cross section of the coupon.

The slice compression test has been applied to polymer-matrix composites, even though it was developed to probe the interface in ceramic-matrix composites (Ref 26). A thin slice sample of unidirectional composite is produced with the cut surface perpendicular to the fiber axis. The surfaces are cut and polished to be parallel to each other and perpendicular to the fibers. The thin slice is loaded in compression in the fiber axis direction with two plates. One of the plates is made of a very hard material, such as silicon nitride, and the other of a soft material, for example, pure aluminum that can deform as the fibers are compressed into it. The thickness of the slice must be controlled to allow the fibers to debond without failing in compression as well as to allow them to slide inside through the matrix. The depth of the fiber indentation into the plate can be related to the interfacial shear strength (Ref 27).

Carman et al. (Ref 28) developed a test called the mesoindentation test that used a hard, spherical ball indenter to apply a compressive force to a surface of the composite perpendicular to the fiber axis. The indenter was much larger than the diameter of a single fiber; therefore, when the ball was forced into the end of the composite, it made a permanent depression in the material. From the size of the depression and the force-deflection curve, they calculated a mean hardness pressure as a function of strain in the coupon. Qualitative differences have been reported in tests conducted on carbon-fiber-epoxy composites where the fiber-matrix adhesion had been varied systematically.

The fiber bundle pullout method (Gopal et al., Ref 29) is similar to the single-fiber pullout method except that instead of using a single fiber, a bundle of fibers is used. A coupon is fabricated in which a bundle of fibers or a lamina of unidirectional fibers is cast in a block of matrix. Transverse notches are cut into the coupon near the end of the fiber bundle. The coupon is loaded in tension with the load applied parallel to the fiber axes. The load versus displacement curve can be monitored and the debonding point detected. In a similar manner to the way data are reduced for the single-fiber pullout test, the interfacial shear strength between the bundle of fibers and matrix can be calculated.

Ko et al. (Ref 30) examined a carbon-fiber- epoxy system in which the interfacial properties have been varied by the use of dynamic mechanical analysis. They report a change in the tan δ-peak attributable to changes in the fiber- matrix adhesion. Chua (Ref 31) also measured a shift in the loss factor for glass-polyester systems that corresponded to changes in the condition of the fiber-matrix interphase. Perret et al. (Ref 32) measured both the loss factor and the change in the shear modulus with increasing displacement and detected a change in

composite properties with a change in the fiber-matrix adhesion. Yuhas et al. (Ref 33) have used ultrasonic wave attenuation to establish correlations with short beam shear data. This method was useful for poorly bonded systems, but was not sensitive to well-bonded interfaces. Wu used localized heating coupled with acoustic emission events to detect interfacial debonding (Ref 34).

Laser Raman spectroscopy can be applied to the fiber-matrix interface in order to determine the actual stresses that exist at the interface. Laser Raman spectroscopy is a visible light spectroscopy that relies on the inelastic scattering of visible light photons from a surface. Certain chemical groups in a material or on a surface can scatter incident radiation at characteristic frequencies. Tuinstra and Koening (Ref 35) showed that certain characteristic frequencies in the Raman active bands of graphite and other fibers are sensitive to the level of applied stress or strain. There is a measurable shift in the characteristic frequency that is proportional to the applied strain. A small (1 μm) spot generated by a laser beam can be scanned along a fiber surface and provide the Raman information, which can be converted to the local stresses in the fiber. A transparent matrix incorporating fibers having a Raman active band (e.g., aramid, high-modulus graphite) can be analyzed with this method (Ref 36).

A recent method for determining information about fiber-matrix adhesion is a technique identified as VCXPS (Ref 37). This method relies on the VCXPS characterization of the fracture surface of high volume fraction fiber composites. A unidirectional coupon is fractured in an opening mode to produce a fracture surface. This fracture surface containing fibers and polymer is placed inside of an x-ray photoelectron spectroscopy spectrometer for analysis. X-ray photons are directed at the surface, causing the emission of photoelectrons. These electrons are collected and analyzed for quantity and energy, which contains useful information about the atomic composition of the surface as well as the molecular environment of the atoms on the surface. During the process of photoelectron emission, nonconducting (insulating) samples will acquire a charge and cause peaks to shift from their neutral position. This happens in nonconductive materials such as polymers, but does not happen in conducting materials such as carbon fibers. As a result, the carbon peak begins to split into two peaks as charge builds up on the surface. One carbon peak, due to the conductive carbon fiber, stays at the neutral position while the other portion, due to the polymer, shifts, depending on the magnitude of the charge on the surface. The height and width of the peaks and the shift in energy are related to the content of the conducting carbon fiber and nonconductive polymer remaining on the fracture surface. As a result, the ratio of the two carbon peaks is a qualitative indicator of the degree of adhesion. For example, if the ratio of the nonconductive carbon peak to the conductive carbon peak is large, the fracture surface contains a large amount of nonconductive polymer and very little conductive carbon fiber. This can be interpreted as being due to good adhesion between the fibers in the matrix, causing failure to occur in the weaker polymer matrix between fibers. On the other hand, if the ratio of the nonconductive carbon peak to the conductive carbon peak is small, many bare carbon fibers are exposed on the fracture surface, indicating poor adhesion between the fiber and the matrix. In cases where the same carbon fibers are used with various polymeric matrices, a semiquantitative relationship between this parameter and fiber-matrix adhesion has been developed.

Composite Laminate Tests. Composite laminate tests are often used to measure fiber-matrix adhesion, but none of these tests measures interfacial properties alone. The obvious tests to be conducted are those in which the fiber-matrix interface dominates the results, such as shear properties. Numerous techniques have been developed for measuring shear properties in fiber-reinforced composite laminates. The most commonly used test methods for in-plane shear characterization are the $[\pm 45]_S$ tension test (Ref 38) and the Iosipescu test (Ref 39). To determine the interlaminar shear strength, the short beam shear test (Ref 40) is more frequently used. In all these cases, standard protocols exist for preparing the samples, conducting the tests, reporting the data, and analyzing the results. These include ASTM and Automotive Composites Consortium standards. A careful experimental study has been published relating differences in fiber-matrix adhesion to these tests (Ref 41).

Issues in the Use of Adhesion Test Methods. Overall, the use of any of the direct, indirect, or composite lamina tests in the hands of a skilled experimenter can provide a consistent way of ranking fiber-matrix adhesion regardless of the method chosen. However, one should be aware that there are various issues related to the use of these tests that limit their applicability. One issue is the identification of the appropriate parameter for characterizing the fiber-matrix interface. All of the direct and indirect tests have been developed with the goal of measuring the fiber-matrix interfacial shear strength. However, several of these tests are really fracture tests and are more properly used if the interfacial fracture energy is calculated. On the other hand, interfacial fracture energy is rarely used to evaluate or measure fiber-matrix adhesion or to design composite materials. Another factor that must be considered is the preparation of the samples. The single-fiber tests are very sensitive to the

careful preparation of samples and the careful selection of fibers for testing within those samples. Testing conditions are likewise very important. While normally one would conduct any of these tests at reasonably slow strain rates, in microtesting, the strain rates used are only nominally slow. These strain rates become extraordinarily high when taking into account the small dimensions of the distances over which these tests are conducted. There is also evidence that in dealing with viscoelastic polymer composites, creep effects can be important and must be considered. Finally, the data analysis methods associated with these techniques rely on the assumption of a value for the modulus of the matrix near the fiber surface for reduction of the test results into a usable parameter, whether it is strength or energy. The literature contains numerous references indicating that the structure of the polymer near the fiber surface can be quite different from the bulk polymer. Indeed, the modulus in some cases can be quite a bit lower or higher than the bulk matrix, depending on the system investigated (Ref 42). At the present time, there is no accurate method for measuring the interface modulus that may exist in dimensions of a few tens to a few hundreds of nanometers from the fiber surface. Until such a quantitative measurement is available, it is not possible to accurately relate interfacial tests, whether single fiber or microscopic, to composite properties.

Interfaces and Interphases

Lawrence T. Drzal, Michigan State University

Interphase Processing

Implicit in the preceding discussion has been the assumption that the fiber-matrix interphase has attained its final equilibrium state. This may not always be true, however. The desire for reducing costs and increasing production speeds is leading to development of alternatives to conventional convective thermal processing methods (e.g., reaction injection molding, microwave processing, radio frequency processing, ultraviolet light processing, electron beam processing) and fast-reacting polymerization chemistries (e.g., urethane, vinyl ester, cationic, etc.), resulting in gelation or consolidation times of minutes or seconds. The fiber-matrix interphase may not reach an equilibrium state under these constraints, especially in systems that rely on the use of fiber finishes and sizings. Research in this area is underway and will eventually lead to time- dependent models for interphase formation, but in the interim, the role of processing must be considered in any fiber-matrix interfacial research or design.

Lawrence T. Drzal, Michigan State University

Interphase Effects on Fiber-Matrix Adhesion

An optimal interphase must be designed with the materials, the process, and the final operational environment of the composite in mind. The choice of surface treatment, finish, or size will depend, to a large extent, on the reinforcing element in the composite as well as the polymeric matrix. Surface treatments should be selected to remove the native surface and leave behind one that is rich in surface functionality to promote thermodynamic wetting. The concept of chemical bonding at the interphase should not be used exclusively in selecting a surface treatment.

The application of surface finishes should be considered for all brittle reinforcements as both a protector of the mechanical strength of the reinforcement as well as an aid in enhancing the infiltration and wetting of the reinforcement during the composite processing steps. The surface free energy and solubility of the finish in the matrix should be considered to ensure optimal processability. The choice of an organic solvent or water-based carrier for the deposition of the finish will be determined by the processing conditions. Water requires temperatures in excess of 100 ^{o}C (210 °F) for complete removal. This must be accomplished at the low-viscosity stage to allow for water migration out of the composite. Organic solvents offer a wide range of processing temperatures, but may be an environmental concern.

The use of a sizing system incorporating silanes (or titanates or zirconates) is a requirement for glass-fiber systems to ensure that the glass- fiber surface is protected from corrosion. At the same time, the silane functionality must be chosen to ensure chemical compatibility with the matrix.

For the treated, finished, or sized systems, close attention must be paid to the level of adhesion generated as well as the interfacial failure mode at the point of fiber fracture. The operational environment of the composite will dictate the level of adhesion and the desirable failure mode. In most cases, an optimum in interfacial properties will be desired.

If the interphase is considered to have some finite size, it plays a role in the mechanical performance of the composite. At a minimal level, the interphase structure is responsible for the level of adhesion that ensures continuity in the transfer of forces from fiber to matrix, allowing the composite to function as one mechanical entity. The interphase also acts as a failure site when a fiber fails. Either interfacial or matrix failure can result. It is tempting to extrapolate that high levels of adhesion are the most desirable condition for the composite, and that a high degree of chemical bonding is the best way to achieve this condition. This is not the case, and there is a practical limit to the adhesion level that can be produced in any fiber-matrix system.

If a stress analysis is conducted on a single isolated fiber in the matrix, an expression for the local shear stress similar to one attributable to Cox (Ref 43) can be derived. Closer inspection of the terms shows that there are fiber-dependent terms, geometric terms related to the fiber geometry and position, and matrix-dependent terms. If the interphase is considered to exist as a component of the composite near the fiber surface, its mechanical properties limit the degree of adhesion. In a study (Ref 44) where single- fiber methods were used to measure fiber-matrix adhesion, a dependence on the interphase shear modulus was found in composites fabricated from identical fibers and with identical matrix chemistries in which the distance between cross links was systematically varied and therefore produced matrices with identical chemistries but with different mechanical properties. Figure 3 shows that the adhesion varied as the product of the square root of the matrix shear modulus. This indicates that when fiber surface treatments affect the resulting structure of the polymer in the interphase, when the surface finishes produce an interphase different in modulus from the bulk, or when the surface sizings create an interphase with a modulus different from the bulk matrix, it is the interphase properties and not the bulk properties that determine the level of adhesion. In a similar manner, the fracture properties of the composite are controlled by the interphase structure and properties.

Interphase and Fiber-Matrix Adhesion Effects on Composite Mechanical Properties

There are numerous examples of published studies in which correlations between the interphase, fiber-matrix adhesion, and composite mechanical properties for different combinations of reinforcing fiber and matrix and fiber-matrix adhesion have been made. The carbon-fiber-epoxy systems have been studied extensively. As an example, results from one recently published study is used for illustration purposes here (Ref 45).

Consider a carbon-fiber-epoxy system consisting of one carbon fiber with three different surface treatments combined with a low-temperature, amine-cured epoxy. Unidirectional composite prepregs were fabricated at 67% fiber volume fraction from one type of carbon fiber whose surface has been modified in three different ways to produce three distinct levels of adhesion and two different failure modes. The mechanical characterization tests were conducted according to ASTM protocols.

The “A”- type carbon fibers used in this study are produced by high-temperature inert gas graphitization of polyacrylonitrile fiber. The AU-4 fibers are “as-received,” that is, removed from the heat treatment ovens without any further surface treatment. The AS-4 fibers are surface treated with an electrochemical oxidation step that optimizes the adhesion to epoxy matrices, and the AS-4C fibers are coated with a 100 to 200 nm layer of epoxy applied from an organic solvent directly onto the surface-treated AS-4 fibers. The surface chemical

and topographical features of these reinforcing fibers have been characterized using a variety of techniques (Ref 46, 47, and 48). The adhesion of these carbon fibers to the epoxy matrix has been quantified through single-fiber fragmentation tests. The results are shown in Fig. 4.

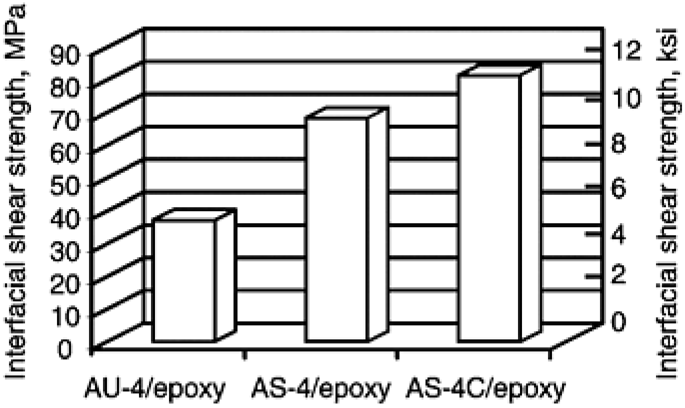

Fig. 4 The adhesion of the A-4 carbon fibers to the epoxy matrix, as quantified through single-fiber fragmentation tests. The fiber-matrix adhesion increases in the order AU-4 > AS-4 > AS-4C. AU-4 has the lowest level of adhesion and fails by a frictional debonding mode; AS- 4 has an intermediate level of adhesion and fails by an interfacial crack growth mode; AS-4C has the highest level of adhesion and fails by a matrix-cracking mode perpendicular to the fiber axis. Source: Ref 45

The adhesion has changed significantly with surface treatment. Compared to the untreated AU-4 fiber, the surface treatment (AS-4) has increased the interfacial shear strength 100%. Application of the fiber sizing (AS-4C) has produced another 25% increase. It is important to note that along with the increase in adhesion is a change in failure mode. Failure of the “as-received” AU-4 interface is through the outer layer of the carbon fiber, while pure interfacial failure takes place in the AS-4 as a result of the surface treatment, indicating that the fiber surface treatment not only adds reactive chemical groups, but also removes the initial defect-laden surface and leaves behind a structurally sound surface that is capable of sustaining high mechanical loads without failure. Both factors are responsible for the improvement in adhesion. The surface- treated carbon fibers are coated with 100 nm of an epoxy resin without any curing agent (AS- 4C). The mechanism by which this surface finish increases the level of fiber-matrix adhesion is that the finish layer interacts with the bulk matrix and causes a local change in properties in the fiber-matrix interphase. The modulus of the in situ epoxy-rich finish layer has been shown to increase over that of the bulk matrix, but the material also becomes more brittle. This can readily be seen in a comparison of the composite fracture surfaces of the A-4/epoxy composites where only the adhesion and interphase have been altered, as shown in Fig. 5. Notice the fractured, brittle-appearing surface on the AS-4C samples that have the stiff and brittle fiber sizing.

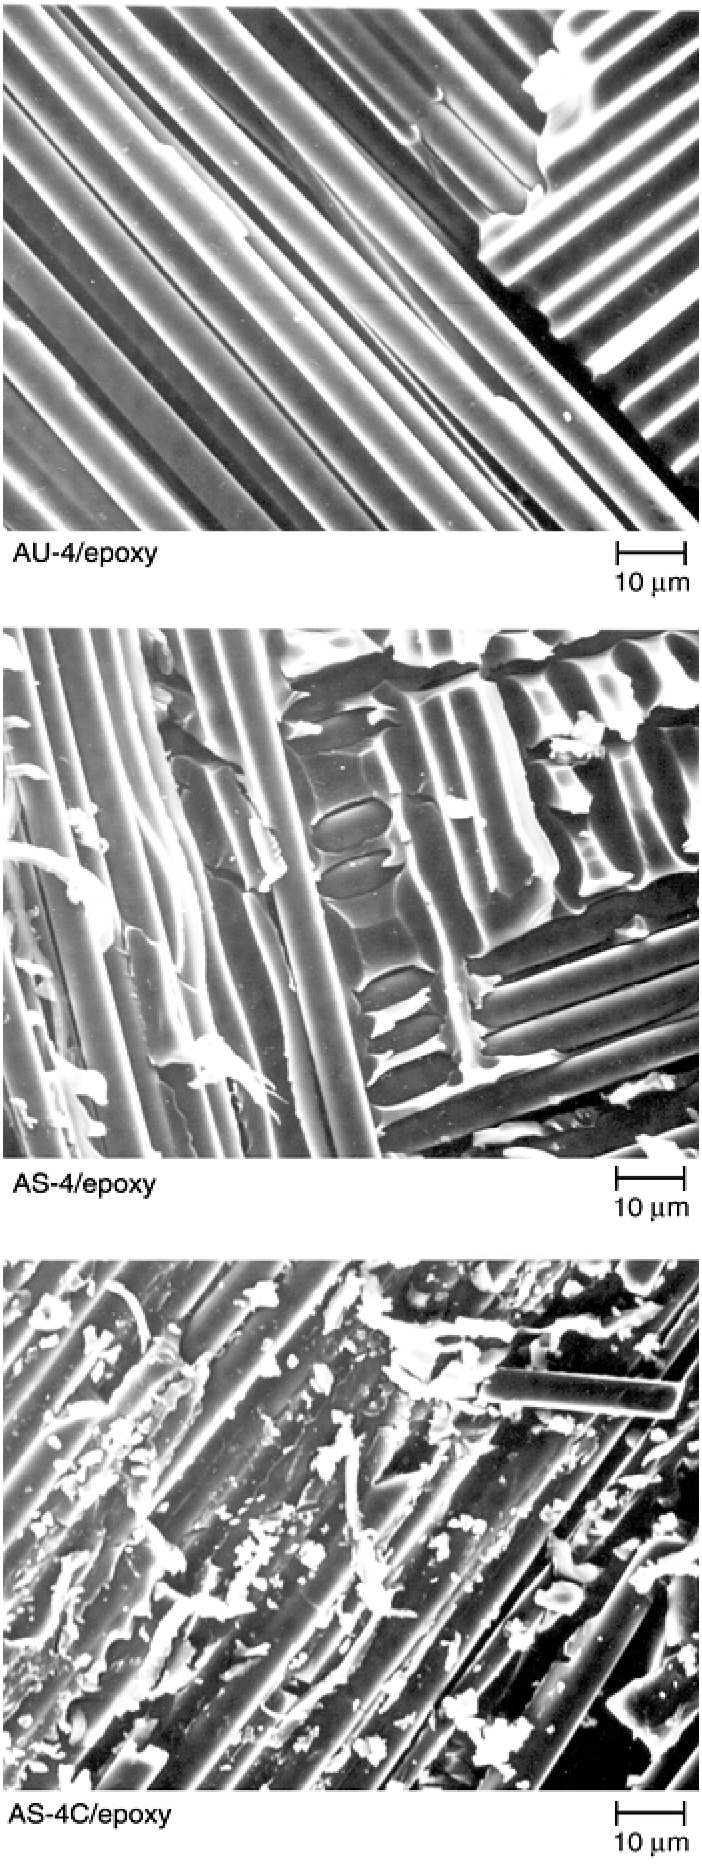

Fig. 5 Fracture surface of A-4/epoxy $[\pm 45]_{3S}$ composites, illustrating the different nature of the failure mode and interphase properties. The fiber-matrix adhesion decreases in the

order AS-4C > AS-4 > AU-4. AU-4 and AS-4 exhibit interfacial failure modes; AS-4C fails in a matrix-dominated mode. The presence of the fiber sizing on the AS-4C fiber has created a brittle interphase. Source: Ref 45

The results obtained for on-axis properties, off-axis properties, and interlaminar fracture toughness present compelling evidence for the effect of the interphase on fiber-matrix adhesion and composite mechanical properties. The on- axis properties (such as longitudinal tensile, compressive, and flexural properties) are dominated by fiber properties, whereas the off-axis properties (such as transverse tensile and flexural, in-plane and interlaminar shear) and interlaminar fracture toughness are dominated by matrix and interfacial properties. The sensitivity of composite properties to fiber-matrix adhesion will be governed by how matrix and fibers are connected and how the applied load is transferred and distributed in composite. For example, in the case of longitudinal tension, the matrix and fibers are connected through fiber-matrix interface in parallel, and most of the applied load is borne by fibers. Therefore, as far as the mechanism of load distribution is concerned, the fiber- matrix adhesion should not be expected to play a dominant role in the longitudinal tensile behavior as long as there is some level of adhesion. If fiber-matrix adhesion is very low, stress transfer at points of fiber fracture will be inadequate, causing the growth of flaws which reduce strength. Changes in the failure modes resulting from the change in fiber-matrix adhesion may have an effect on the longitudinal tensile strength. On the other hand, in the case of transverse tension, the matrix and fibers are connected through the fiber-matrix interface in series, and all the three components, that is, fiber, matrix, and interface/interphase, carry equal load. In such a case, the fiber-matrix adhesion should be expected to have a dominant effect on the composite properties.

Composite On-Axis Properties. Figure 6 compares the longitudinal compressive and longitudinal tensile strength properties of the three composite systems. The longitudinal tensile and compressive moduli are insensitive to fiber-matrix adhesion, because in on-axis specimens, fiber and matrix are connected through the interface in parallel. The applied load is carried by the longitudinal fibers. The role of interface (and matrix) is limited to transferring stress from highly stressed fibers to the neighboring fibers carrying relatively low stress, so as to result in a uniform stress distribution in the composite.

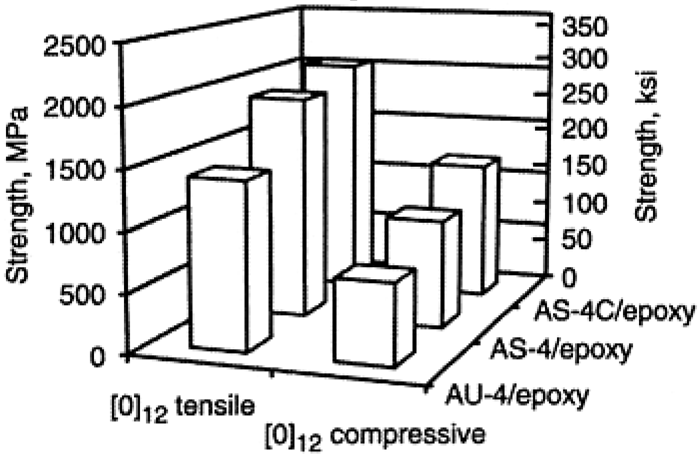

Fig. 6 Comparison between the tensile and compressive properties of the three types of $[0]_{12}$ A-4 carbon-fiber-epoxy composites. The modulus values are similar in both the loading modes. The compression test yields much smaller strength than tensile strength. Also, the compressive strength is more sensitive than the tensile strength to fiber-matrix adhesion. The fiber-matrix adhesion decreases in the order AS-4C > AS-4 > AU-4. AU-4 and AS- 4 exhibit interfacial failure modes; AS-4C fails in a matrix- dominated mode. Source: Ref 45

The average longitudinal tensile strengths (σ_{11}^{f}) of the three composite materials increase with increasing fiber-matrix adhesion for the low (AU-4) and intermediate (AS-4) values. However, when the fiber-matrix adhesion is increased to the highest level (AS-4C), the strength does not increase. Analysis of the failure modes of the tensile coupons indicates that tensile strength increases with increasing interfacial shear strength only as

long as the failure is primarily interfacial. However, if the interfacial strength is too weak, the composite fails prematurely, because of cumulative weakening of the material. On the other hand, when interfacial bond strength is very large, the failure mode changes from interfacial to matrix, and the composite behaves like a brittle material, that is, it becomes "notch-sensitive." Thus, excessive fiber-matrix bond strength may have a detrimental effect on the longitudinal tensile strength of the composite.

There is an increasing trend toward greater composite compressive strength, with increasing fiber-matrix adhesion as well. The increase in the compressive strength corresponding to the increase in the fiber-matrix adhesion from the low (AU-4) to the intermediate (AS-4) value and then the subsequent more rapid increase in the strength at the highest (AS-4C) value suggests that both the improved shear strength between fiber and matrix coupled with the presence of the high-modulus, brittle interphase around the graphite fibers contribute to the greater compressive strength of these composites. The fibers surrounded by matrix material in unidirectional composites subjected to compressive load are like beam columns that are laterally supported on an elastic foundation. The integrity of fiber- matrix interface will determine the effectiveness of the surrounding elastic foundation, which will, in turn, affect the compressive properties of a unidirectional composite. In the composites having the poorest value of fiber-matrix adhesion, the fibers in the delaminated regions are easily separated from the matrix, resulting in global delamination buckling under in-plane compressive loading. In the composites with the intermediate values of fiber-matrix adhesion, delamination is contained only near the specimen edges. Local interfacial failure, however, does take place, and in such a case, the fiber columns may locally behave like beam columns, resting in matrix tunnels. With increasing applied load, local microbuckling may start in this fiber column and propagate in the adjacent fiber columns, resulting in final failure of the specimen. In the AS-4C/epoxy composites where the interlaminar shear strength (ISS) is the highest, the delamination, interfacial failure, and transverse tensile failure due to Poisson's effect are prevented by the strong fiber-matrix adhesion. In addition, the high-modulus, strong interphase around carbon fibers in AS-4C/epoxy composites provides strong lateral support to the graphite-fiber columns. Thus, the fibers can be compressively loaded to their maximum capacity.

Composite Off-Axis Properties. A comparison between transverse flexural, tensile, and short beam shear strength is shown in Fig. 7. There is a significant difference between transverse flexural and transverse tensile strengths. Not only is the transverse flexural strength more sensitive to changes in fiber-matrix adhesion, it is much higher than the transverse tensile strength. The higher values and higher sensitivity of the transverse flexural strength compared to the transverse tensile strength can be explained by the nonuniformity of stress in the three-point flexure test.

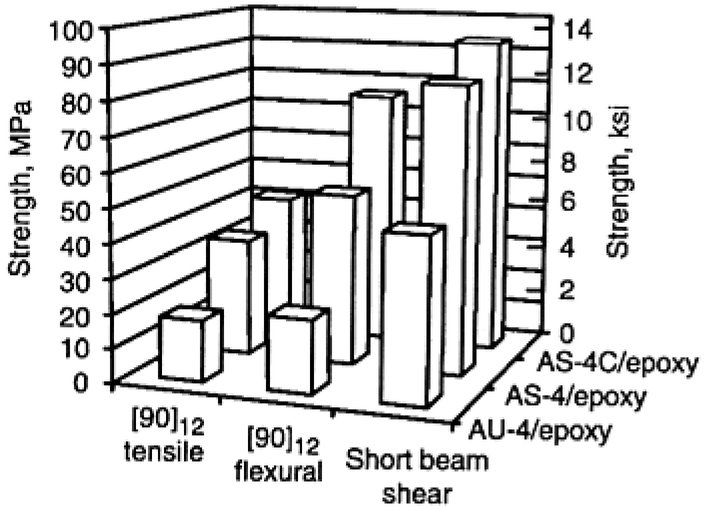

Fig. 7 Comparison between the transverse tensile and flexural properties for $[90]_{12}$ and the short beam shear strength of A-4 carbon-fiber-epoxy composites. The flexural strength is much higher than the tensile strength. The interlaminar shear strength and transverse tensile and flexural strengths all show the same trends. The fiber-matrix adhesion decreases in the order AS-4C > AS-4 > AU-4. AU-4 and AS-4 exhibit interfacial failure modes; AS-4C fails in a matrix-dominated mode. Source: Ref 45

In the case of short beam shear strength, increasing composite shear strength is measured with the intermediate level of adhesion, but levels off or slightly decreases for the composite with the highest level of adhesion. This

is also explained earlier by the different failure mode produced by the samples with the highest level of adhesion. The short beam shear specimens fail prematurely under matrix-failure-dominated conditions encountered with the AS-4C specimen.

Composite Fracture Properties. A comparison between the mode I and mode II interlaminar fracture toughness (G_{Ic} and G_{IIc}) for the three material systems is shown in Fig. 8. The dominant micromechanical event responsible for the increased mode I fracture toughness of AS- 4C/epoxy compared to that of the AS-4/epoxy is increased matrix deformation resulting from the improved fiber-matrix adhesion. Although the AS-4C fibers are surrounded by the low fracture toughness interphase, the gain in the composite fracture toughness from the improved adhesion is larger than the loss resulting from the brittle interphase. Thus, even in the composite system having highly cross-linked, brittle epoxy system, the interfacial strength must be increased to a sufficiently high level in order to maximize the composite interlaminar fracture toughness.

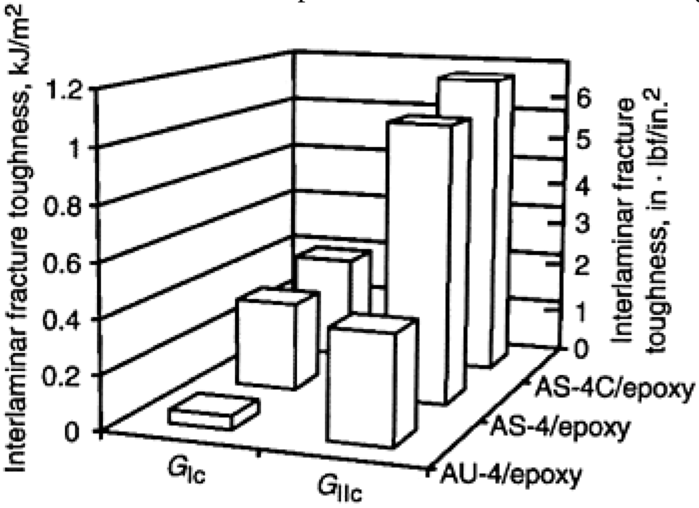

Fig. 8 Comparison between the mode I and mode II fracture toughness of the three composite materials. The mode II fracture toughness is about three times higher than the mode I fracture toughness. The fiber-matrix adhesion decreases in the order AS-4C > AS-4 > AU-4. AU-4 and AS-4 exhibit interfacial failure modes; AS-4C fails in a matrix-dominated mode. Source: Ref 45

This observation suggests that resin fracture toughness is fully transferred to the composite. In addition, there are several other toughening mechanisms that are present in composite but are absent in the bulk resin specimen. For example, in a composite, if the interfacial shear strength is stronger than the matrix strength, the crack will prefer to go through the weaker resin rather than breaking the stronger fibers. However, because of intermingling of fibers (resulting from high consolidation pressures during processing) and very small thickness between the plies (of the order of one fiber diameter), there is no plane containing only resin. In such a situation, the crack must always go around fibers, creating a much larger fracture surface area. Moreover, the resistance to crack growth will be increased by the misaligned fibers that may lie in the path of the advancing crack. All these mechanisms contribute to the composite fracture toughness. It has been suggested that the contribution of each of these toughening mechanisms to the composite fracture toughness will be highest for an optimal thickness of the resin-rich region (Ref 49).

In correlating the effect of fiber-matrix adhesion on G_{IIc} and the observed failure modes, it is shown that by improving the adhesion, the primary failure mode changes from interfacial failure to the matrix failure. The work required to cause matrix fracture is significantly larger than that to cause the failure of the interface having low ISS. When the fiber-matrix adhesion is strong, several energy-absorbing phenomena, such as matrix deformation, matrix cracking, fiber pullout, interfacial failure, and so on, take place. As a result, the G_{IIc} of the composites shows significant improvement when fiber-matrix adhesion is increased. At a certain level when the interfacial strength approaches the matrix strength, the additional increase in the ISS may not yield much improvement in the fracture toughness of the composite. The similarities in the fracture surface morphologies of the AS-4/ epoxy and AS-4C/epoxy suggest that almost the full potential of the interface has already been realized in the AS-4/epoxy composites. Therefore, the percentage increase in the G_{IIc} corresponding to the increase in the ISS from the medium to the highest levels is much smaller than that corresponding to the increase in the ISS from the low to the medium levels. The brittle matrix failure that was believed to be due to

the presence of the brittle interphase around the AS- 4C fibers also may have canceled part of the gain in the G_{IIc} resulting from the increase in fiber- matrix adhesion.

Comparison between results from the single- fiber and composite tests indicates that two key parameters must be obtained from single-fiber tests in order to explain composite property data. They are the level of adhesion and the failure mode, that is, interfacial or matrix. Fiber-matrix adhesion and the "interphase" affect composite properties in different ways, depending on the state of stress and failure mode created at the fiber-matrix interphase.

Conclusions

The fiber-matrix interphase structure exists and can be the major factor in controlling fiber- matrix adhesion and can strongly influence the resulting composite properties. Although many studies have been conducted with the goal of deriving structure-property relationships for fiber- matrix interphases in composite systems, little analytical success has been achieved. As our understanding of the chemistry, physical properties, and morphology of the interphase increases, predictive relationships between the interphase, fiber-matrix adhesion, and composite mechanical properties can be expected to develop. In the future, microengineering of the fiber-matrix interphase will be used to optimize the properties and performance of composites materials.

Lightweight Structural Cores

Jim Kindinger, Hexcel Composites

Introduction

LIGHTWEIGHT STRUCTURAL CORES were first used on aircraft in the 1940s to reduce weight and increase payload and flight distance. They were incorporated into the aircraft design to replace the heavier conventional sheet and stringer or beam support approach, and their incorporation into sandwich panels has been a basic structural concept in the aerospace industry since the 1950s. In 2000, virtually every commercial and military aircraft depends on the integrity and reliability offered by lightweight structural cores. Current lightweight structural cores are classified into three primary types: honeycomb, balsa, and foam. There are numerous substrate materials within the honeycomb and foam categories. Lightweight structural cores can have a density as small as 16 kg/m^3 (1 lb/ ft^3).

Lightweight Structural Cores

Jim Kindinger, Hexcel Composites

Honeycomb

Four primary manufacturing methods are used to produce honeycomb:

- Adhesive bonding and expansion
- Corrugation and adhesive bonding
- Corrugation and braze welding
- Extrusion

The most common manufacturing method for honeycomb is adhesive bonding and expansion. Honeycomb substrates are bonded using heat- curable epoxy-based adhesives. Corrugation is a slower method and typically is used to manufacture higher-density honeycombs, which are either adhesive bonded or braze welded. Adhesive bonding is less expensive than braze welding. Braze welding is used only with steel and specialty metal honeycomb materials, which are usually used in high-temperature applications. The extrusion process is used with ceramic honeycomb and a few thermoplastic honeycombs.
Honeycomb Cell Technology. The honeycomb industry has its own terminology to define the various aspects of honeycomb core (Fig. 1). The bonded portion of a honeycomb cell is called the node, while the single-sheet portion is called a free cell wall. Cell size is measured between two parallel sides of the hexagonal cell. Honeycomb is available in cell sizes ranging from 1.6 to 35 mm (0.062–1.375 in.); most common sizes are 3, 5, 6, 9, 13, and 25 mm (0.125, 0.1875, 0.25, 0.375, 0.5, 0.75, and 1 in.). Honeycomb densities range from 16 to 880 kg/m^3 (1–55 lb/ft^3). When specifying honeycomb, the user needs to stipulate the material, cell configuration, cell size, and density.

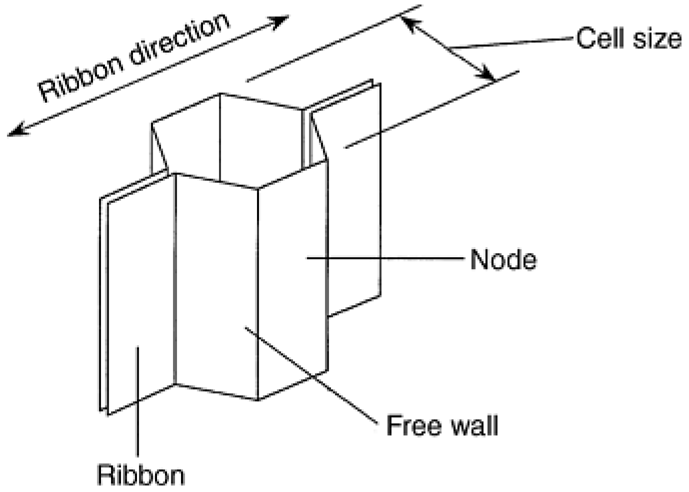

Fig. 1 Honeycomb cell terminology

Cell Configuration. Honeycomb is available in a variety of cell configurations; the most appropriate configuration depends on application requirements. Available honeycomb cell configurations include:

- Hexagonal
- Reinforced hexagonal
- Overexpanded (OX)
- Square
- Flex-Core
- Double Flex-Core
- Spirally wrapped (Tube-Core)
- Cross-Core
- Circular (tubular core)

Flex-Core, Tube-Core, and Cross-Core are trademarks of Hexcel Corporation (San Francisco, CA).

Figure 2 illustrates various honeycomb cell configurations; the most common is hexagonal. A hexagon is one of nature's most efficient shapes for providing structural support. A reinforcement layer can be incorporated in the cellular structure along the nodes in the ribbon direction (reinforced hexagonal configuration) to increase mechanical properties. An OX cell configuration is a hexagonal honeycomb overexpanded in the width (W), or transverse direction. This configuration approaches a rectangular shape, which is preferred when the core needs to be curved or formed around one axis. The OX cell increases shear properties in the W direction and decreases length (L), or longitudinal shear properties compared with hexagonal honeycomb. Making the node very narrow relative to the length of a free cell wall results in a square cell configuration, which provides nearly equal shear strength and modulus in the L and W directions. A Flex-Core or double-Flex-Core cell configuration is ideal when necessary to form parts having compound curvatures. A Tube-Core spirally wrapped cylinder or a cross-core cell configuration is used in applications requiring specific energy absorption. Cross-Core provides energy absorption strength in multiple directions. A circular cell configuration is available for some solvent-bonded thermoplastic honeycombs. In addition to the above cell configurations for structural applications, a very small square cell configuration is available for use in catalytic-converter and heating, ventilation, and air conditioning (HVAC) applications.

Various corrosion-resistant coatings are available for aluminum and steel honeycomb. The most common corrosion-resistant coatings are chromate based and phosphoric acid anodization based. Phosphoric acid anodization provides enhanced honeycomb-to-facing bond strength in sandwich panel construction and enhanced protection in hot/wet and salt environments. Cell wall thicknesses for aluminum, steel, and specialty metal honeycombs range from 0.002 to 0.15 mm (0.0009–0.006 in.). Metallic honeycomb cell walls are available either perforated or nonperforated.

In addition to the substrate, some of the nonmetallic honeycombs are reinforced with resin, which increases density and mechanical properties. Honeycomb substrate materials that can be strengthened with the addition of resin include kraft paper, aramids, fiberglass, and carbon. Resins used to reinforce nonmetallic honeycombs are phenolic, polyimide, and epoxy.

Phenolic resin is by far the most common due to its adherence, fire resistance, and relatively low cost. Polyimide resin is much more expensive than phenolic resin, but provides high-temperature resistance and low dielectric properties. Epoxy resin, also relatively expensive, is used in specialty applications, such as satellites.

Each honeycomb material provides certain properties and has specific benefits. Selection of the proper honeycomb material for a given application is a trade-off between properties and cost. General attributes of honeycomb materials are:

- *Kraft paper:* Relatively low strength, good insulating properties, available in large quantities, lowest cost
- *Thermoplastics:* Good insulating properties, good energy absorption and/or redirection, smooth cell walls, moisture and chemical resistance, environmentally compatible, aesthetically pleasing, relatively low cost

- *Aluminum:* Best strength-to-weight ratio and energy absorption, good heat transfer properties; electromagnetic shielding properties; smooth, thinnest cell walls; machinable; relatively low cost
- *Steel:* Strong, good heat transfer properties, electromagnetic shielding properties, heat resistance
- *Specialty metals:* Relatively high strength-to- weight ratio, good heat transfer properties, chemical resistance, heat resistance to very high temperatures
- *Aramid fiber:* Flammability resistance, fire retardance, good insulating properties, low dielectric properties, good formability
- *Fiberglass:* Tailorable shear properties by lay-up, low dielectric properties, good insulating properties, good formability
- *Carbon:* Good dimensional stability and retention, high-temperature property retention, high stiffness, very low coefficient of thermal expansion, tailorable thermal conductivity, relatively high shear modulus, very expensive
- *Ceramic:* Heat resistance to very high temperatures, good insulating properties, available in very small cell sizes, very expensive

Properties. Most honeycombs are anisotropic; that is, properties are directional. Honeycomb L, W, and T orientation is shown in Fig. 3. The highest compressive and tensile strength of honeycomb is in the T direction; other directions are substantially weaker. Honeycomb provides shear strength in the L and W directions. For the hexagonal-cell configuration, the shear strength and modulus are greatest in the L direction. The shear strength is nearly equivalent in the L and W directions in both the rectangular and the square cell configurations. The Cross- Core cell configuration is designed to have good structural properties in two directions. The most important strength properties used to quantify honeycomb are:

- Compressive strength, either as bare core or stabilized with facings
- Compressive modulus, measured as stabilized with facings
- Crush strength, for energy absorption applications
- Shear strength and modulus in the L and W directions

Figure 4 shows a typical load-deflection curve for honeycomb.

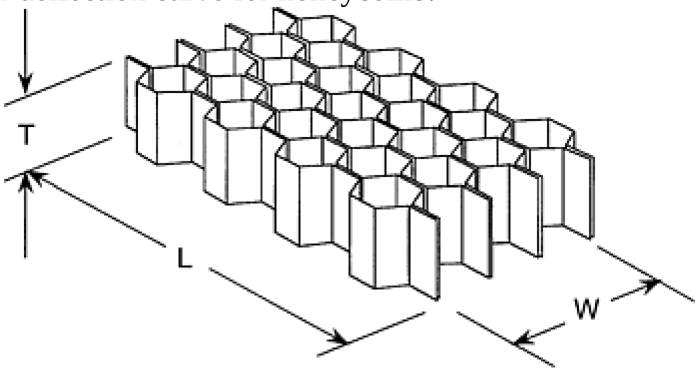

Fig. 3 Honeycomb orientation: L (length or ribbon), W (width), and T (thickness) directions

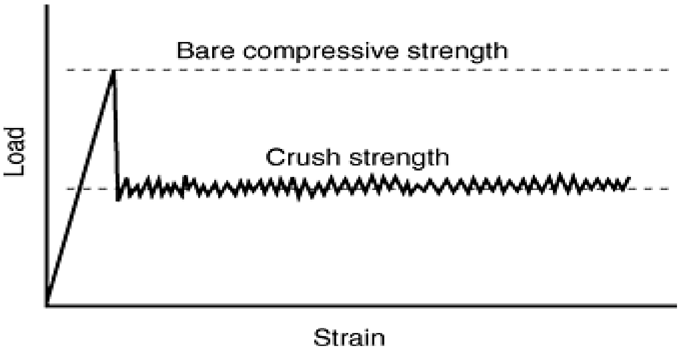

Fig. 4 Typical load-deflection curve for honeycomb

Balsa

Balsa is a natural wood product with elongated closed cells; it is available in a variety of grades that correlate to the structural, cosmetic, and physical characteristics. The density of balsa (96–288 kg/m^3, or 6–18 lb/ft^3) is less than one- half of the density of conventional wood products (480–720 kg/m^3, or 30–45 lb/ft^3). However, balsa has a considerably higher density than the other types of structural cores. Balsa is not available in densities less than 96 kg/m^3 (6 lb/ft^3).

Lightweight Structural Cores

Jim Kindinger, Hexcel Composites

Foam

The mechanical properties of foams are typically isotropic. A variety of foams can be used as core including:

- Polystyrene (better known as styrofoam)
- Phenolic
- Polyurethane
- Polypropylene
- Polyvinyl chloride (PVC), under the tradenames Divinycell, Klegecell, and Airex
- Polymethacrylimide, under the tradename Rohacell

Polystyrene foam is the least expensive, but has relatively low mechanical properties. It is commonly used for disposable packaging. Phenolic foam has very good fire-resistant properties and can have very low densities, but it has relatively low mechanical properties. Polyurethane foam is relatively inexpensive and is used primarily in automotive applications, requiring moderate structural properties. Polypropylene foam is used primarily in automotive applications requiring more demanding structural properties. Polyvinyl chloride (PVC) foam is used primarily in the marine industry for pleasure craft. Polymethacrylimide foam is much more expensive than the other types of foams, but has greater mechanical properties and is used primarily in aerospace and recreation product applications.

Lightweight Structural Cores

Specifying Structural Core

Determining which structural core type to use requires knowing the relevant application requirements. Factors to consider include:

- Materials

- Size
- Density
- Mechanical properties
- Environmental compatibility
- Formability
- Durability
- Thermal behavior
- Cost versus performance

The various attributes of honeycomb, balsa, and foam are compared in Table 1. A relative cost/performance comparison is shown in Fig. 5. Aluminum honeycomb offers the optimal cost/ performance characteristics.

Table 1 Comparison of selected properties and attributes for lightweight structural core materials

Property or attribute	Honeycomb	Balsa	Foam
Density (typical), kg/m^3 (lb/ft^3)	Expanded: 32–192 (2–12) Corrugated: 160–880 (10–55)	96–288 (6–18)	32–288 (2–18)
Moisture resistance	Excellent	Fair	Excellent
Chemical resistance	Fair to excellent	Fair to very good	Fair to very good
Flammability resistance	Excellent	Poor	Fair to excellent
High-temperature resistance	Adhesive bonded: to 177 °C (350 °F) Braze welded: to between 370 and 815 °C (700 and 1500 °F) depending on material	To at least 95 °C (200 °F)	Typically to 80 °C (180 °F); varies by type, but mechanical properties decrease significantly at higher temperatures
Strength and stiffness	Excellent	Excellent	Fair
Energy absorption and crush strength	Constant crush strength value	Not used for energy absorption	Increasing stress with increasing strain
Impact resistance	Fair to excellent	Very good	Fair to poor
Fatigue strength	Good to excellent	Very good	Fair to poor
Abrasion resistance	Good integrity	Fair	Friable
Acoustic attenuation	Yes	Yes	Yes
Formability	Various cell configurations for different shapes	Must cut (e.g., scoring), or use joined strips	Requires molds or scoring
Cost	Inexpensive (kraft paper) to very expensive (carbon)	Moderate	Very inexpensive (polystyrene) to expensive (polymethacrylimide)

Lightweight Structural Cores

Jim Kindinger, Hexcel Composites

Sandwich Structures

In many applications, lightweight structural cores are used in a sandwich panel. The primary advantages of a sandwich panel design are weight savings and increased stiffness compared with alternative designs.

A typical sandwich consists of two thin, high- strength facings bonded to a thick, lightweight core. Each component by itself is relatively weak and flexible, but when combined in a sandwich panel they produce a structure that is stiff, strong, and lightweight. Common facing materials for sandwich panels include aluminum, steel, fiberglass, kraft paper, wood, carbon, nonwovens, and prepregs.

Sandwich Concept. The basic concept of a sandwich panel is that the facings carry the bending loads and the honeycomb core carries the shear loads. In most cases the facing stresses are uniformly distributed. The honeycomb core offers no resistance to bending. In other words, the bending modulus, E', of the core is assumed to be zero. This assumption leads to a uniform shear stress throughout the core thickness.

Deflection, in all structures, consists of two components: bending deflection and shear deformation. In nonsandwich structures, such as steel plate, the shear deformation often is negligible and therefore is neglected. In a sandwich structure, on the other hand, the shear deformation can be significant. In most cases it accounts for about 1% of the bending deflection, although it can be much greater for thick panels or short spans. A typical sandwich panel, formed by adhesive bonding thin skins to a honeycomb core, is shown in Fig. 6.

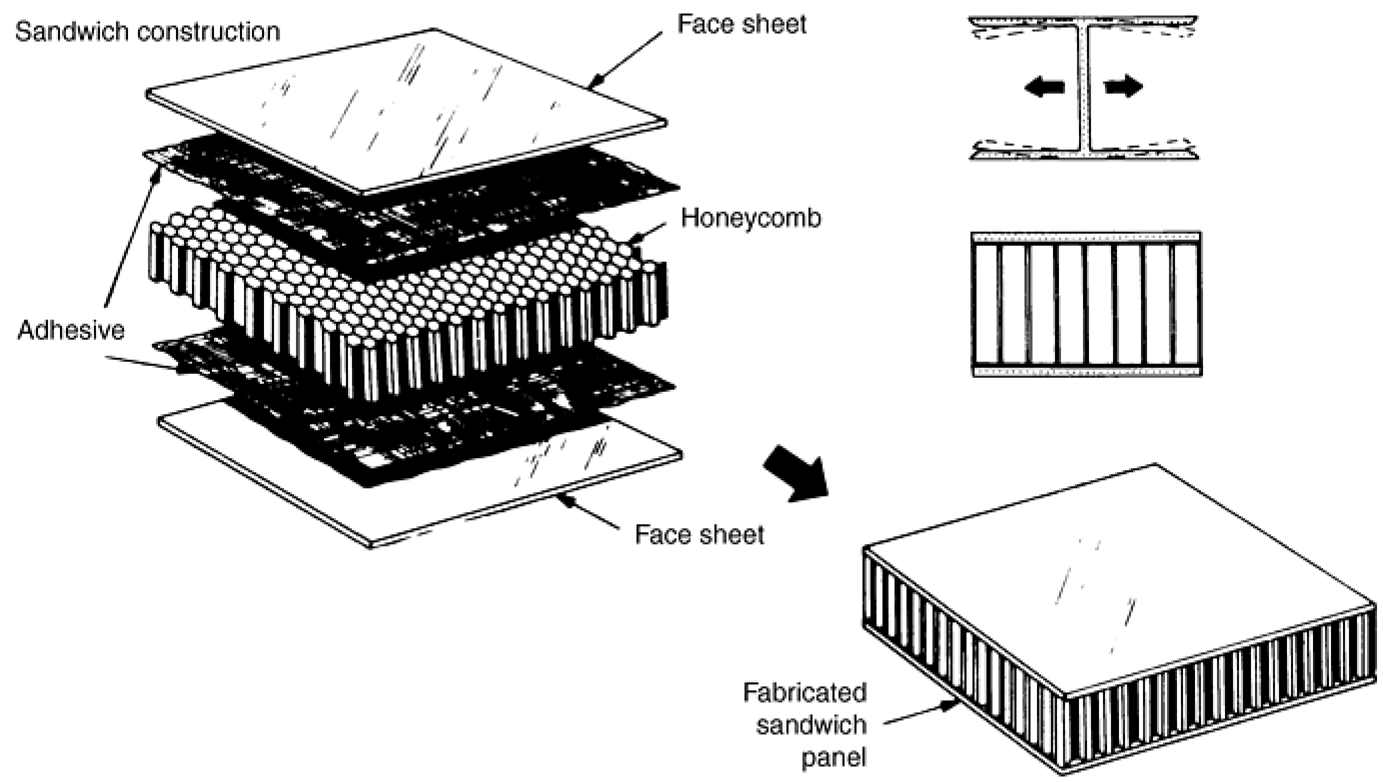

Fig. 6 Honeycomb sandwich panel components

The honeycomb concept produces extremely stiff and strong structures at minimum weight. Table 2 is a generic example of honeycomb effectiveness: a 0.81 mm (0.032 in.) thick piece of aluminum is compared to two sandwiches made by halving the aluminum into two facings and bonding honeycomb core between them. In bending, the thickest of the two sandwich panels is 37 times stiffer and more than 9 times stronger than the aluminum sheet, with a weight increase of only 6%.

Table 2 Honeycomb sandwich panel structural efficiency

Property	A	B	C
Relative stiffness (*D*)	100	700	3700
Relative strength	100	350	925
Relative weight	100	103	106

Benefits of sandwich panels containing lightweight structural cores instead of alternative designs include:

- High strength-to-weight ratio
- Impact and damage resistance
- High rigidity (stiffness)-to-weight ratio
- Fatigue resistance
- Durability
- Tailorable heat transfer and insulation properties
- Fire resistance with tailored self-extinguishing and low-smoke properties
- Ability to include fasteners and attachments

Bio-Based Resins and Natural Fibers

Richard P. Wool and Shrikant N. Khot, University of Delaware

Introduction

ADVANCES in genetic engineering, natural fiber development, and composite science offer significant opportunities for new, improved materials from renewable resources, which can be biodegradable and/or recyclable with enhanced support for global sustainability. Newly developed soy-based plastics and adhesive materials are being evaluated and tested by end-users and converters for high-volume applications in agricultural equipment (Fig. 1), automotive components (car and truck parts), civil infrastructure (bridges and highway components), marine structures (pipes and offshore equipment), rail infrastructure (carriages, box cars, and grain hoppers), and the construction industry (formaldehyde-free particle board, ceilings, engineered lumber). This article describes the synthesis, manufacturing, and properties of both the neat soy-based resins and the glass, flax, and hemp composites.

Bio-Based Resins

Polymers and polymeric composites are derived from petroleum reserves, and as the number of applications of polymeric materials continues to increase, an alternative source of these materials becomes more important. Since 1996, a broad range of chemical routes to use natural triglyceride oils as a basis for polymers, adhesives, and composite materials has been developed (Ref 1, 2, and 3). These materials have economical and environmental advantages over petroleum-based materials, making them an attractive alternative. Natural oils, which can be derived from both plant and animal sources, are abundantly found in all parts of the world, making them an ideal alternative chemical feedstock. These oils are predominantly made up of triglyceride molecules, which have the 3-armed star structure shown in Fig. 2. Triglycerides are composed of three fatty acids joined at a glycerol juncture. Most common oils contain fatty acids that vary from 14 to 22 carbons in length, with 0 to 3 double bonds per fatty acid. In Table 1, the fatty-acid distributions of several common oils are shown (Ref 4). There are more exotic oils, which are composed of fatty acids with other types of functionalities, such as epoxies, hydroxyls, cyclic groups, and furanoid groups (Ref 5). Due to the many different fatty acids present, it is apparent that on a molecular level, these oils are composed of many different types of triglycerides with numerous levels of unsaturation. With newly developed genetic engineering techniques, the variation in unsaturation can be controlled in plants such as soybean, flax, and corn.

(b) Genetically engineered high oleic-acid-content soybean oil (DuPont)

Besides their application in the foods industry, triglyceride oils have been used quite extensively to produce coatings, inks, plasticizers, lubricants, and other agrochemicals (Ref 6, 7, 8, 9 , 10, 11, and 12). Within the polymer field, the application of these oils to toughen polymer materials has been investigated. There has been an extensive amount of work in their use to produce interpenetrating networks (IPNs), which has been reviewed by Barrett and coworkers (Ref 13). It was found that IPNs formed by triglycerides could increase the toughness and fracture resistance in conventional thermoset polymers. For example, Qureshi and coworkers developed an IPN consisting of cross-linked polystyrene and an epoxidized linseed-oil elastomer (Ref 14). Similarly, Devia and coworkers produced IPNs with cross-linked polystyrene and castor-oil elastomers (Ref 15, 16, and 17). Many other efforts have been made to use various types of triglycerides as tougheners in the polymer field (Ref 18, 19 20, and 21).

Recently, there has been renewed interest in developing polymers predominantly based on triglyceride-derived monomers. Such materials do not depend on triglycerides as additives within the material, but rather as major components in the polymer matrix. Li and coworkers have examined using fish, soybean, and tung oil as comonomers in producing rigid plastic materials (Ref 22, 23, 24, and 25). Using these oils in their natural form and in conjugated forms, thermoset polymers were formed by cationic polymerization with other monomers, such as styrene, divinyl benzene, and cyclopentadiene. Similarly, work in the authors' laboratory at the University of Delaware since 1996 has developed several methods for producing polymers from triglycerides.

Synthetic Pathways for Triglyceride-Based Monomers. The triglyceride contains many active sites amenable to chemical reactions. These are the double bond, the allylic carbons, the ester group, and the carbon alpha to the ester group. These active sites can be used to introduce polymerizable groups on the triglyceride using the same synthetic techniques that have been applied in the synthesis of petroleum-based polymers. The key step is to reach a high level of molecular weight and cross-link density, as well as to incorporate chemical groups that are known to impart stiffness in a polymer network (e.g., aromatic or cyclic structures). Several synthetic pathways have been found to accomplish this, as illustrated in Fig. 3 (Ref 3). In structures 5, 6, 7, 8, and 11, the double bonds of the triglyceride are used to functionalize the triglyceride with polymerizable chemical groups. From the natural triglyceride, it is possible to attach maleinates (5) (Ref 7, 12) or convert the unsaturation to epoxies (7) (Ref 26, 27, and 28) or hydroxyl functionalities (8) (Ref 29, 30). Such transformations make the triglyceride capable of reaction via ring-opening or polycondensation polymerization. These particular chemical pathways are also accessible via natural epoxy- and hydroxyl-functional triglycerides, as demonstrated by past work (Ref 13, 15, 16, and 17). It is also possible to attach vinyl functionalities to the epoxy- and hydroxyl-functional triglycerides. Reaction of the epoxy-functional triglyceride with acrylic acid incorporates acrylates onto the triglyceride (6), while reaction of the hydroxylated triglyceride with maleic anhydride incorporates maleate half-esters and esters onto the triglyceride (11). These monomers can then be blended with a reactive diluent, similar to most conventional vinyl-ester resins, and cured by free-radical polymerization.

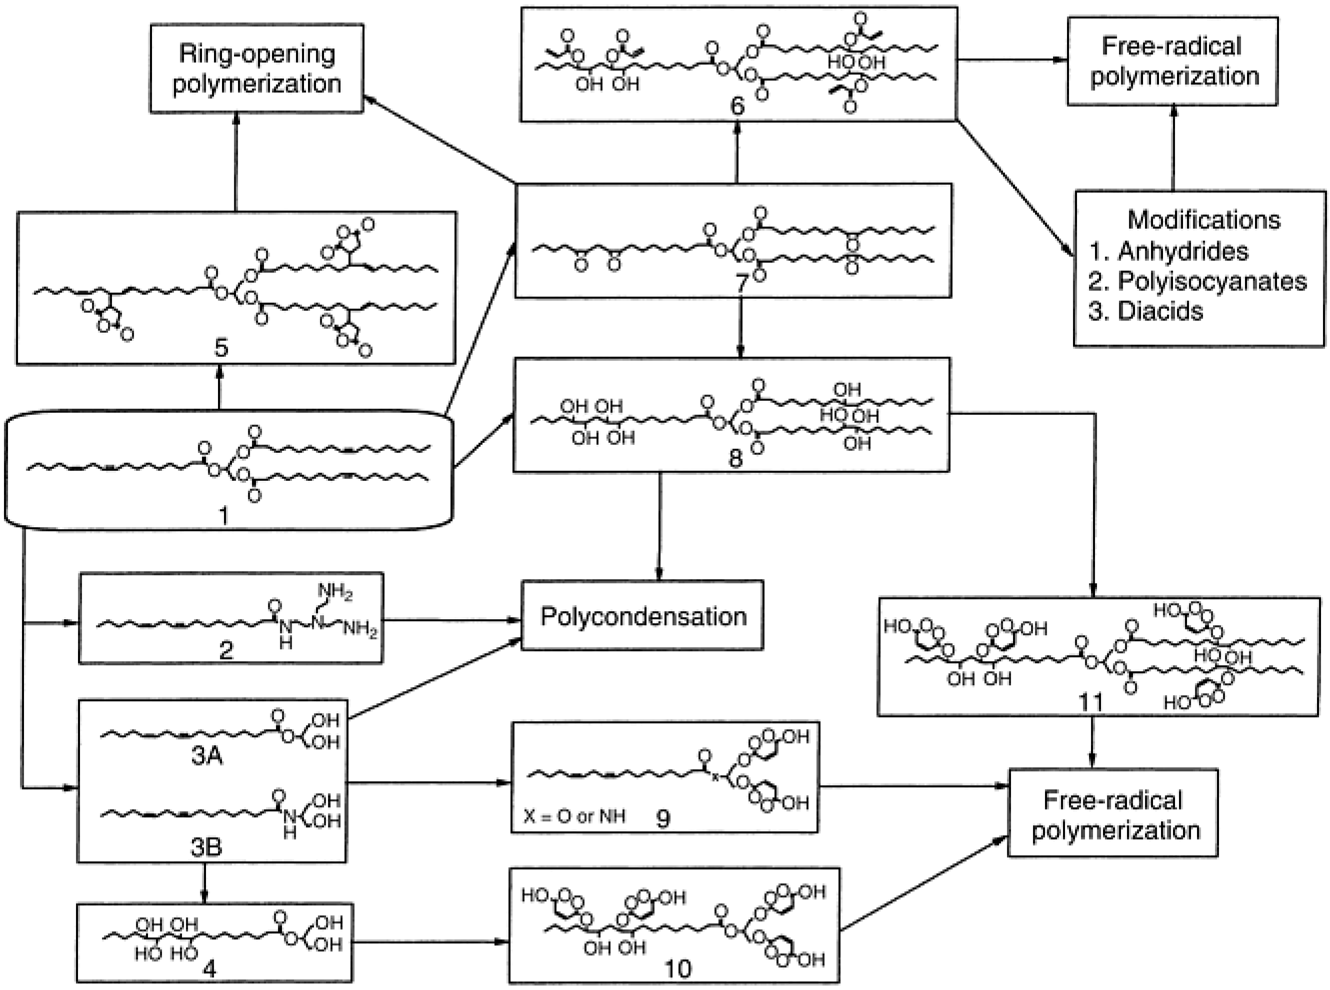

Fig. 3 Chemical pathways leading to polymers from triglyceride molecules. See text for discussion. Source: Ref 1, 3

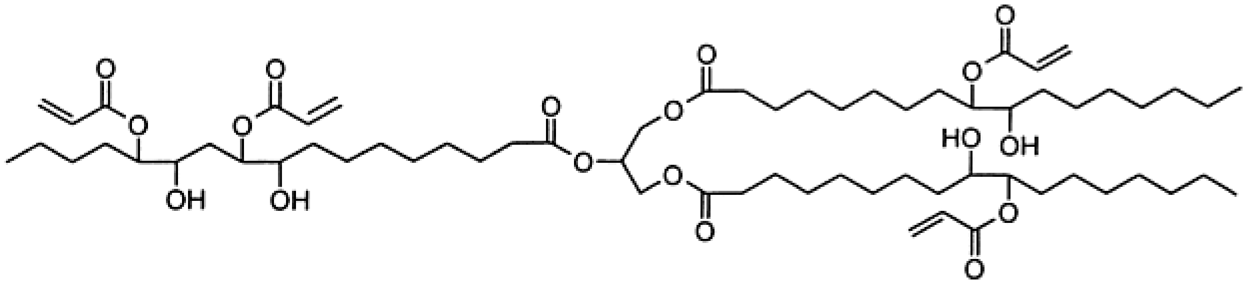
The second method for synthesizing monomers from triglycerides is to reduce the triglyceride to monoglycerides through a glycerolysis (3A) reaction or an amidation reaction (2, 3B) (Ref 31, 32 33, 34, 35, and 36). Monoglycerides have found much use in the field of surface coatings, commonly referred to as alkyd resins, due to their low cost and versatility (Ref 32). In those applications, the double bonds of the monoglyceride are reacted to form the coating. However, monoglycerides are also able to react through the hydroxyl groups via polycondensation reactions with a comonomer, such as a diacid, epoxy, or anhydride. Alternatively, maleate half-esters can be attached to these monoglycerides (9), allowing them to polymerize via free-radical polymerization.

The third method is to functionalize the unsaturation sites as well as reduce the triglyceride into monoglycerides. This can be accomplished by glycerolysis of an unsaturated triglyceride, followed by hydroxylation (4), or by glycerolysis of a hydroxy-functional triglyceride. The resulting monomer can then be reacted with maleic anhydride, forming a monomer capable of polymerization by free-radical polymerization (10).

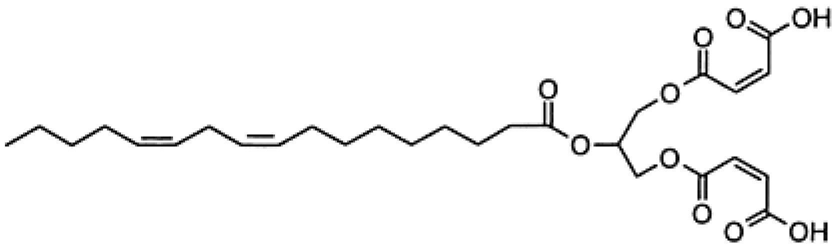
These bio-based monomers, when used as a major component of a molding resin, exhibit properties comparable to conventional polymers and composites, and these properties are presented. Additionally, their use as a matrix in synthetic- and natural-fiber-reinforced composites is presented

Acrylated epoxidized soybean oils (AESO) (Fig. 4) are synthesized from the reaction of acrylic acid with epoxidized triglycerides. Epoxidized triglycerides can be found in natural oils, such as vernonia plant oil, or can be synthesized from more common unsaturated oils, such as soybean oil or linseed oil, by a standard epoxidation reaction (Ref 37). The natural epoxy oil, vernonia oil, has an epoxy functionality of 2.8 epoxy rings per triglyceride (Ref 14). Epoxidized soybean oil is commercially available (e.g., Vikoflex 7170, Atofina Chemicals Inc.) and is generally sold with a functionality of 4.1 to 4.6 epoxy rings per triglyceride, which can be identified via proton nuclear magnetic resonance (^{1}H-NMR) (Ref 19, 38). Epoxidized linseed oil is also commercially available (Vikoflex 7190, Elf Atochem Inc.) when higher epoxy content is required.

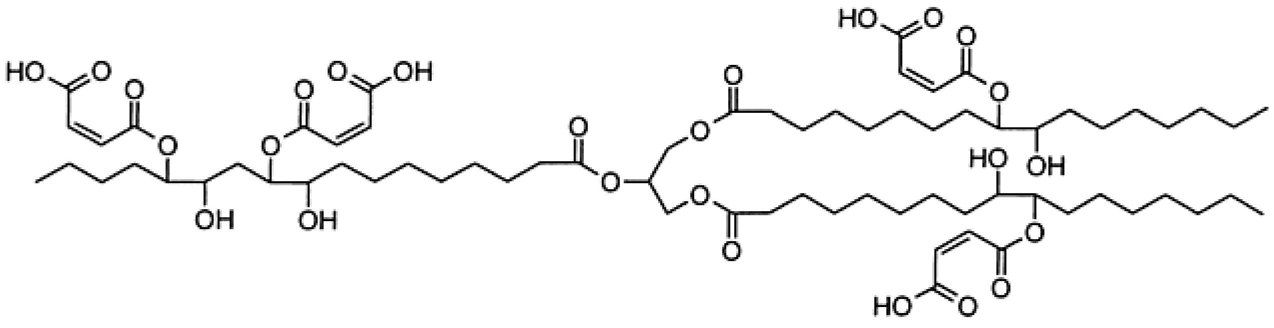
Predominantly, these oils are used as an alternative plasticizer in polyvinyl chloride in place of phthalates (Ref 39, 40, 41). However, research has been done to explore their use as a toughening agent (Ref 19, 20, 21, 42, and 43). With the addition of acrylates, the triglyceride can be reacted via addition polymerization. Acrylated epoxidized soybean oil has been used extensively in the area of surface coatings and is commercially manufactured in forms such as Ebecryl 860 (UCB Chemicals Co.) (Ref 8, 44, and 45). Urethane and amine derivatives of AESO have also been developed for coating and ink applications (Ref 9, 10, and 46).



Acrylated epoxidized soybean oil (AESO)



Maleinated soybean oil monoglyceride (SOMG/MA)



Maleinated hydroxylated soybean oil (HSO/MA)

Fig. 4 Triglyceride-based monomers

The reaction of acrylic acid with epoxidized soybean oil occurs through a substitution reaction and has been found to have first-order dependence with respect to epoxy concentration and second-order dependence with respect to acrylic acid concentration (Ref 47). However, epoxidized oleic methyl ester has been found to display second-order dependence on both epoxy and acrylic acid concentrations (Ref 48). Although the reaction of epoxidized soybean oil with acrylic acid is partially acid catalyzed by the acrylic acid, the use of additional catalysts is common. Tertiary amines, such as N,N-dimethyl aniline, triethylamine, and 1,4-diazabicyclo[2.2.2]octane, are commonly used (Ref 38, 49). Additionally, organometallic catalysts have been developed that are more selective, reducing the amount of epoxy homopolymerization (Ref 50, 51).

Acrylated epoxidized soybean oil can be blended with a reactive diluent, such as styrene, to improve its processability and control the polymer properties to reach a range acceptable for structural applications. By varying the amount of styrene, it is possible to produce polymers with different moduli and glass transition temperatures. Changing the molecular weight or functionality of the acrylated triglyceride can also modify the polymer properties. Consequently, a range of properties and therefore, applications, can be found. After the acrylation reaction, the triglyceride contains both residual amounts of unreacted epoxy rings as well as newly formed hydroxyl groups, both of which can be used to further modify the triglyceride by reaction with a number of chemical species, such as diacids, diamines, anhydrides, and isocyanates. The approach presented

here is to oligomerize the triglycerides with reagents that have chemical structures conducive to stiffening the polymer, such as cyclic or aromatic groups. Reaction of the AESO with cyclohexane dicarboxylic anhydride (CDCA) forms oligomers, increasing the entanglement density and introducing stiff cyclic rings to the structure. Reaction of the AESO with maleic acid also forms oligomers as well as introduces more double bonds. While it is desirable to maximize the conversion of hydroxyls or epoxies, at high levels of conversion the viscosity increases dramatically. Eventually, this can lead to gelation, so careful monitoring of the reaction must be conducted. After oligomerization, the modified AESO resin can be blended with styrene and cured in the same manner as the unmodified AESO resin.

Maleinized soyoil monoglyceride (SOMG/ MA) (Fig. 4) is synthesized from the triglyceride oil in two steps (Ref 33). The first step is a standard glycerolysis reaction to break the triglycerides into monoglycerides. This reaction involves a breakdown of the triglycerides by reaction with glycerol, which has been reviewed in detail by Sonntag (Ref 31). The product is generally a mixture of mono- and diglycerides. To aid in the conversion, excess glycerol can be used. Additionally, the reaction can be run in solvent or in the presence of an emulsifier catalyst (Ref 34). Once the reaction is completed, it is possible to separate a portion of the unreacted glycerol by rapidly cooling the product (Ref 33). However, the presence of glycerol is not detrimental to the end polymer, because it can be reacted with maleic anhydride in the same manner as the monoglycerides and incorporated into the end-polymer network.

The maleinization of the SOMG mixture at temperatures below 100 °C (210 °F) produces monoglycerides, diglycerides, and glycerol maleate half-esters. This reaction makes no attempt to produce a polyester, and the half-ester formation is expected to proceed at low temperatures in the presence of either acid or base catalysts without any by-products. A good indication of the success of this reaction is to follow the signal intensity ratio of maleate vinyl protons to fatty-acid vinyl protons (N_M/N_{FA}) in the ^{1}H-NMR spectrum. The use of 2-methylimidazole and triphenyl antimony as catalysts has been shown to be successful when conducting the reaction at temperatures of 80 to 100 °C (175 to 210 °F) with a 3 to 2 weight ratio of glycerides to maleic anhydride (N_M/N_{FA}= 0.85) (Ref 33, 52). Once these maleates have been added, the monoglycerides can react via addition polymerization. Since maleates are relatively unreactive to each other, the addition of styrene increases the polymerization conversion as well as imparts rigidity to the matrix.

To increase the glass transition temperature (T_g) and modulus of the SOMG/MA polymer for higher performance, more rigid diols can be added during the maleinization reaction. Such diols are neopentyl glycol (NPG) and bisphenol A (BPA), which are known to produce rigid segments in polymer chains. While their addition to the maleinization mixture will reduce the renewable resource content of the final resin, they should result in higher T_g values for the end polymer. The synthesis of maleate half-esters of organic polyols, including NPG and BPA, and the cross linking of the resulting maleate half- esters with a vinyl monomer, such as styrene, have been reported in two patents (Ref 53, 54). The literature is replete with examples of unsaturated polyesters prepared from NPG and maleic anhydride with some other polyols and diacids (Ref 55, 56 57, and 58). However, the copolymers of NPG and BPA bis-maleate half-esters with SOMG maleate half-esters is new.

Maleinized hydroxylated oil (HO/MA), as shown in Fig. 4, is synthesized in a manner similar to both the AESO monomer and the SOMG/ MA monomer. The double bonds of the triglyceride are converted to hydroxyl groups, which are then used to attach maleates similar to the SOMG/MA synthesis. As can be seen in Fig. 3, there are two routes to synthesize the hydroxylated triglyceride. The first path is through an epoxidized intermediate. By reacting the epoxidized triglyceride with an acid, the epoxies can be easily converted to hydroxyl groups (Ref 29, 59). Alternatively, the hydroxylated oil can be synthesized directly from the unsaturated oil in a manner similar to that described by Swern and coworkers (Ref 30). After hydroxylation, the oil can be reacted with maleic anhydride to functionalize the triglyceride with maleate half-esters. A molar ratio of 4 to 1 anhydride to triglyceride was used in all cases, and the reaction catalyzed with N,N-dimethylbenzylamine. Once the maleinization reaction is finished, the monomer resin can be blended with styrene, similar to the other resins presented here.

Bio-Based Resins and Natural Fibers

Richard P. Wool and Shrikant N. Khot, University of Delaware

Neat Resin Properties

AESO Polymer Properties. The pure AESO polymer exhibits a tensile modulus of approximately 440 MPa (64 ksi). At a styrene content of 40 wt%, the modulus increases significantly to 1.6 GPa (232 ksi), almost a fourfold increase. In this region, the dependence on composition appears to be fairly linear. The ultimate tensile strengths of these materials also show linear behavior. The pure AESO exhibits a strength of approximately 6 MPa (0.9 ksi), while the polymers with 40 wt% styrene show much higher strengths of approximately 21 MPa (3.0 ksi). The dynamic mechanical analysis (three-point bending geometry) indicates that even at temperatures as low as–130 °C (–200 °F), these polymers have not reached a characteristic glassy plateau. All compositions exhibit moduli on the order of 4 GPa (580 ksi), but have not reached a plateau. At higher temperatures in the rubber behavior region, the compositions show moduli inversely proportional to the amount of styrene present. According to rubber elasticity theory (Ref 60), the lower-styrene-content polymers have a higher cross-link density, as observed in Fig. 5.

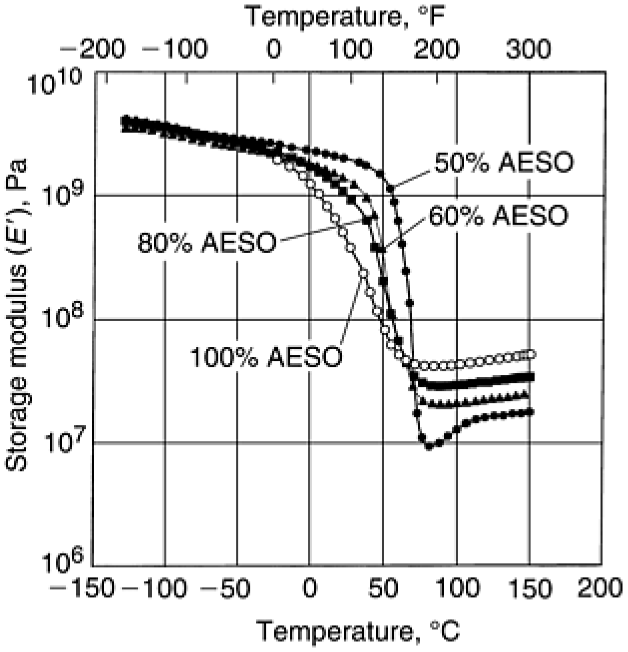

Fig. 5 Storage modulus (*E′*) of AESO-styrene copolymer as a function of temperature

The dynamic mechanical properties of the AESO polymers modified by CDCA and maleic acid were found to be better than the unmodified polymers. The storage modulus (E') of the unmodified AESO resin at room temperature is 1.3 GPa (189 ksi), while the CDCA modification increases E' to 1.6 GPa (232 ksi). The maleic acid modification provides the most improvement, raising the E' to 1.9 GPa (276 ksi). The glass transition temperature, as indicated by the peak in tan δ (the ratio of the loss modulus, E'', to the storage modulus, E'), does not show any large increase from the anhydride modification. However, the maleic acid modification shifts the tan δ peak by almost 40 °C (72 °F), showing a peak at 105 °C (220 °F). The increased broadness of the peak can be attributed to increased cross-link density.

The previous dynamic mechanical behavior is a combination of two factors, cross-link density and plasticization. As the amount of AESO is increased, the number of multifunctional monomers also increases. Therefore, the overall cross- link density is expected to be greater with increasing amounts of AESO, as supported by the high-temperature moduli shown in Fig. 5. Increasing the cross-link density has been found to slow the transition in E' from glassy to rubbery behavior. Additionally, the tan δ peak broadens and decreases in height (Ref 61). The other factor in the dynamic mechanical behavior, plasticization, is due to the molecular nature of the triglyceride. The starting soybean oil contains fatty acids that are completely saturated and cannot be functionalized with acrylates. Therefore, these fatty acids act in the same manner as a plasticizer, introducing free volume and enabling the network to deform more easily. The addition of even small amounts of plasticizer to polymers has been known to drastically broaden the transition from glassy to rubbery behavior and reduce the overall modulus (Ref 61).

This plasticizer effect presents an issue that may be inherent to all-natural triglyceride-based polymers that use the double bonds to add functional groups. However, with advances in genetic engineering capabilities, it may be possible to reduce this trend by reducing the amount of saturated fatty acids present, thus sharpening the glass-rubber transition. This issue is addressed later in the properties of HO/MA polymers produced from genetically engineered high-oleic- content oil and synthetic triolein oil. The existence of some saturated fatty acids, though, can contribute to improved toughness and ballistic impact resistance (Ref 62).

SOMG/MA Polymer Properties. The tan δ peak for the SOMG/MA polymer occurs at around 133 °C (271 °F), and the polymer has an E' value of approximately 0.92 GPa (133 ksi) at room temperature. The T_g of this polymer is lower due to the broad molecular weight distribution of the SOMG maleates. The distribution of soyoil monoglyceride monomaleates, monoglyceride bismaleates, diglyceride monomaleates, and glycerol trismaleates has been confirmed by mass spectral analysis, which has been reported in a previous publication (Ref 63). Additionally, the molecular structure of the monomer is such that the fatty acid “tail” is not incorporated into the network, introducing additional free volume. The tensile tests performed on the copolymers of SOMG maleates with styrene showed a tensile strength of 29.4 MPa (4.26 ksi) and a tensile modulus of 0.84 GPa (122 ksi).

SOMG/NPG Maleates (SOMG/NPG/MA) Polymer Properties. The dynamic mechanical analysis of SOMG/NPG/MA polymers showed a tan δ peak at approximately 145 °C (293 °F) and an E' value of 2 GPa (290 ksi) at room temperature. The 12 °C (22 °F) increase in the T_g and the considerable increase in the modulus of the copolymers of SOMG/NPG maleates with styrene compared to that of the SOMG maleates can be attributed to the replacement of the flexible fatty-acid chains by the rigid methyl groups of NPG. The overall dynamic mechanical behavior of the SOMG/NPG/MA polymer was very similar to that of the SOMG/MA. However, despite the higher T_g and modulus, there remained a broad glass transition. The tensile strength of the SOMG/NPG/MA polymer was found to be 15.6 MPa (2.26 ksi), whereas the tensile modulus was found to be 1.49 GPa (216 ksi).

Maleinized pure NPG polymerized with styrene (NPG/MA) has been prepared in work by E. Can et al. (Ref 64) to compare its properties with the SOMG/NPG/MA polymer. Dynamic mechanical analysis of the NPG/MA showed a tan δ peak at around 103 °C (217 °F) and an E' value around 2.27 GPa (329 ksi) at 35 °C (95 °F). The high T_g value observed for the SOMG/ NPG/MA system (~145 °C) must be a synergetic effect of both the NPG and SOMG together, because the T_g value observed for the NPG/MA system (~103 °C, or ~217 °F) is much lower. This is probably due to the incorporation of the fatty-acid unsaturation into the polymer in the SOMG/NPG/MA system. The comparatively higher E' value observed for the NPG maleates, on the other hand, explains the increase in the E' observed for the SOMG/NPG/ MA system compared to that of the SOMG/MA system. The decrease in tensile strength of the SOMG/NPG/MA system compared to that of SOMG/MA might be attributed to a broader molecular weight distribution of this system compared to that of the SOMG maleates.

SOMG/BPA Maleates (SOMG/BPA/MA) Polymer Properties. The dynamic mechanical analysis of this polymer showed a tan δ peak at around 131 °C (239 °F) and an *E*′ value of 1.34 GPa (194 ksi) at 35 °C (95 °F). The introduction of the rigid benzene ring on the polymer backbone made a considerable increase on the modulus of the final polymer, compared to that of the SOMG maleates. The T_g of this polymer, however, was not very different from that of the SOMG maleates (133 °C, or 271 °F). This has been attributed to a lower yield in the maleinization of the BPA, as determined from ^{1}H-NMR data (Ref 52). Like the SOMG/NPG/MA polymer, the SOMG/BPA/MA displayed the characteristic gradual glass transition.

HO/MA Dynamic Mechanical Polymer Properties. The dynamic mechanical properties of the HO/MA polymers were found to be better than those of the AESO polymers. Little variation was seen between the polymers made from the different oils. At room temperature, the storage moduli for all of the oils existed between 1.45 and 1.55 GPa (210 and 225 ksi), showing no dependence on saturation level. The dynamic mechanical behavior was very similar between the different oils, with the typical behavior shown in Fig. 6. The maximum in tan δ ranged from 107 to 116 °C (225 to 241 °F), which are all substantially higher than the AESO-based resin. These properties are fairly close to those shown by conventional petroleum-based polymers. However, the distinctive triglyceride behavior still exists, in that the glass transitions are extremely broad, and even at room temperature, the materials are not completely in a glassy state. Again, this is probably due to the saturated fatty acids of the triglycerides acting as a plasticizer. As shown in Fig. 7, the behavior is linear, suggesting that if higher levels of functionality are reached, the properties should improve accordingly. However, it is expected that past a certain extent of maleate functionality, the property dependence will plateau. Work is currently being pursued to test the limits of this behavior.

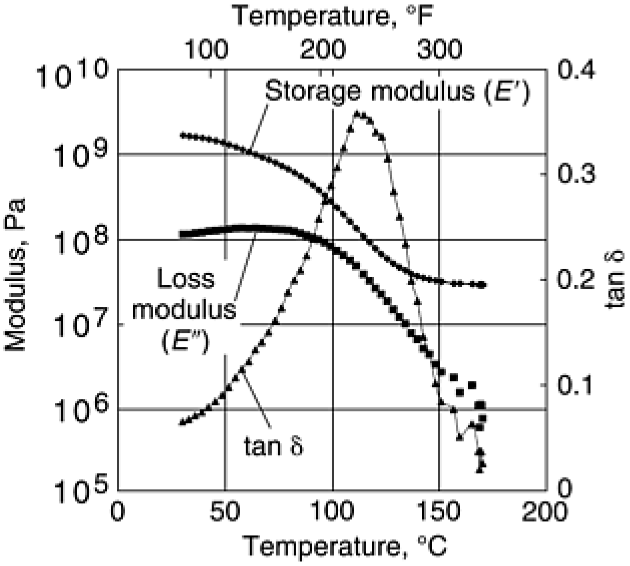

Fig. 6 Representative dynamic mechanical behavior for HO/MA polymers

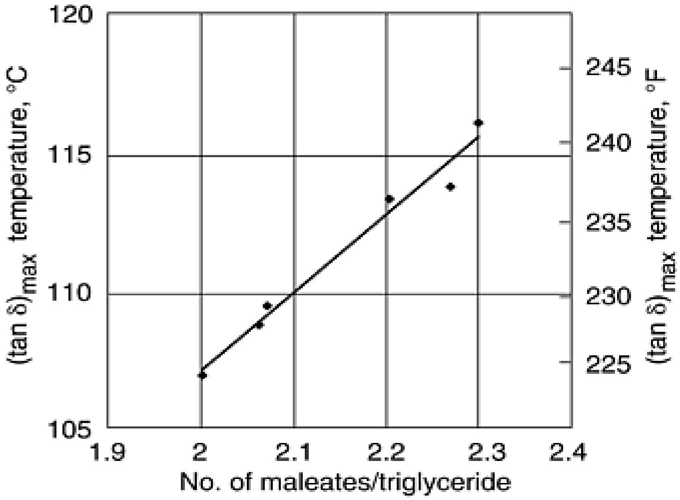

Fig. 7 Peak in tan δ as a function of maleate functionality

It was previously stated that the broadness in the glass transition might be inherent to all triglyceride-based polymers. However, work with genetically engineered oil and synthetic oil has shown that it is possible to reduce this characteristic (Ref 65). The genetically engineered high-oleic soybean oil has an average triglyceride functionality of three double bonds/triglyceride and the fatty-acid distribution shown in Table 1. The maleinized form of this oil had a maleate functionality of two maleates/triglyceride. The properties of polymers from this material were compared to polymers from triolein oil, which is monodisperse, consisting only of oleic fatty-acid esters (18 carbons long, one double bond). The maleinized triolein oil had a maleate functionality of 2.1 maleates/triglyceride. Thus, the only difference between the two oils is the fatty-acid distribution of the high-oleic oil versus the monodisperse triolein oil. It was found that the T_g of these two polymers does not seem to differ much, judging from either their tan δ peak or the inflection in the E', but the broadness of the transitions do differ: the triolein polymer has a sharper E' transition from the glassy region to the rubbery region. This was evident also in the tan δ peak, which has a higher peak height. However, the transition is not yet as sharp as petroleum-based polymers. This is probably due to the triolein monomer having a functionality of only two maleates/triglyceride. Consequently, there is still a plasticizer effect present. However, this effect may be reduced by controlling the reaction conditions to reach higher conversions.

Bio-Based Resins and Natural Fibers

Richard P. Wool and Shrikant N. Khot, University of Delaware

Triglyceride-Based Composite Materials

Four types of triglycerides typically make up a composite resin system: sizing, matrix, rubber toughening, and material modification. For natural fibers, or unsized glass or carbon, about 1% of the system consists of the sizing molecules. These have groups that allow them to bond both to the surface as well as to the matrix. A strong fiber-matrix interface bond is critical for high- strength composites. The ability to apply the sizing in situ offers considerable savings of time and cost, especially for all-natural composites that are intended to be low-cost. The chemical modification on the sizing is chosen with respect to specific interactions on the natural-fiber surface. The matrix consists of the dominant phase binding the fibers together in the composite, and it can be selected with respect to required material properties (hydrophilicity, biodegradability, flammability, dielectric, etc.). The rubber- generating molecules (5 to 20%) can be made in situ or synthesized separately, depending on the manufacturing conditions. The rubber particles, when used at the optimal concentration, impart considerable

impact resistance to both the neat resin and the composite. Other triglycerides are chemically modified to tailor the optical, thermal, electrical, and mechanical properties of the composite.

All of the resins presented here are suitable for use as a matrix in a composite material. Their low viscosity and method of curing make them ideal candidates for use in conventional resin transfer molding (RTM) processes. Most polymer-matrix composites are made by embedding strong fibers, such as carbon, aramid, glass, or natural fibers, in a polymer matrix. The high strength and modulus of the embedded fibers impart strength and rigidity to the material that surpass that of the neat polymer (Ref 66).

Natural-Fiber Reinforcements. While most composite materials use synthetic fibers such as carbon or glass, in recent years, natural fibers have attracted the attention of the composite community as a potential reinforcement, due to the high cost of synthetic fibers. These natural fibers are based on cellulose and offer advantages of biodegradability, low density, nonabrasive nature, and low cost.

Depending on their origin, natural fibers can be grouped into seed, bast, leaf, and fruit qualities. Bast- and leaf-quality fibers are the most commonly used in composite applications. Examples of bast fibers include hemp, jute, flax, ramie, and kenaf. Leaf fibers include sisal and banana leaf fibers. Properties for these fibers include excellent tensile strength and modulus, high durability, low bulk density, good moldability, and recyclability. These natural fibers have an advantage over glass fibers in that they are less expensive, are abundantly available from renewable resources, and have a high specific strength. While high-performance carbon fibers remain superior to natural fibers in high-end applications, natural fibers have comparable properties to glass fibers in high-volume applications (Ref 67). The properties of flax, jute, sisal, and hemp fibers are shown in Table 2 and compared to the commonly used E-glass fiber (Ref 68). The most notable natural fiber is the flax fiber, which has a modulus higher than that of E-glass. Flax is also less dense, thereby producing a lighter composite with good mechanical properties.

Table 2 Properties of natural and E-glass fibers

Fiber	Density,	Tensile modulus		Tensile strength	
	g/cm^3	**GPa**	**ksi**	**MPa**	**ksi**
Flax	1.50	100	14,500	1100	160
Jute	1.45	2.5–13	360–1885	460–530	67–77
Sisal	1.45	9.4–15.8	1363–2292	570–640	83–93
Hemp	1.48	…	…	690	100
E-glass	2.54	76	11,022	1500	218

Source: Ref 68

Numerous studies on the properties of natural- fiber composites have appeared in the literature. These studies have considered a range of natural fibers, including jute (Ref 69, 70, 71, 72, and 73), banana (Ref 74), agave (Ref 74), hemp (Ref 74, 75), flax (Ref 75, 76, 77), bamboo (Ref 78), pineapple (Ref 79), and rubber wood (Ref 80). For certain applications, the mechanical properties of natural-fiber composites, such as those made from flax or hemp fiber, are not sufficient due to the low strength of these fibers. However, combining natural fibers with stronger synthetic fibers, such as glass, could offer an optimal balance between performance and cost. These “hybrid” composites (discussed in a later section), which use two different types of fiber, have been examined in such forms as jute/glass hybrids with epoxy- and polyester-matrix materials (Ref 81, 82).

In all of the previous work, the natural fibers were combined with petroleum-derived matrix resins. The resins presented here offer the unique potential of combining natural fibers with resins based on natural, renewable resources. The properties of glass-reinforced composite materials made from the AESO and HSO/MA resins, as well as all-natural fiber-composite materials reinforced by flax and hemp fibers, are presented here (Ref 83). Additionally, the properties of hybrid composites manufactured from AESO- based resins reinforced with flax and glass fibers are reviewed (Ref 84).

Bio-Based Resins and Natural Fibers

Richard P. Wool and Shrikant N. Khot, University of Delaware

AESO and HSO/MA Glass-Fiber Composites

The properties of the glass-fiber reinforced AESO composites made by RTM are shown in Table 3 (Ref 3). The tensile strength, tensile modulus, and compressive modulus are similar to the properties of the commercial vinyl-ester resin, Dow PC100 (Dow Chemical Co.). The only shortcoming is the compressive strength of the AESO resin, which can be attributed to the lower strength of the AESO neat polymer. However, according to dynamic mechanical analysis, the AESO composite still displayed a T_g close to that of the neat polymer at approximately 80 °C (175 °F). This is much lower than the T_g of the vinyl-ester polymer, which was found to

be about 128 °C (262 °F). Figure 8 shows a commercial composite part that was made with soy- based resins and glass fibers by RTM. The agricultural equipment part in Fig. 1 was manufactured similarly.

Table 3 Tensile and compressive properties of glass-fiber reinforced AESO-based polymer and Dow PC100 vinyl-ester polymer

Polymer	Testing direction	Tensile strength		Tensile modulus		Compressive strength		Compressive modulus	
		MPa	**ksi**	**GPa**	**10^6 psi**	**MPa**	**ksi**	**GPa**	**10^6 psi**
AESO	0°	463	67.2	24.8	3.60	303	43.9	24.8	3.60
Dow PC100	0°	458	66.5	23.8	3.45	421	61.1	23.4	3.39
AESO	90°	322	46.7	20.7	3.00	181	26.3	20.7	3.00
Dow PC100	90°	324	47.0	17.6	2.55	339	49.2	17.9	2.60

Fig. 8 Round hay bailer. The 2.5 × 1 m (8 × 3 ft) panel containing the name "John Deere" was made from a soy- based resin. Courtesy of John Deere, Moline Illinois

The HSO/MA composite properties were found to be even more successful at replicating the properties of a vinyl-ester composite, as shown in Table 4. The flexural modulus and compressive strength for the HSO/MA composite were of the same magnitude as the vinyl-ester composite, while the flexural strength was found to be slightly lower. Additionally, the T_g of the HSO/MA composite was found to be approximately 128 °C (262 °F), which equals that found for the vinyl-ester composite.

Table 4 Flexural and compressive properties of HSO/MA-based polymer and Dow 411C50 vinyl-ester polymer

Polymer	Flexural modulus		Flexural strength		Compressive strength	
	GPa	**10^6 psi**	**MPa**	**ksi**	**MPa**	**ksi**
HSO/MA	34.5	5.00	669	97	200	29
Dow DK 411C50	35.8	5.19	813	118	290	42

These results indicate that although the properties of the neat soyoil-based polymers are less than those of the vinyl-ester polymers, the composite material properties with the same fiber and resin content are very similar.

In tensile deformation, the fiber reinforcement is able to support the majority of the load, leading to an acceptable modulus and strength. The area in which improvement is needed is in compression deformation, where the polymer bears the majority of the stress.

Bio-Based Resins and Natural Fibers

Richard P. Wool and Shrikant N. Khot, University of Delaware

Natural-Fiber Composites

The use of natural fibers with the natural-oil resins described herein promises to give economical, potentially biodegradable or recyclable engineering materials with a high level of vegetable-based raw materials. Such materials have a low market cost and are attractive with respect to global sustainability. As the composite industry becomes more environmentally responsible, resins such as these should find increasing commercial use. Excellent inexpensive composites were made using natural fibers, such as hemp, straw, flax, jute, and wood. It has been found that the soy-based resins have a strong affinity for natural fibers and form an excellent fiber-matrix interface, as determined by scanning electron microscope analysis of fractured composites. Other abundantly available natural products, such as lignin and starch, can make substantial contributions to the composite properties by acting as toughening agents, increasing adhesion between matrix, fillers, and fibers, modifying the biodegradability, improving the antistatic properties, and acting as reinforcement fillers.

The use of natural fibers as a reinforcing fiber or filler in composites has received a lot of attention, as recently reviewed by Williams et al. (Ref 83) and Mohanty et al. (Ref 85). The fibers possess certain properties that make them an attractive alternative to glass fibers. These properties include high specific strength and modulus, low density, low cost, and easy recyclability. The fibers are also safer to handle than glass fibers. Glass fibers produce glass particles that can damage the lungs if inhaled during handling. Natural fibers have been used as reinforcements in both thermoplastics and thermosets. However, the combination of hydrophilic lignocellulosic fibers with hydrophobic resins has led to compatibility problems at the interface. The interface between the matrix and the fibers is very crucial in determining the mechanical properties in composites, and researchers have focused on studying ways to improve the fiber-matrix interface. This problem is often addressed through the use of sizing agents within the composite.

Sizing agents are specifically designed to have chemical functionalities to adhere to both the reinforcing fibers and the polymer matrix. Typically, the sizing agent concentration is of the order of 1 to 2 wt% and provides stronger bonding between the fibers and the matrix, which is essential to the manufacture of high-performance composite materials. Some of the soy-based resins presented here can be used as sizing agents for the natural fibers, with the selection of the correct functional groups. For example, hydrophilic hydroxylated oils that have been maleinized can bond to the fiber as well as the matrix, strengthening the interface.

The low density of natural fibers makes them an attractive alternative to glass fibers in certain applications. The automotive industry is currently using this to their advantage in the battle to reduce the weight of vehicles in order to improve fuel efficiency. The German automotive industry has been a leader in this trend, and several U.S. companies are exploring their use. Parcel shelves, door panels, instrument panels, arm- and headrests, and seat shells can all be made using natural fibers. The construction and furniture industry is also embracing the use of these composites. Superior particle- and fiberboard can be manufactured using natural fibers as reinforcement or fillers in a polymeric matrix. The panel-type composites produced have properties that are comparable to that for wood. The most common resin used to bond the lignocellulosic fibers together is urea formaldehyde. Phenol and melamine formaldehyde are also used as adhesives. The possibility of more stringent regulation of resins containing formaldehyde and the need to reduce the dependence on petroleum products has

lead to the search for alternative adhesives for particle- and fiberboards. The use of a plant-triglyceride-based resin as an adhesive in particleboard production is an interesting possibility that is currently being investigated. The farm machinery industry is another industry that provides an attractive application for these materials. It provides a good marketing point for farm machinery producers to use products made by their customers in their products. Combining the natural fibers with plant-triglyceride-based resins produces a very attractive low-cost composite with much potential in this industry. In the future, the greatest impact of natural fibers with bio-based resins may be seen as a wood lumber substitute.

Flax Composites. Flax comes from the stem of the flax plant of the species *Linum usitatissimum*. The flax plant provides linseed oil from the seeds and fibers from the stem. Fibers obtained from the stem of the plant are known as bast fibers. The fiber can be processed to produce linen fabric, which happens to be one of the first plant fibers used by man for making textile. The same fibers obtained from the stem can be used as reinforcement in composite applications. Flax is readily available in North America and Europe. Canada is the world's leader in the production and export of flax, growing 2.1 million acres in 1997. However, only 15% of these acres are being used in industrial pulping of fine paper. Clearly, there is a huge source of untapped flax fibers available for use in composite applications. In the United States, 146,000 acres of flaxseed was planted in 1997, producing 2.17 million bushels (55,143 metric tons) of flax. Most of the flax in the United States is grown in Minnesota, North Dakota, and South Dakota.

The tensile strength of the AESO/flax-fiber composite was found to have a maximum value of 30 MPa (4.4 ksi) at 34% fiber content, which is comparable to the tensile strength of the AESO neat resin (~30 MPa). The flexural strength showed a similar trend, exhibiting a maximum value at approximately 34% fiber content. The flexural moduli of these materials behaved similarly, showing a maximum at 34% fiber content. However, the tensile moduli showed an increase with fiber content, as shown in Fig. 9. Other researchers have noticed this optimization phenomena in strength, which has been explained in terms of increasing fiber-fiber interactions as the fiber content increases (Ref 67). This reduces the level of fiber-matrix interaction, thereby weakening the composite. Percolation theory has also been used to explain this effect (Ref 62).

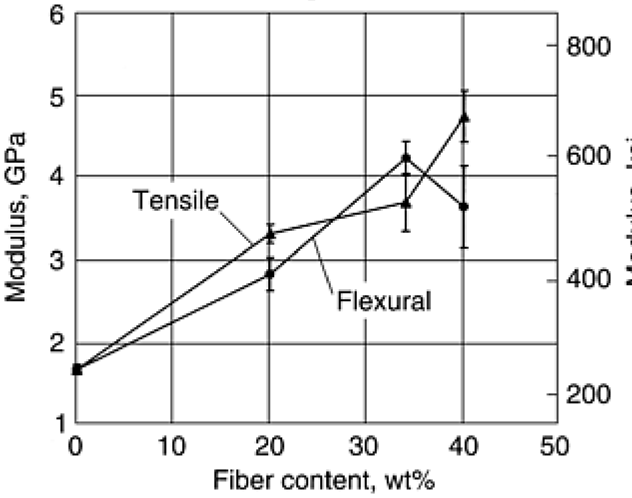

Fig. 9 Modulus dependence on composition for flax (Durafiber-grade 2)-reinforced AESO polymer

The tensile or flexural fracture stress, σ, of composites with natural fibers can be determined by the vector percolation model of fracture (Ref 86):

$$\sigma \sim \left[E(\phi)(1-\phi/\phi_c)\right]^{1/2}$$

where $E(\varphi)$ is the composite modulus as a function of fiber volume fraction, φ, and φ_c is a critical fiber fraction. This assumes that natural fibers have defects distributed along their length whose concentration is proportional to φ. At a critical concentration $\varphi=\varphi_c$, the latter equation predicts that the composite becomes fragile. Since the composite stiffness $E(\varphi)$ is typically an increasing function of φ, as shown in Fig. 9, this relation predicts that in the linear approximation for $E(\varphi)$, σ will attain a maximum at some φ^* value. From the work of Williams et al. (Ref 83), $\varphi^* \approx 35\%$, such that we expect $\varphi_c \approx 70\%$. Elimination of such defects via sizing design, internal repair, and healing processes would substantially increase the tensile properties of natural-fiber composites.

Hemp Composites. Hemp fibers are obtained from the bast fibers of the plant *Cannabis sativa*. The fiber has received much negative publicity due to its close relation to marijuana. Both plants are identical in appearance, but differ in their level of tetrahydrocanabinol (THC). Tetrahydrocanabinol is the chemical responsible for giving marijuana its psychoactive properties. Industrial hemp fibers contain less than 0.5% THC, whereas marijuana has anywhere from 3 to 15% THC. The hemp plant is native to China, but by 1750 had become the largest agricultural crop in the world, with extensive use as cloth, canvas, rope, and oil. The 1937 Marijuana Tax Act lead to the demise of industrial hemp as an agricultural crop in the United States. At the time, the government had no way of telling the plants apart. Both plants ended up being regulated under the same law, and by 1958, the government had stopped granting licenses to grow hemp. However, the hemp industry is making a strong comeback. Hemp is a very versatile fabric and can be used in many different products. It has found use in textile, home furnishing, paper, construction, and automotive industry.

Composites made of 20 wt% hemp fiber (supplied by Hempcore of England) were found to display tensile strength of 35 MPa (5.1 ksi) and modulus of 4.4 GPa (638 ksi). The mechanical properties of the all-natural composites are comparable to the properties shown by wood. For example, a typical hardwood has a tensile modulus of about 10 GPa (1450 ksi), with a fracture stress of about 30 MPa (4.4 ksi) when the stress is exerted parallel to the fiber axis and about 3 MPa (0.4 ksi) when the stress is exerted normal to the fiber-grain axis. The considerable advantage of the all-natural composites is that the unidirectional high properties of wood can be obtained in all directions for the randomly oriented fiber composite. In addition, the ease of manufacturing complex shapes via normal composite liquid molding operations provides a significant cost as well as ease-of-fabrication advantage for these materials. In countries such as China, the depletion of forests to supply wood for the housing industry is strongly discouraged, and the natural-fiber composites would make an excellent substitute for construction lumber.

Hybrid composites were manufactured using glass (E-glass woven fiber) and Durafiber grade 2 flax fibers (Cargill Limited Inc.) in an AESO- based polymer (Ref 84). These were manufactured in symmetric and asymmetric manners by RTM. In the symmetric hybrid composites (G/F/ G), a layer of flax fiber (F) was sandwiched in between two layers of glass fiber (G). The asymmetric composites (G/G/F) were produced by uniformly arranging the flax fibers at the bottom of the mold in a random mat and then placing the two layers of woven glass fabric on top. The AESO resin was then injected with vacuum assist into the mold and cured. The tensile modulus, tensile strength, and compressive strength of hybrid composites for different glass/flax ratios and composite constructions are shown in Table 5. As can be expected, these properties all increase with increasing glass-fiber content. The 100% flax-fiber-reinforced materials show a tensile strength and modulus of 26.1 ± 1.7 MPa (3.8 ± 0.2 ksi) and 1.9 ± 0.1 GPa (275 ± 15 ksi), respectively, while the 100% glass-fiber-reinforced materials show tensile strength and modulus of 128.8 ± 1.1 MPa (18.7 ± 0.16 ksi) and 5.2 ± 0.1 GPa (754 ± 15 ksi), respectively. As shown in Table 6, the asymmetric composites have tensile moduli very similar to the moduli of the symmetric composites. However, the tensile and compressive strengths of the asymmetric composites were noticeably less than the symmetric composites. This is due to the different modes of failure exhibited by the two types of composites. The symmetric composites undergo tensile failure at the peak load while the asymmetric composites fail by shear delamination at the glass/flax interface due to the difference in the tensile moduli of the two fiber types.

Table 5 Tensile and compression properties of symmetric glass/flax hybrid composites

Glass/flax ratio	Weight fractions		Tensile modulus		Tensile strength		Compressive strength	
	Glass	**Flax**	**GPa**	**ksi**	**MPa**	**ksi**	**MPa**	**ksi**
100/0	0.35	0.00	5.2 ± 0.1	754 ± 15	128.8 ± 1.1	18.7 ± 0.16	89.8 ± 3.2	13.0 ± 0.46
80/20	0.25	0.06	3.5 ± 0.1	508 ± 15	123.3 ± 1.2	17.9 ± 0.17	71.6 ± 2.6	10.4 ± 0.38
60/40	0.23	0.16	3.2 ± 0.1	464 ± 15	109.1 ± 1.0	15.8 ± 0.15	62.3 ± 3.1	9.0 ± 0.45
40/60	0.16	0.24	2.9 ± 0.2	420 ± 29	82.6 ± 1.4	12.0 ± 0.20	33.6 ± 0.8	4.9 ± 0.12
0/100	0.00	0.31	1.9 ± 0.1	275 ± 15	26.1 ± 1.7	3.8 ± 0.25	18.5 ± 2.4	2.7 ± 0.35

Table 6 Tensile and compression properties of asymmetric glass/flax hybrid composites

Glass/flax ratio	Weight fractions		Tensile modulus		Tensile strength		Compressive strength	
	Glass	**Flax**	**GPa**	**ksi**	**MPa**	**ksi**	**MPa**	**ksi**
80/20	0.25	0.06	3.4 ± 0.1	493 ± 15	111.7 ± 2.1	16.2 ± 0.30	65.3 ± 4.8	9.5 ± 0.70
60/40	0.24	0.16	3.1 ± 0.1	450 ± 15	90.6 ± 2.4	13.1 ± 0.35	46.2 ± 0.6	6.7 ± 0.09
40/60	0.16	0.25	2.7 ± 0.3	392 ± 44	68.9 ± 2.1	10.0 ± 0.30	30.1 ± 2.2	4.3 ± 0.32

The flexural properties of the glass/flax hybrid composites are shown in Table 7. The flexural modulus and strength for the glass-fiber composite are much higher than those for the flax- fiber composite due to the higher modulus and strength of glass fibers. The 100% flax-reinforced composites display a flexural strength and modulus of 61.0 ± 3.4 MPa (8.8 ± 0.5 ksi) and 3.8 ± 0.2 GPa (551 ± 29 ksi), respectively. The 100% glass-fiber-reinforced composites have a flexural strength and modulus of 205.5 ± 4.5 MPa (29.8 ± 0.65 ksi) and 9.0 ± 0.2 GPa (1305 ± 29 ksi), respectively. Additionally, there is an obvious anisotropy in the behavior of the asymmetric composites, depending on the surface that bears the load. The maximum flexural strengths were obtained when the flax surface was the surface bearing the exerted load or impact. In such an orientation, the glass fibers bear a tensile load during the bending of the sample.

Table 7 Flexural properties and energy absorption on impact of glass/flax hybrid composites

Glass/flax ratio	Weight fractions		Composite construction	Loading/impact face	Flexural modulus		Flexural strength		Energy absorbed

	0.24	0.16	Asymmetric	Flax	4.7 ± 0.3	682 ± 44	146.9 ± 5.5	21.3 ± 0.80	27.6 ± 2.6	20.3 ± 1.9
40/60	0.16	0.24	Symmetric	…	5.8 ± 0.5	841 ± 73	83.3 ± 5.4	12.1 ± 0.78	18.5 ± 0.2	13.6 ± 0.1
	0.16	0.25	Asymmetric	Glass	3.8 ± 0.1	551 ± 15	73.2 ± 7.5	10.6 ±	15.1 ± 0.3	11.1 ± 0.2

								1.09		
	0.16	0.25	Asymmetric	Flax	3.3 ± 0.4	479 ± 58	111.1 ± 9.5	16.1 ± 1.38	28.7 ± 1.2	21.2 ± 0.9
0/100	0.00	0.31	…	…	3.8 ± 0.2	551 ± 29	61.0 ± 3.4	8.8 ± 0.49	1.4 ± 0.2	1.0 ± 0.1

The impact energy of the hybrid composites ranged from 13.3 ± 0.3 to 28.7 ± 1.2 J (9.8 ± 0.2 to 21.2 ± 0.9 ft · lbf). The maximum impact energy absorbed (28.7 ± 1.2 J, or 21.2 ± 0.9 ft · lbf) was shown by the asymmetric 40/60 glass/ flax ratio composite when the flax surface was the load-bearing face. The energy absorption by the symmetric hybrid composites seems to be only marginally higher than that of the 100% glass-fiber composite, a difference made even more insignificant considering the standard deviations. Thus, to reduce cost and weight, flax could be used in place of glass as the outer laminates in composites subjected to impact. The transverse impact is the most common in-service loading mode in composites. In structural applications it could be an impact from a dropped tool; in aircraft applications it could be an impact from a bird; and in aerospace applications it could be an impact from space debris.

Ballistic Impact Resistance of Soy Resin Composites

High-performance polymer composites based on aramid fibers, S-glass fibers, and more recently, gel-spun polyethylene fibers are widely used in applications demanding protection from ballistic impact. These applications include personal armor and armor for equipment. The armor is designed with respect to the threat level, that is, anticipated projectiles, type of ammunition and weapons, velocity of projectiles, and so on. For very high-velocity protection, an armor with a ceramic front plate and a polymer composite backing is selected. For personal protection where the weight of the armor is an important issue, fibers with a low density, such as aramid and gel-spun polyethylene, are commonly used. For equipment protection, on the other hand, S- glass fibers are used.

The ballistic impact of composites is measured in terms of the $V50$ parameter, which is defined as the velocity, V, at which the probability of complete penetration of the target by the projectile is 50%. This involves firing a minimum of six shots at the target, such that three are complete penetrations and three are partial penetrations. The $V50$ is then given by the average of the six strike velocities. In the current study, ballistic impact resistance was determined on S-glass fiber-reinforced soy-based resin panels (305 × 305 × 19 mm, or 12 × 12 × 0.75 in.).

The panels were made by the Seeman composite resin infusion molding process (SCRIMP) method at room temperature and cured at 110 °C (230 °F) for 60 min. The composite consisted of 28 woven S-glass fabric layers. The composite was found to have a *V*50 of about 550 m/s (1,800 ft/s) using 50 caliber (13.5 g) blunt-nosed fragment-simulating projectiles. This ballistic impact resistance is at least comparable to, if not better than, epoxy- and vinyl-ester-based composites. The composites were found to absorb the kinetic energy of the impacting projectiles by tensile failure of fibers, fiber pull-out, delamination, and shear between different layers in the composite.

When 19 mm (0.75 in.) thick ceramic tiles (Coors alumina, CoorsTec) were placed on the soy-based composite, the ballistic impact *V*50 resistance improved to 950 m/s (3,100 ft/s) for 20 mm (53.75 g) projectiles. The role of a ceramic frontface backed by a polymer composite backplate is to spread the impact energy over a larger area. The hard ceramic plate also deforms and blunts the projectile. On ballistic impact, the ceramic is shattered and it spreads the impact over a much larger area. The delocalized energy is then absorbed by the polymer-composite backplate. This increases the amount of energy absorbed and therefore improves the ballistic performance. The enhanced impact resistance of soy-based composites is also attributed to both the low-temperature beta relaxation (similar to polycarbonate), which occurs by virtue of the floppy nature of the triglyceride, coupled with the excellent frictional energy dissipation, which the resin-fiber interface generates during impact.

Biodegradable Composites

Most of the plant-oil-based composite resins described in this article were found to be nonbiodegradable, as required for the traditional long-life applications, but some, such as the amidated monoglyceride, were found to be biodegradable (as determined by weight loss in soil burial tests), as might be expected for materials made with triglycerides. The biodegradable composites could be useful in applications where the biodegradability is an important component of the materials performance in aquatic and terrestrial environments, or in municipal solid waste management where composting and landfill reclamation are considered to be important. Compostable packaging and products that are disposed in the environment would particularly benefit from the new soy-based materials. The variety of biodegradable thermoplastics resins, natural fibers, and their biocomposite properties have recently been reviewed by Mohanty et al. (Ref 85). The four mechanisms of degradation of composites (biodegradation, microorganism degradation, photo degradation, and chemical degradation) and the kinetics of biodegradation of starch-based composites have also been examined (Ref 85).

Conclusions

Triglyceride oils derived from plants have been used to synthesize several different monomers for use in structural applications. These monomers have been found to form polymers with a wide range of properties. Composite materials have been manufactured using these resins and have produced a variety of durable and strong materials. Besides glass fibers, natural fibers such as flax and hemp were used. The properties exhibited by both the natural- and synthetic-fiber-reinforced composites can be combined through the production of hybrid composites. These materials combine the low cost of natural fibers with the high performance of synthetic fibers. Their properties lie between those displayed by the all-glass and all-natural composites. Characterization of the polymer properties also presents opportunities for improvement through genetic engineering technology.

This area of research sets a foundation from which completely new materials can be produced with novel properties. Work is continuing to optimize the properties of these materials and understand the fundamental issues that affect them. In this manner, more renewable resources can be used to meet the material demands of many industries.

Introduction to Engineering Mechanics, Analysis, and Design

Scott Reeve, National Composite Center

Introduction

COMPOSITE MATERIALS offer amazing opportunities for delivering structures that are optimized to meet design requirements. The flexibility to tailor a design for each application also means that design and analysis for composites are more complex than for traditional materials. Full utilization of the advantages of composite materials requires an understanding of the mechanics at multiple levels, the analytical approaches and tools, and the methodologies employed in the design process. This Section of the Volume introduces many of the engineering approaches used in composite industry. The Section is comprised of three general areas: mechanics, analysis, and design.

Introduction to Engineering Mechanics, Analysis, and Design

Scott Reeve, National Composite Center

Mechanics

The mechanics area addresses composites at two levels: micromechanics and macromechanics. The article "Micromechanics" provides an understanding of the behavior of the fiber and resin constituents and how their combination affects higher level composite behavior. Micromechanics played a significant role in the formative years of composites development. Micromechanics has limitations in predicting higher level lamina properties, so many current approaches use macromechanics (addressed in the article "Macromechanics Analysis of Laminate Properties"). As composite analysis continues to expand, refinements in micromechanics and fracture mechanics will enable the full capability of composites to be modeled and exploited.

Introduction to Engineering Mechanics, Analysis, and Design

Scott Reeve, National Composite Center

Analysis

Macromechanics uses the ply level as the building block for analyzing composite laminate behavior. Lamination theory is used to accurately predict laminate properties. These analysis methods address:

- Stress-strain relationship for membrane and bending response
- Thermal and moisture effects
- Inelastic behavior
- Strength and failure
- Interlaminar stresses

The article “Hygrothermal Behavior” illustrates the importance of considering thermal and moisture effects. The article “Characterizing Strength from a Structural Design Perspective” concerns analyzing the strength of composites, critical to predicting failure of any laminate. Successful use of two-dimensional composites requires an understanding of interlaminar stresses, and fracture mechanics offers a promising method for this need (see the article “Fracture Mechanics of Composite Delamination”). Composites provide excellent damping properties and are much less sensitive to fatigue degradation than metals. Two articles, “Damping Properties” and “Fatigue and Life Prediction,” address these topics.

Structural analysis is the next level beyond laminate analysis. It addresses loadings and geometries that occur when the composite laminates are used in functional structure. The structural analysis topics discussed in this Volume include:

- Bolted and bonded joints
- Stability
- Damage tolerance
- Out-of-plane effects
- Sandwich structure

“Bolted and Bonded Joints” discusses considerations necessary to integrate all composite parts in the overall product. The stress concentrations associated with the load transfer at joints are one of the most important areas that must be analyzed. “Instability Considerations” addresses buckling analyses specially formulated for orthotropic materials and laminates. The article “Damage Tolerance” addresses the use of empirical and analytical methods for assessing the damage tolerance of composite laminates and structures. Design guidelines and lessons learned for damage tolerance have been accumulated in three decades of composite applications. As the advantages of composites in integrated structures are exploited, the complex configurations often result in out-of-plane loads on the laminate shells and integrated parts. Analyses of the out- of-plane effects are needed to ensure satisfactory performances, as discussed in the article “Out- of-Plane Analysis.” Sandwich structures continue to be widely used as weight-efficient designs to carry bending and pressure loads. “Analysis of Sandwich Structures” discusses design and analysis along with unique aspects when using composite facesheets.

The orthotropic nature of composites along with the complexity of integrated structures necessitates the use of numerical analysis to fully determine the loads, stresses, and strains that occur in the composite structure. The capabilities of numerical analyses to address the unique issues of composite structures has greatly increased in the past years, and the article “Finite Element Analysis” addresses current methods, limitations, and uses. The article “Computer Programs” reviews current state-of-the-art software that is available and easily used on personal computers. The software programs analyze all levels of composites, from micromechanics to macromechanics to structure.

The final article on analysis, “Testing and Analysis Correlation,” addresses the importance of correlating test results and analytical data. Tests results inspire improvements to the scope and accuracy of analysis methods. Validated analysis methods that correctly predict test failure modes and strengths can confidently be used to reduce the quantity of tests (and costs) necessary to substantiate the use of composites in structures.

Scott Reeve, National Composite Center

Design

The third general area in this Section addresses design. The first article, “Design Criteria,” describes the types of criteria that must be considered when applying composite materials. The next article, “Design Allowables,” explains the procedures involved in generating design allowables. Establishing design values is a critical foundation for beginning the design and analysis process. The ability to design complex and integrated

composite structures has been greatly enhanced by the availability of computer aided design (CAD), described in “Computer-Aided Design and Manufacturing.” The exponential growth of computing power and software packages provides the designer with tools to quickly and accurately develop composite designs. The CAD packages are now integrated with downstream manufacturing functions. This integration of design, tooling, and manufacturing, discussed in “Design, Tooling, and Manufacturing Interaction,” is very important to the successful and cost-efficient application of composites.

In the design and analysis of practical composites structures, one factor that must not be overlooked is cost, discussed in “Cost Analysis.” Future growth of composite applications is dependent on the design of cost-effective parts. Affordability has become much more important, even in high-performance aircraft. The article on cost analysis emphasizes this issue and discusses the development of cost models to assist the designer. Another tool to reduce the overall cost of composite development is discussed in the article “Rapid Prototyping.” Low-cost methods of prototyping parts provides quick feedback to improve designs and identify manufacturing issues early in the design process. The composite industry has developed a collective body of knowledge that provides guidelines and lessons learned for using composite materials (see the article “Design Guidelines”). These assist both new and experienced users in all aspects of composite material selection, design, analysis, and manufacturing. The guidelines are especially beneficial for topics in which analysis methods have not been fully developed and designers must rely on empirical results and experience.

The final two articles, “Engineering Mechanics, Analysis, and Design of Metal-Matrix Composites” and “Fracture Analysis of Fiber-Reinforced Ceramic-Matrix Composites,” address the unique aspects that must be considered when using metal-matrix and ceramic-matrix composites.

Micromechanics

Introduction

WITH INCREASING USE of high-strength and high-stiffness fibers in materials designed to yield a desired set of properties, new interest has arisen in the relationships between the mechanical and physical properties of composites and those of their constituents. A study of the property relationships facilitates analysis of the performance of structures using these heterogeneous materials and provides guidelines for the development of improved materials.

The entire design process has been greatly affected by inclusion of the material design phase in the structural design process. In the preliminary design, the materials considered will usually include many that are still experimental, for which property data are not available. Thus, preliminary material selection may be based on analytically predicted properties. The analytical methods used are the result of studies of the relationship between the effective properties of composites and their constituents (studies that, although not actually conducted at a microscopic level, are frequently described by the term micromechanics). When the relationships between the overall or average response of a composite and the properties of its constituents are understood, the nonhomogeneous composite can be represented by an effective homogeneous (and, usually, anisotropic) material. The properties of this homogeneous material are the effective properties of the composite; that is, they are the properties that give the average values of the state variables in the composite. When the effective properties of a unidirectional composite have been determined, the material may be viewed as a homogeneous anisotropic material for many aspects of the design process. The evaluation of these effective properties is the major topic of this article.

Physical Properties of Fiber Composites: General Concepts

A unidirectional fiber composite (UDC) consists of aligned continuous fibers that are embedded in a matrix (Fig. 1). Fibers currently used are glass, carbon, graphite, and boron; typical matrices are polymeric, such as epoxy, and light metallic, primarily aluminum alloys. The physical properties of a UDC as measured by means of laboratory specimens are called effective properties. A typical specimen is a flat coupon containing many fibers. The effective physical properties are functions of both fiber and matrix physical properties, of their volume fractions, and perhaps also of statistical parameters associated with fiber distribution. The fibers usually have circular cross sections with little variability of diameters. A UDC is clearly anisotropic, because properties in the fiber direction are different from properties transverse to the fibers. The effective properties that are considered herein include elasticity, thermal expansion coefficients, moisture swelling coefficients, static and dynamic viscoelastic properties, conductivity, and moisture diffusivity.

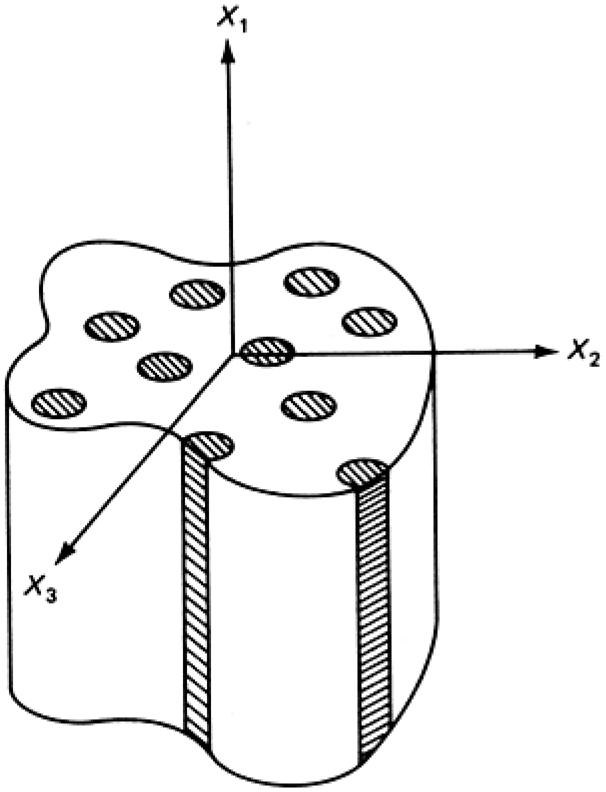

Fig. 1 Unidirectional fiber-reinforced composite

Traditionally, material properties have been obtained experimentally and have been compiled in handbooks. Such an approach is not practical for fiber composites because of their large variety. There are many kinds of carbon and graphite fibers with different anisotropic properties, and there are many kinds of matrix materials with different properties (Ref 1). There also are different environmental effects on those matrix properties. Because experimental determination of all the effective anisotropic properties of interest is impossible, analytical procedures must be developed (on the basis of fiber and matrix properties, volume fractions, and perhaps fiber distribution) to determine those properties. The task of experimentation is to check the validity of the analytical procedures. Thus, the properties are determined from the point of view of structural mechanics, not of materials science. Indeed, composite materials are complicated structures, not materials in the classical sense.

A variety of analytical methods that may be used to determine various properties of a UDC are described in the following sections. Details of derivations may be found in Ref 2 and 3. Reference 4 is also helpful.

Elastic Properties

The elastic properties of a material are a measure of its stiffness and are used to determine the deformations produced by loads. In a UDC, the stiffness is provided by the fibers; the matrix prevents lateral deflection of the fibers. An illustration may be obtained by comparing a bundle of stiff fibers with a UDC containing the same amount of fibers embedded in a polymeric matrix. If the stiffness of the polymer is neglected, the bundle and the UDC will have the same stiffness for a tensile load; in this case, the bundle functions like a rope. However, if compressive load is applied to the bundle in the fiber direction, the bundle will buckle at once; its stiffness for this load is zero. This is in contrast to the UDC, which has the same stiffness for compressive and tensile loads, because the matrix prevents fiber buckling until high values of load are applied. Similarly, the bundle has no transverse tensile stiffness, because the fibers will separate at once. This again will be prevented in the UDC by the matrix.

The elastic properties of a UDC are functions of the elastic properties of fibers and matrix and of their relative volumes in the composite material. Clearly, the stiffness in the fiber direction is much greater than the stiffness transverse to the fibers. If a load is applied in the fiber direction, it is carried primarily by the fibers, which deform very little and constrain the matrix to small deformation. On the other hand, in the direction normal to the fibers, the matrix is a continuous load-carrying structure and the fibers move with the deforming matrix, not significantly impeding deformation. Therefore, the stiffness in the direction transverse to the fibers is much less than the stiffness in the fiber direction, making the material highly anisotropic.

For engineering purposes, it is necessary to determine Young's modulus in the fiber direction (large), Young's modulus transverse to the fibers (small), shear modulus along the fibers, and shear modulus in the plane transverse to the fibers, as well as various Poisson's ratios. This can be done in terms of simple analytical expressions.

Elastic properties of homogeneous materials are defined by relations between homogeneous (constant) stress and strain. Because of the various symmetries, there are 21 independent elastic moduli or compliances in the most general case.

The fundamental property of a fiber composite or any other composite material is statistical homogeneity. This implies that the properties of a sufficiently large sample element containing many fibers are the same as those of the entire specimen. Because the fibers are usually randomly placed, there is no preferred direction in the transverse x_2 x_3 plane, which implies that the UDC is statistically transversely isotropic.

Experimental determination of the properties of homogeneous materials is based on induction of homogeneous states of stress and strain in suitable specimens. The mathematical interpretation is the application of suitable boundary conditions in terms of tractions of displacements that produce homogenous states of stress and strain, or so-called homogeneous boundary conditions. Examples are simple tension, pure shear, and hydrostatic loading. An experimenter would naturally think to apply the same homogeneous boundary conditions to composite specimens. In this case, however, the states of stress and strain in the specimen are no longer homogeneous but highly complex. The variations of stress and strain on any plane through the composite material are random; nothing specific distinguishes the variation on one plane from that on another. Such stress and strain fields are called statistically homogeneous. They consist essentially of constant averages with superimposed random noise and are produced in geometrically statistically homogeneous specimens subjected to homogeneous boundary conditions. Consequently, effective elastic properties are defined by relations between average stress and average strain.

A typical transverse section of a UDC shows random fiber placement; hence, the material is statistically transversely isotropic. Its effective elastic stress-strain relations have the form:

$$\Delta t_p = \frac{P}{P/d} \qquad \text{(Eq 1a)}$$

$$\bar{\sigma}_{12} = 2G_L^* \bar{\varepsilon}_{12}$$

$$\bar{\sigma}_{23} = 2G_T^* \bar{\varepsilon}_{23} \qquad \text{(Eq 1b)}$$

$$\bar{\sigma}_{13} = 2G_L^* \bar{\varepsilon}_{13}$$

with inverse

$$\bar{\varepsilon}_{11} = \frac{\bar{\sigma}_{11}}{E_L^*} - \frac{\nu_L^*}{E_L^*}\bar{\sigma}_{22} - \frac{\nu_L^*}{E_L^*}\bar{\sigma}_{33}$$

$$\bar{\varepsilon}_{22} = -\frac{\nu_L^*}{E_L^*}\bar{\sigma}_{11} + \frac{\bar{\sigma}_{22}}{E_T^*} - \frac{\nu_T^*}{E_T^*}\bar{\sigma}_{33} \qquad \text{(Eq 1c)}$$

$$\bar{\varepsilon}_{22} = -\frac{\nu_L^*}{E_L^*}\bar{\sigma}_{11} - \frac{\nu_T^*}{E_T^*}\bar{\sigma}_{22} + \frac{\bar{\sigma}_{33}}{E_T^*}$$

where * denotes effective property relating values of state property, *n** is C_{11}^*, $\ell^*$is C_{12}^*(refer to Eq 12), $E_L^*$is the longitudinal Young's modulus in fiber direction, $\nu_L^*$is the associated longitudinal Poisson's ratio, $E_T^*$is the transverse Young's modulus, normal to fibers $\nu_T^*$is the associated transverse Poisson's ratio (in transverse plane), $G_T^*$is the transverse shear modulus, $G_L^*$is the longitudinal shear modulus, and *k** is the transverse bulk modulus. Figure 2 illustrates the loadings associated with these properties. The Poisson's ratio, ν_L^*, is an abbreviated notation for ν_{LT}^*, which defines the transverse strain due to a stress E^*_L in the fiber (L or 1) direction. Similarly, the Poisson's ratio $\nu_T^*$is an abbreviated notation for ν_{TT}^*, which defines strain in transverse direction 3 due to stress E_T in transverse direction 2, or vice versa. There is also a Poisson's ratio ν_{TL}^*, which defines strain in the longitudinal direction due to stress E^*_T in the transverse direction, but it is seldom used and does not enter into the stress-strain relations presented here. Its value is given by $\nu_{TL}^* = \nu_{LT}^* E_T^* / E_L^*$. All of these Poisson's ratios are illustrated in Fig. 2.

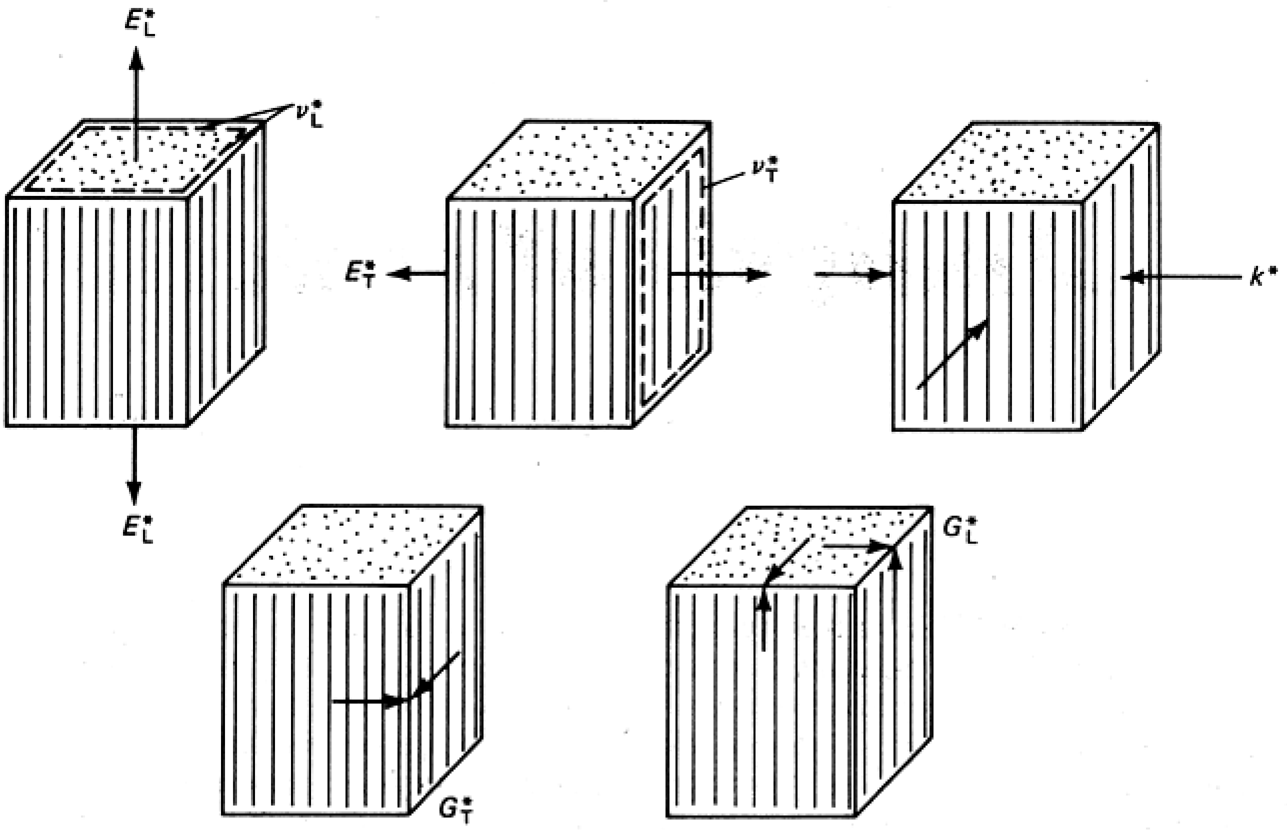

Fig. 2 Basic loadings associated with effective elastic properties. Symbols are defined in text.

The longitudinal shear modulus $G_L^*$is an abbreviation for G_{LT}^*= G_{TL}^*, which is associated with shear acting on perpendicular longitudinal and transverse planes. Similarly, the transverse shear modulus $G_T^*$is an abbreviation for G_{TT}^*, associated with shear or transverse perpendicular planes.
The effective modulus *k** is obtained by subjecting a specimen to the average state of strain:

$$\bar{\varepsilon}_{22} = \bar{\varepsilon}_{33}$$

All others vanish, in which case it follows that:

$$(\bar{\sigma}_{22} + \bar{\sigma}_{33}) = 2k^* (\bar{\varepsilon}_{22} + \bar{\varepsilon}_{33})$$

Unlike the other properties listed, *k** is of little engineering significance but is of considerable analytical importance.
Only five of the properties in Eq 1a are independent. The most important interrelations of properties are:

$$n^* = E_L^* + 4k^* \nu_L^{*2} \quad \text{(Eq 2a)}$$

$$\ell^* = 2k^* \nu_L^* \quad \text{(Eq 2b)}$$

$$4/E_T^* = 1/G_T^* + 1/k^* + 4\nu_L^{*2}/E_L^* \quad \text{(Eq 2c)}$$

$$2/(1-\nu_T^*) = 1 + k^*/\left(1 + 4k^* \nu_L^{*2}/E_L^*\right)G_T^* \quad \text{(Eq 2d)}$$

$$G_T^* = E_T^*/2(1+\nu_T^*) \quad \text{(Eq 2e)}$$

Computation of effective elastic moduli is a difficult problem in elasticity theory. It is first necessary to assume a suitable arrangement of fibers and thus a geometrical model of UDC. Suitable homogeneous boundary conditions are then applied to fiber-reinforced specimens. For example, to compute k^*, it is convenient to apply displacement boundary conditions for which there is not external longitudinal deformation and for which the plane deformation in the transverse plane is isotropic, preserving the shape of the cross section. To find the associated average stress, however, it is necessary to determine in detail the elastic displacement fields in

matrix and fibers. These displacements must satisfy the differential equation of elasticity theory in matrix and fibers, the displacement and traction continuity conditions at fiber-matrix interfaces, and the external boundary conditions. Once these displacements are known, the strain fields are computed by differentiation, the stress fields are found from the local Hooke's laws, and then the stress average, which is necessarily proportional to the strain average, is computed. Then, $2k^*$ is the coefficient of proportionality.

In view of the difficulty of the problem, only a few simple models permit exact analysis. One kind of model is periodic arrays of identical circular fibers, for example, square and hexagonal periodic arrays (Fig. 3). These models are analyzed by numerical finite-difference or finite-element procedures. It is necessary in each case to identify a suitable repeating element of the fiber composite and to express its boundary conditions on the basis of symmetry requirements in terms of the external boundary conditions (see, for example, Ref 2). The hexagonal array was apparently analyzed first in Ref 5 and the square array in Ref 6. It should, however, be noted that the square array is not a suitable model for most UDC analyses because it is tetragonal but not transversely isotropic. Further discussion on periodic arrays is available in Ref 7.

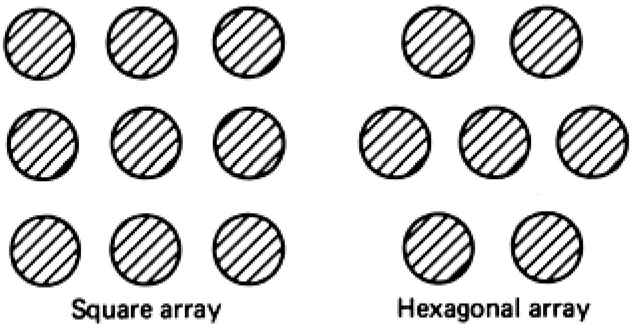

Fig. 3 Models of fiber arrays for numerical computation of properties

The only existing model that permits exact analytical determination of effective elastic moduli is the composite cylinder assemblage (CCA), introduced in Ref 8. To construct the model, one might imagine a collection of composite cylinders, each consisting of a circular fiber core and a concentric matrix shell. The sizes of outer radii b_n of the cylinders may be chosen at will. The size of fiber core radii a_n is restricted by the requirement that in each cylinder the ratio a_n/b_n be the same, which also implies that matrix and fiber volume fractions are the same in each composite cylinder. It may be shown that for various loadings of interest, each composite cylinder behaves as some equivalent homogeneous cylinder. A hypothetical homogeneous cylindrical specimen is assigned these equivalent properties and is progressively filled out with composite cylinders. Because the radii of the cylinders can be arbitrarily small, the remaining volume can be made arbitrarily small. In the limit, the properties of the assemblage converge to the properties of one composite cylinder. The construction of CCA is shown in Fig. 4. A desirable feature of the model is the randomness of fiber placement; an undesirable feature is the large variation of fiber sizes. It will be shown, however, that the latter is not of serious concern.

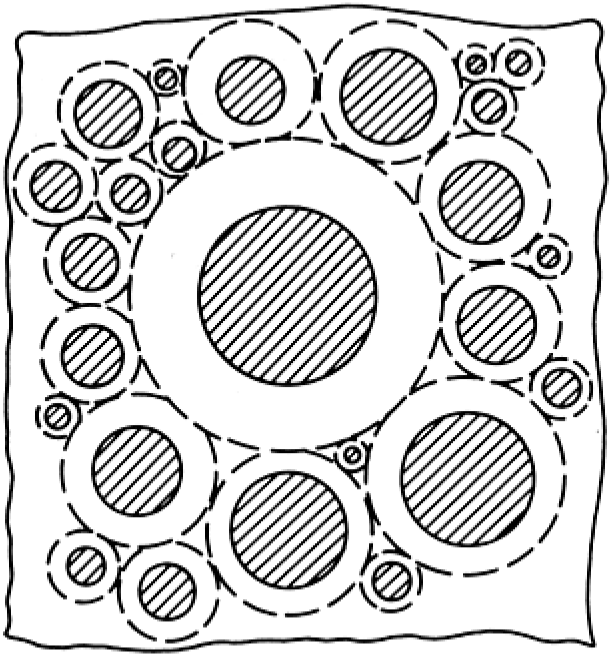

Fig. 4 Composite cylinder assemblage (CCA)

Analysis of the CCA gives closed-form results for the effective properties k^*, E^*_{L}, ν^*_{L}, n^*, ℓ^*, and G^*_{L} and close bounds for the properties G^*_{T}, E^*_{T}, and ν^*_{T}. Such results are listed below for isotropic fibers, with the necessary modifications for transversely isotropic fibers. Details of derivation are given in Ref 2 and 9.

$$k^* = \frac{K_{\mathrm{m}}(K_{\mathrm{f}}+G_{\mathrm{m}})V_{\mathrm{m}} + K_{\mathrm{f}}(K_{\mathrm{m}}+G_{\mathrm{m}})V_{\mathrm{f}}}{(K_{\mathrm{f}}+G_{\mathrm{m}})V_{\mathrm{m}} + (K_{\mathrm{m}}+G_{\mathrm{m}})V_{\mathrm{f}}} = K_m + \frac{V_{\mathrm{f}}}{1/(K_{\mathrm{f}}-K_{\mathrm{m}}) + V_{\mathrm{m}}/(K_{\mathrm{m}}+G_{\mathrm{m}})} \qquad \text{(Eq 3)}$$

$$E^*_{\mathrm{L}} = E_{\mathrm{m}}V_{\mathrm{m}} + E_{\mathrm{f}}V_{\mathrm{f}} + \frac{4(\nu_{\mathrm{f}}-\nu_{\mathrm{m}})^2 V_{\mathrm{m}}V_{\mathrm{f}}}{V_{\mathrm{m}}/K_{\mathrm{f}} + V_{\mathrm{f}}/K_{\mathrm{m}} + 1/G_{\mathrm{m}}} \cong E_{\mathrm{m}}V_{\mathrm{m}} + E_{\mathrm{f}}V_{\mathrm{f}} \qquad \text{(Eq 4)}$$

where K_{m} and K_{f} are the bulk moduli of elasticity of matrix and fiber, and V_m and V_{f} are the volume fractions of matrix and fiber. The last is an excellent approximation for all UCDs.

$$\nu^*_{\mathrm{L}} = \nu_{\mathrm{m}}V_{\mathrm{m}} + \nu_{\mathrm{f}}V_{\mathrm{f}} + \frac{(\nu_{\mathrm{f}}-\nu_{\mathrm{m}})(1/K_{\mathrm{m}} - 1/K_{\mathrm{f}})V_{\mathrm{m}}V_{\mathrm{f}}}{V_{\mathrm{m}}/K_{\mathrm{f}} + V_{\mathrm{f}}/K_{\mathrm{m}} + 1/G_{\mathrm{m}}} \qquad \text{(Eq 5)}$$

$$G^*_{\mathrm{L}} = G_{\mathrm{m}}\left[\frac{G_{\mathrm{m}}V_{\mathrm{m}} + G_{\mathrm{f}}(1+V_{\mathrm{f}})}{G_{\mathrm{m}}(1+V_{\mathrm{f}}) + G_{\mathrm{f}}V_{\mathrm{m}}}\right] = G_{\mathrm{m}} + \frac{V_{\mathrm{f}}}{1/(G_{\mathrm{f}}-G_{\mathrm{m}}) + V_{\mathrm{m}}/2G_{\mathrm{m}}} \qquad \text{(Eq 6)}$$

As indicated previously, the result for G^*_T is a pair of bounds on the actual value. One or the other of these bounds is recommended, depending on the ratios of the constituent properties (to compute the resulting E^*_{T} and υ^*_{T} Eq 2cc and 2d are used). When $G_{\mathrm{f}}>G_{\mathrm{m}}$ and $K_{\mathrm{f}}>K_{\mathrm{m}}$, the upper bound is recommended:

$$G^*_{\mathrm{T}(+)} \sim G^*_{\mathrm{T}} = G_{\mathrm{m}}\left[1 + \frac{(1+\beta_{\mathrm{m}})V_{\mathrm{f}}}{\rho - \left[1 + 3\beta_{\mathrm{m}}^2 V_{\mathrm{m}}^2/(\alpha V_{\mathrm{f}}^3 + 1)\right]V_{\mathrm{f}}}\right] \qquad \text{(Eq 7)}$$

where

$$\alpha = \frac{\beta_m - \gamma\beta_f}{1 + \gamma\beta_f} \quad \rho = \frac{\gamma + \beta_m}{\gamma - 1}$$

$$\beta_m = \frac{1}{3 - 4\nu_m} \quad \beta_f = \frac{1}{3 - 4\nu_f}$$

$$\gamma = \frac{G_f}{G_m}$$

When $G_f < G_m$ and $K_f < K_m$, the lower bound is recommended:

$$G^*_{T(-)} \sim G^*_T = G_m \left[1 + \frac{(1+\beta_m)V_f}{\rho - \left[1 + \beta_m{}^2 V_m{}^2 / \left(\alpha V_f^3 - \beta_m\right)\right] V_f} \right] \quad \text{(Eq 8)}$$

The result (Eq 8) is of interest for metal matrix composites consisting of carbon and graphite fibers in an aluminum matrix because in that case, the elastic properties G_m and K_m of the matrix are larger than the G_{Tf} and K_f of the fibers. Note that K_m in Eq 3 is the isotropic plane-strain bulk modulus.

For transversely isotropic fibers, there are the following modifications (Ref 2, 9):

For k^* k_f is the fiber transverse bulk modulus

$$\text{For } E^*_L, \nu^*_L \quad \begin{aligned} & E_f = E_{Lf} \\ & \nu_f = \nu_{Lf} \\ & k_f \text{ as above} \end{aligned} \quad \text{(Modification 1)}$$

$$\text{For } G^*_L \quad G_f = G_{Lf}$$

$$\text{For } G^*_T \quad \begin{aligned} & G_f = G_{Tf} \\ & \beta_f = k_f / (k_f + 2G_{Tf}) \end{aligned}$$

A rational approximate evaluation of G^*_T of the CCA model is developed (Ref 3) by assuming that any composite cylinder behaves as if it were embedded in the effective medium with effective shear modulus G^*_T.

Numerical analysis of the effective elastic properties of the hexagonal-array model reveals that their values are extremely close to those predicted by the CCA model, as given by the preceding equations. The simple analytical results given here predict effective elastic properties with sufficient engineering accuracy. They are of considerable practical importance for two main reasons. They permit easy determination of effective properties for a variety of matrix properties, fiber properties, and volume fractions, and they constitute the only approach known today for experimental determination of carbon fiber properties.

With respect to the first reason, it is to be noted that the variety of matrix properties to be considered arises not only from the choice of different materials but also, and perhaps more importantly, from environmental changes of properties of a specified matrix. Significant examples are property changes due to temperature, moisture absorption, fatigue damage accumulation, and radiation. Thus, environmental changes of composite stiffness can be determined by measurement of environmental matrix stiffness changes and computation of such changes for the composite. This avoids a great deal of expensive experimentation.

With respect to the second reason, it should be recalled that a carbon or graphite fiber has five independent elastic properties (Eq 2aa to 2e) and that its diameter is of the order of 0.01 mm (0.0004 in.). It is thus impossible to measure directly the elastic properties except for E_L in the fiber direction. A remaining alternative is to measure the elastic modulus of the matrix and the five effective elastic moduli of the composite and then to compute the five fiber elastic properties from Eq 3 to 7 with Modification 1. The current standard method for doing this is to prepare a flat UDC specimen and measure the effective elastic properties by ultrasonic wave propagation. The principle of the method is to measure various wave velocities in various directions relative to the fiber direction. Because wave velocities are defined in terms of elastic moduli and density, their measurement determines the elastic moduli. Table 1 lists the anisotropic elastic properties of a carbon fiber having an axial modulus of 350 GPa (50×10^6 psi). Its properties were determined in this fashion by using carbon-epoxy specimens. The fiber properties obtained were then used to compute the elastic properties of a

UDC consisting of an aluminum matrix and the carbon fiber. Also shown is the comparison between measured and computed composite elastic properties, based on the results (Eq 3 to 6, Eq 8) of Ref 10. The agreement is excellent.

Table 1 Comparison of experimental and analytical results for elastic properties of a graphite-aluminum composite

Property	Value
Graphite fiber (T50)	
Young's modulus, GPa (10^6 psi)	
Longitudinal (E_L)	388 (56.3)
Transverse (E_T)	7.17 (1.04)
Bulk modulus (K), GPa (10^6 psi)	7.03 (1.02)
Shear modulus, GPa (10^6 psi)	
Transverse (G_T)	2.41 (0.350)
Longitudinal (G_L)	6.79 (0.985)
Poisson's ratio	
Longitudinal (ν_L)	0.23
Transverse (ν_T)	0.486
Matrix (aluminum 201)	
Young's modulus (E), GPa (10^6 psi)	71.0 (10.3)
Shear modulus (G), GPa (10^6)	26.7 (3.87)
Poisson's ratio (ν)	0.33
Composite (30% T50, 70% Al)	
Young's modulus, GPa (10^6 psi)	
Longitudinal (E^*_L)	
Experimental	160 (23.2)
Analytical	166 (24.1)
Transverse (E^*_L)	
Experimental	29.6 (4.30)
Analytical	32.0 (4.64)
Shear modulus, GPa (10^6 psi)	
Transverse (E^*_L)	
Experimental	10.3 (1.50)
Analytical	10.4 (1.51)
Longitudinal (E^*_L)	
Experimental	18.5 (2.69)
Analytical	18.6 (2.70)
Poisson's ratio, transverse (E^*_L)	
Experimental	0.43
Analytical	0.41

The foregoing results are of sufficient accuracy and reliability to provide a predictive tool for evaluation of effective elastic properties of fiber composites. Various approximate treatments given in the literature are at least as complex and are less reliable than those presented here. Attempts have also been made to devise empirical or semiempirical equations for effective elastic properties, but in view of the complexity of the problem, this is not a helpful approach.

For purposes of laminate analysis, it is important to consider the plane-stress version of the effective stress-strain relations. Let x_3 be the normal to the plane of a thin, unidirectionally reinforced lamina. The plane-stress condition is defined by:

$$\bar{\sigma}_{33} = \bar{\sigma}_{13} = \bar{\sigma}_{23} = 0 \quad \text{(Eq 9)}$$

Then, from Eq 1a:

$$\bar{\varepsilon}_{11} = \frac{\bar{\sigma}_{11}}{E_L^*} - \frac{\nu_L^*}{E_L^*}\bar{\sigma}_{22}$$

$$\bar{\varepsilon}_{22} = -\frac{\nu_L^*}{E_L^*}\bar{\sigma}_{11} + \frac{\bar{\sigma}_{22}}{E_T^*} \qquad \text{(Eq 10)}$$

$$2\bar{\varepsilon}_{12} = \frac{\bar{\sigma}_{12}}{G_L^*}$$

The inversion of Eq 10 is:

$$\bar{\sigma}_{11} = C_{11}^*\bar{\varepsilon}_{11} + C_{12}^*\bar{\varepsilon}$$

$$\bar{\sigma}_{22} = C_{12}^*\bar{\varepsilon}_{11} + C_{22}^*\bar{\varepsilon}_{22} \qquad \text{(Eq 11)}$$

$$\bar{\sigma}_{12} = 2G_L^*\bar{\varepsilon}_{12}$$

where

$$C_{11}^* = \frac{E_L^*}{1 - \nu_L^{*2} E_T^* / E_L^*}$$

$$C_{12}^* = \frac{\nu_L^* E_T^*}{1 - \nu_L^{*2} E_T^* / E_L^*} \qquad \text{(Eq 12)}$$

$$C_{22}^* = \frac{E_T^*}{1 - \nu_L^{*2} E_T^* / E_L^*}$$

The value of ν_L^* for polymeric matrix composites at the usual 60 vol% of fiber is of the order of 0.25, while the ratio E_T^*/E_L^* is of the order of 0.1 to 0.2. Consequently, the denominator is usually practically equal to unity; hence, the approximation:

$$C_{11}^* \cong E_L^*$$

$$C_{12}^* \cong \nu_L^* E_T^* \qquad \text{(Eq 13)}$$

$$C_{22}^* \cong E_T^*$$

Thermal Expansion and Moisture Swelling

The elastic behavior of composite material discussed in the previous section was concerned with deformations produced by stresses, thus by loads. Deformations are also produced by temperature changes and absorption of moisture, thus by environmental changes. The two phenomena are similar and therefore discussed together. A change of temperature in a free body produces thermal strains, while moisture absorption produces swelling strains. The relevant physical parameters to quantify these phenomena are coefficients of thermal expansion (CTEs) and coefficients of swelling.

Fibers have significantly smaller CTEs than do polymeric matrices. The CTE of glass fibers is 5.0×10^{-6}/K while a typical epoxy value is 54×10^{-6}/K. Carbon and graphite fibers are anisotropic in thermal expansion. The CTEs in the fiber direction are usually extremely small, either positive or negative, of the order of 0.9×10^{-6}/ K. It follows that a UDC will have very small CTEs in the fiber direction because the fibers will restrain matrix expansion. On the other hand, transverse CTEs will be much larger because the fibers move with the expanding matrix and thus provide less restraint to matrix expansion.

These phenomena are of considerable practical importance, particularly for laminates made of unidirectionally reinforced layers. When such a laminate is heated, the free expansion of any layer is prevented by the adjacent laminae because the fiber directions in all layers are different. This causes internal stresses that could be considerable. To compute these stresses, it is necessary to know the CTEs of the layers. Procedures to determine the CTEs in terms of elastic properties and the CTEs of component fibers and matrix are discussed in this section.

A physically similar situation arises in moisture swelling. Polymers absorb moisture in a wet environment and consequently swell. When this swelling is restrained, stresses are produced. If a UDC is placed in a wet environment, the matrix absorbs moisture but, with the exception of aramid, the fibers do not. Therefore, the fibers restrain—literally prevent—swelling in the fiber direction but not in the direction transverse to the fibers. Thus, the UDC is highly anistropic with respect to moisture swelling.

When a laminate absorbs moisture, the same phenomenon occurs as with heating. Because free swelling of the layers cannot take place, internal stresses develop, which can be computed if the UDC coefficients of swelling are known. Procedures for computing those coefficients are also discussed in this section.

The CTEs of homogeneous solids are defined by the strains produced by unit change of temperature in bodies that are free of load and thus free of stress. The main engineering importance of thermal expansion is in the stresses produced when temperature changes occur under conditions of constraint and free expansion is prevented.

The CTEs of a composite are defined by the average strains produced by unit temperature change. In this case, however, free thermal expansion cannot take place on the microscale, because the difference in constituent CTEs will produce microstresses when the temperature changes. Thus, failure of a composite material can be caused by changes in temperature. The CTEs of a UDC are indispensable for stress analysis of laminates subjected to temperature changes.

Consider a free cylindrical specimen of a UDC under uniform temperature change, ΔT, implying that the boundary temperature T is changed $T+\Delta T$. When a composite body is subjected to uniform boundary temperature, the temperature will also be uniform throughout the constituents. On the other hand, the stresses and strains in the phases are nonuniform and complex. The stress-strain relations of Eq 1a in the presence of temperature change then assume the form:

$$\bar{\varepsilon}_{11} = \frac{\bar{\sigma}_{11}}{E_L^*} - \frac{\nu_L^*}{E_L^*}\bar{\sigma}_{22} - \frac{\nu_L^*}{E_L^*}\bar{\sigma}_{33} + \alpha_L^*\Delta T$$

$$\bar{\varepsilon}_{22} = -\frac{\nu_L^*}{E_L^*}\bar{\sigma}_{11} + \frac{\bar{\sigma}_{22}}{E_T^*} - \frac{\nu_T^*}{E_T^*}\bar{\sigma}_{33} + \alpha_T^*\Delta T \qquad \text{(Eq 14)}$$

$$\bar{\varepsilon}_{33} = -\frac{\nu_L^*}{E_L^*}\bar{\sigma}_{11} - \frac{\nu_T^*}{E_T^*}\bar{\sigma}_{22} + \frac{\bar{\sigma}_{33}}{E_T^*} + \alpha_T^*\Delta T$$

where α^*_L is the effective axial expansion coefficient, and α^*_T is the effective transverse expansion coefficient. This definition would indicate that to compute α^*_{ij}, it would be necessary to compute the detailed strain fields in the two phases of a composite subjected to uniform temperature rise. Fortunately, however, this is not necessary; it has been found (Ref 11) that there is a unique mathematical relation between the effective CTEs and the effective elastic properties of a two-phase composite (for the general relations, see Ref 2 and 12). The present discussion is confined to specific cases of interest for a UDC. When fibers and matrix are isotropic:

$$\alpha_L^* = \alpha_m + \frac{\alpha_f - \alpha_m}{1/K_f - 1/K_m}\left[\frac{3(1-2\nu_L^*)}{E_L^*} - \frac{1}{K_m}\right]$$

$$\alpha_T^* = \alpha_m + \frac{\alpha_f - \alpha_m}{1/K_f - 1/K_m}\left[\frac{3}{2k^*} - \frac{3(1-2\nu_L^*)\nu_L^*}{E_L^*} - \frac{1}{K_m}\right] \qquad \text{(Eq 15)}$$

where α_m and α_f are the matrix and fiber isotropic expansion coefficients, K_m and K_f are the matrix and fiber three-dimensional bulk modulus, and E^*_L, ν^*_L, and k^* are the effective axial Young's modulus, axial Poisson's ratio, and transverse bulk modulus. These equations are suitable for glass-epoxy and boron-epoxy or boron-aluminum composites. They have also been derived in Ref 13 and 14.

For carbon and graphite fibers, it is necessary to consider the case of transversely isotropic fibers whose elastic and thermal expansion behavior is characterized by five independent elastic constants and two independent thermal expansion coefficients. This complicates the results considerably (Ref 7, 9):

$$\begin{aligned}\alpha_L^* &= \alpha_m + (\alpha_{Lf} - \alpha_m)\left[P_{11}(S_{11}^* - S_{11})\right. \\ &\quad \left. + 2P_{12}(S_{12}^* - S_{12})\right] + 2(\alpha_{Tf} - \alpha_m) \\ &\quad \left[P_{12}(S_{11}^* - S_{11}) + (P_{22} + P_{23})(S_{12}^* - S_{12})\right] \\ \alpha_T^* &= \alpha_m + (\alpha_{Lf} - \alpha_m)\left\{P_{11}(S_{12}^* - S_{12})\right. \\ &\quad \left. + P_{12}\left[S_{22}^* + S_{23}^* - (S_{22} + S_{23})\right]\right\} \\ &\quad + 2(\alpha_{Tf} - \alpha_m)\left\{P_{12}(S_{12}^* - S_{12}) + \tfrac{1}{2}(P_{22} + P_{23})\right. \\ &\quad \left.\left[S_{22}^* + S_{23}^* - (S_{22} + S_{23})\right]\right\}\end{aligned} \qquad \text{(Eq 16)}$$

where

$$P_{11} = (\Delta S_{22} + \Delta S_{23})/D$$

$$P_{12} = -\Delta S_{12}/D$$

$$P_{22} + P_{23} = \Delta S_{11}/D$$

$$D = \Delta S_{11}(\Delta S_{22} + \Delta S_{23}) - 2\Delta S_{12}^2$$

$$\Delta S_{11} = 1/E_{Lf} - S_{11}$$

$$\Delta S_{12} = -\nu_{Lf}/E_{Lf} - S_{12}$$

$$\Delta S_{22} + \Delta S_{23} = \tfrac{1}{2}(1/k_f + 4\nu_{Lf}^2/E_{Lf}) - (S_{22} + S_{23})$$

$$S_{11} = 1/E_m$$

$$S_{12} = -\nu_m / E_m$$

$$S_{22} + S_{23} = (1 - \nu_m)/E_m$$

$$S^*_{11} = 1/E^*_L$$

$$S^*_{12} = -\nu^*_L / E^*_L$$

and

$$S^*_{22} + S^*_{23} = \tfrac{1}{2}(1/k^* + 4\nu^{*2}_L / E^*_L)$$

Frequently, fiber and matrix CTEs are functions of temperature. It is not difficult to show that Eq 15 and 16 remain valid for temperature- dependent properties if elastic properties are taken at final temperature and CTEs are taken as secant values between that temperature and the stress-free temperature.

To evaluate the CTEs from Eq 15 or Eq 16, it is necessary to know the effective elastic properties k^*, E^*_L, and ν^*_L. These may be taken as the values predicted by the CCA model as given by Eq 3, 4, and 5 with Modification 1 when the fibers are transversely isotropic. Comparison of the values thus obtained with a numerical analysis performed for a hexagonal array of carbon fibers (with an axial modulus of 210 GPa) in epoxy (Ref 15) shows that the results obtained are numerically indistinguishable.

The CTEs of carbon and graphite fibers can be measured directly only in the fiber direction, thus obtaining α_L. Direct measurement of transverse α_T is not possible because of the minute fiber diameters. Again, the only possible way to evaluate α_T is to measure α^*_L and α^*_T experimentally for a specified composite and then compute α_T from Eq 16. If the equations are written in the form:

$$\alpha^*_L = \alpha_m + (\alpha_{Lf} - \alpha_m)a_{11} + (\alpha_{Tf} - \alpha_m)a_{12}$$
$$\alpha^*_T = \alpha_m + (\alpha_{Lf} - \alpha_m)a_{21} + (\alpha_{Tf} - \alpha_m)a_{22} \quad \text{(Eq 17)}$$

it follows that:

$$\alpha_{Lf} = \alpha_m + \frac{(\alpha^*_L - \alpha_m)a_{22} - (\alpha^*_T - \alpha_m)a_{12}}{a_{11}a_{22} - a_{12}a_{21}}$$
$$\alpha_{Tf} = \alpha_m + \frac{(\alpha^*_T - \alpha_m)a_{11} - (\alpha^*_L - \alpha_m)a_{21}}{a_{11}a_{22} - a_{12}a_{21}} \quad \text{(Eq 18)}$$

Figure 5 shows typical plots of the effective CTEs of graphite-epoxy. For 0.50 fiber volume fraction, the axial expansion coefficient, α^*_L, is practically equal to that of the fibers. Because many carbon and graphite fibers have small negative axial expansion coefficients, many composites with such fibers have small negative or practically vanishing axial expansion coefficients. It is also interesting that for small fiber volume fractions, the transverse CTE becomes larger than the matrix CTE, which is the maximum constituent CTE.

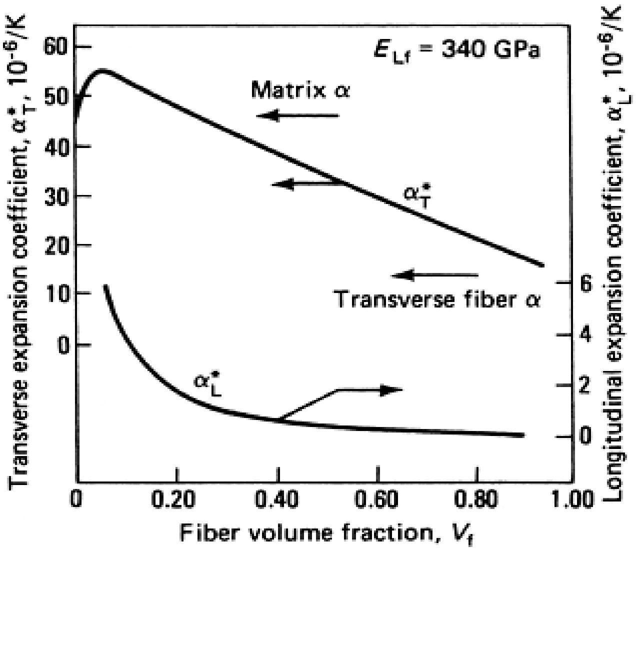

Fig. 5 Effect of fiber volume fraction on thermal expansion for representative carbon-epoxy composite

With respect to deformation due to moisture, when a body that absorbs moisture is placed in a wet environment, moisture will diffuse through the external boundary. The internal moisture concentration, *C*, is defined by the mass of moisture accumulated per unit volume and is initially a function of space and time. Ultimately, the moisture concentration will stabilize and become time independent. The time-dependent stage is called the transient stage, and the ultimate time- independent stage is called the stationary stage. There is a complete mathematical analogy between the equations describing heat conduction and moisture diffusion, in both the transient and stationary stages. Thus, in the latter stage, the concentration *C* satisfies the Laplace equation.

When a composite with a polymeric matrix is placed in a wet environment, the matrix will begin to absorb moisture. However, the moisture absorption of most fibers used in practice is negligible. Aramid fibers alone do absorb significant amounts of moisture when exposed to high humidity. The total moisture absorbed by an aramid-epoxy composite, however, may not be substantially greater than that absorbed by other epoxy composites.

In most composites, the fibers act as barriers to moisture diffusion, analogous to perfect insulators in heat conduction, After sufficient time has elapsed, the matrix will be in an equilibrium moisture state with uniform concentration on the boundary. After a long time in this stage, the moisture concentration throughout the matrix will also be uniform, and thus the same as the boundary concentration. It is customary to define the specific moisture concentration, *c*, by:

$$c = C/\rho \qquad \text{(Eq 19)}$$

Thus, *c* is the mass of moisture per unit mass, a nondimensional number. The swelling strains due to moisture are functions of *c* and, to a first approximation, are given by:

$$\epsilon_{ij}=\beta_{ij}c \qquad \text{(Eq 20)}$$

where β_{ij} are the swelling coefficients.

If there are also mechanical stresses and strains, the swelling strains are superimposed on the latter, which is exactly analogous to the thermoelastic stress-strain relations of an isotropic material where β replaces the CTE and *c* replaces the temperature. The swelling coefficients of most fibers are zero since their moisture absorption is negligible. (Aramid fiber swelling coefficients are unknown.) It follows that moisture swelling of a UDC is mathematically analogous to thermal expansion of such a composite with vanishing fiber expansion coefficients. Therefore, all of the results previously given for thermal expansion can be transcribed to moisture swelling. The effective swelling coefficients, β^*_{ij}, are defined by the average strains produced in a free sample subjected to uniform unit change of specific moisture concentration in the matrix. Thus, these coefficients follow directly from the equations for CTEs.

Other aspects of moisture absorption and transient and steady state are discussed in Ref 16 and 17, which also contain survey articles on this subject.

With respect to the important question of simultaneous moisture swelling and temperature rise, often called hygrothermal behavior, the simplest approach is to assume that thermal expansion strains and moisture swelling strains can be superimposed. Thus, for a free specimen:

$$\begin{aligned} \bar{\varepsilon}_{11} &= \alpha^*_{\mathrm{L}}\Delta T + \beta^*_{\mathrm{L}}c \\ \bar{\varepsilon}_{22} = \bar{\varepsilon}_{33} &= \alpha^*_{\mathrm{T}}\Delta T + \beta^*_{\mathrm{T}}c \end{aligned} \qquad \text{(Eq 21)}$$

In this situation, the matrix elastic properties in Eq 15 and 16 may be functions of the end temperature and the equilibrium moisture concentration, *c*; this dependence must be known in order to evaluate α^*_{L}, α^*_{T}, β^*_{L}, and β^*_{T} in Eq 21.

Viscoelastic Properties

All polymers exhibit time dependence. This manifests itself by the increase with time of deformations under constant load, which is called creep, and, conversely, by the decrease with time of stresses under deformation constraints, which is called relaxation. Another important effect of time dependence is the damping of vibrations due to energy dissipation in the polymeric matrix. The significance of all these phenomena increases with rise in temperature.

The effects described are of considerable engineering importance for fiber-reinforced composite structures, because stresses and deformations determined on the basis of elastic analysis may change considerably with time because of polymeric matrix time dependence. Vibration damping is a beneficial effect that is of particular significance for the higher vibration modes, which often become negligible because of damping.

The simplest description of time dependence is linear viscoelasticity. Viscoelastic behavior of polymers manifests itself primarily in shear and is negligible for isotropic stress and strain. This implies the elastic stress-strain relation:

$$\sigma_{11} + \sigma_{22} + \sigma_{33} = 3K\,(\varepsilon_{11} + \varepsilon_{22} + \varepsilon_{33}) \quad \text{(Eq 22)}$$

where K, the three-dimensional bulk modulus, remains valid for polymers. When a polymeric specimen is subjected to shear strain ϵ_{12}, which does not vary with time, the stress needed to maintain this shear strain is given by:

$$\sigma_{12}(t) = 2G\,(t)\varepsilon_{12}^{0} \quad \text{(Eq 23)}$$

where $G(t)$ is defined as the shear relaxation modulus. When a specimen is subjected to shear stress σ_{12}^{0} constant in time, the resulting shear strain is given by:

$$\varepsilon_{12}(t) = \tfrac{1}{2} g(t)\sigma_{12}^{0} \qquad \text{(Eq 24)}$$

and $g(t)$ is defined as the shear creep compliance.

Typical variations of relaxation modulus and creep compliance with time are shown in Fig. 6. These material properties change significantly with temperature. The relaxation modulus decreases, and the creep compliance increases. This implies that stiffness decreases with temperature. The initial values of these properties at time-zero (at the beginning of deformation) are denoted $G(0)$ and $g(0)$ and are the elastic properties of the matrix. Note that $G(0)\ g(0) = 1$. If the applied shear strain is an arbitrary function of time, commencing at time zero, Eq 23 is replaced by:

$$\sigma_{12}(t) = 2G(t)\sigma_{12}(0) + 2\int_0^t G(t-t')\frac{d\varepsilon_{12}}{dt'}dt' \qquad \text{(Eq 25)}$$

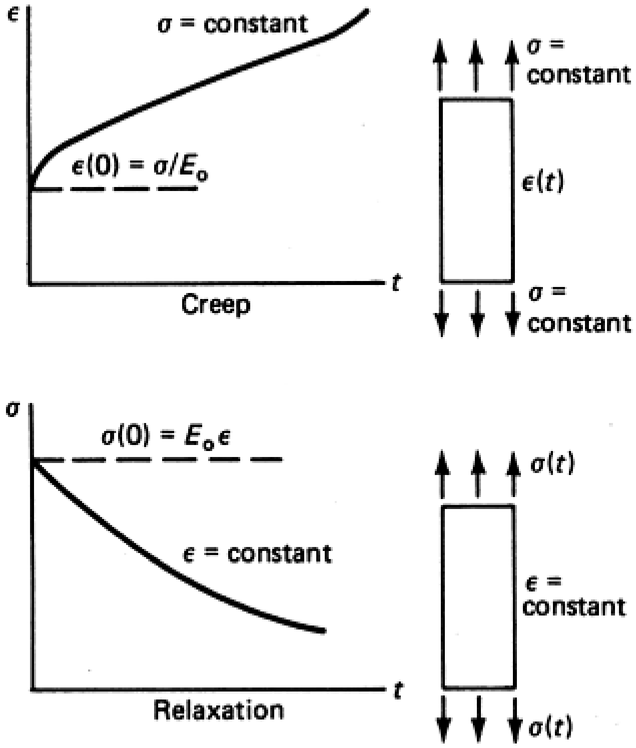

Fig. 6 Viscoelasticity as shown by the creep and stress relaxation behavior over time

Similarly, for applied shear stress, which is a function of time, Eq 24 is replaced by:

$$\varepsilon_{12}(t) = \tfrac{1}{2} g(t)\sigma_{12}(0) + \tfrac{1}{2}\int_0^t g(t-t')\frac{d\sigma_{12}}{dt'}dt' \qquad \text{(Eq 26)}$$

The viscoelastic counterpart of the Young's modulus is obtained by subjecting a cylindrical specimen to axial strain ϵconstant in space and time. Then:

$$\sigma_{11}(t) = E(t)\varepsilon_{11}^{0} \qquad \text{(Eq 27)}$$

and $E(t)$ is the Young's relaxation modulus. If the specimen is subjected to axial stress σ_{11}^{0}constant in space and time, then:

$$\varepsilon_{11}(t) = e(t)\sigma_{11}^{0} \qquad \text{(Eq 28)}$$

and $e(t)$ is the Young's creep compliance (Fig. 6).

Obviously $E(t)$ is related to K and $G(t)$, and $e(t)$ is related to k and $g(t)$. The relations are not simple (Ref 18). To write the viscoelastic stress- strain relations for general states of three-dimensional stress and strain, it is customary to separate stress and strain into isotropic (or hydrostatic) and deviatoric parts. Thus:

$$\sigma_{ij} = \sigma\delta_{ij} + S_{ij} \qquad \sigma = \tfrac{1}{3}(\sigma_{11} + \sigma_{22} + \sigma_{33})$$

$$\varepsilon_{ij} = \varepsilon\delta_{ij} + e_{ij}$$

$$\varepsilon = \tfrac{1}{3}(\varepsilon_{11} + \varepsilon_{22} + \varepsilon_{33}) \quad \text{(Eq 29)}$$

where *ij* represents range indices varying from 1 to 3. Then:

$$\sigma(t) = 3K\varepsilon(t)$$
$$S_{ij}(t) = 2G(t)e_{ij}(0) + 2\int_o^t G(t-t')\frac{\partial e_{ij}}{\partial t'}dt' \quad \text{(Eq 30)}$$
$$e_{ij}(t) = \tfrac{1}{2}g(t)s_{ij}(0) + \frac{1}{2}\int_o^t g(t-t')\frac{\partial s_{ij}}{\partial t'}dt'$$

where S_{ij} represents the deviatoric stress components.

The problem is to evaluate the effective viscoelastic properties of a UDC in terms of polymeric matrix viscoelastic properties and the elastic properties of the fibers. (It is assumed that the fibers themselves do not experience any time- dependent effect.) This problem has been resolved in general fashion in Ref 19 and 20, which show that the Laplace transforms of the effective relaxation moduli and creep compliances of a composite can be written in terms of expressions for effective elastic moduli in which elastic matrix properties are replaced by Laplace transforms of viscoelastic matrix properties. The main difficulty is the inversion of these Laplace transforms into the time domain. Details and applications of such procedures are given in Ref 2. Only some simple illustrative cases are presented here.

Detailed analysis shows that the viscoelastic effect in a UDC is significant only for axial shear, transverse shear, and transverse uniaxial stress. For any of average strains $\overline{\epsilon}_{22}$, $\overline{\epsilon}_{23}$, and $\overline{\epsilon}_{12}$ constant in time, thus stress relaxation, the time- dependent stress responses will be, respectively:

$$\bar{\sigma}_{22}(t) = E_T^*(t)\bar{\varepsilon}_{22}$$
$$\bar{\sigma}_{23}(t) = 2G_T^*(t)\bar{\varepsilon}_{23} \quad \text{(Eq 31)}$$
$$\bar{\sigma}_{12}(t) = 2G_L^*(t)\bar{\varepsilon}_{12}$$

For any of stresses $\overline{\sigma}_{22}$, $\overline{\sigma}_{23}$, and $\overline{\sigma}_{12}$ constant in time, thus creep deformation, the time-dependent strain responses will be, respectively:

$$\bar{\varepsilon}_{22}(t) = e_T^*(t)\bar{\sigma}_{22}$$
$$\bar{\varepsilon}_{23}(t) = \tfrac{1}{2}g_T^*(t)\bar{\sigma}_{23} \quad \text{(Eq 32)}$$
$$\bar{\varepsilon}_{12}(t) = \tfrac{1}{2}g_L^*(t)\bar{\sigma}_{12}$$

where the material properties in Eq 31 are effective relaxation moduli and the properties in Eq 32 are associated effective creep functions. All other effective properties may be considered elastic. This implies in particular that if a fiber composite is subjected to stress $\overline{\sigma}_{11}(t)$ in the fiber direction, then:

$$\bar{\sigma}_{11}(t) \cong E_L^*\bar{\varepsilon}_{11}(t)$$
$$\varepsilon_{22}(t) = \bar{\varepsilon}_{33}(t) \sim -\nu_L^*\bar{\varepsilon}_{11}(t) \quad \text{(Eq 33)}$$

where E_L^* and ν_L^* are the elastic results (Eq 4 and 5) with matrix properties taken as initial (elastic) matrix properties. Similar considerations apply to the relaxation modulus k^*.

The simplest case of the viscoelastic properties entering into Eq 31 and 32 is the relaxation modulus $G_L^*(t)$ and its associated creep compliance, $g_L^*(t)$. A simple result has been obtained for fibers that are infinitely more rigid than the matrix (Ref 2). In this case, the elastic result (Eq 6) reduces to:

$$G_L^* = G_m\frac{1+V_f}{1-V_f}$$

For a viscoelastic matrix, the corresponding results are:

$$G_L^*(t) = G_m(t)\frac{1+V_f}{1-V_f}$$
$$g_L^*(t) = g_m(t)\frac{1-V_f}{1+V_f} \quad \text{(Eq 34)}$$

This result is an acceptable approximation for glass fibers in a polymeric matrix and an excellent approximation for boron fibers in a polymeric matrix. However, it is not applicable to carbon or graphite fibers in a polymeric matrix, since the axial shear modulus of these fibers is not large enough in relation to the matrix shear modulus to justify rigid-fiber approximation. In this case, it is necessary to use the correspondence principle previously mentioned. Laplace transform inversion can be carried out by representing the matrix in terms of a viscoelastic spring-dashpot model (see Ref 2 and 19). The situation for transverse shear is more complicated and involves complicated Laplace transform inversion (Ref 20).

All polymeric matrix viscoelastic properties, such as creep and relaxation functions, are significantly temperature dependent. If this temperature dependence is known, all of the results given in this section can be obtained for the temperature of interest by introducing into the results matrix properties at that temperature.

At elevated temperatures, the viscoelastic behavior of the polymeric matrix may become nonlinear. In this event, the UDC will also be nonlinearly viscoelastic and all the results given are not valid. The problem of analytical determination of nonlinear properties is, of course, much more difficult than the linear problem. Some results are given in Ref 21.

Conduction and Moisture Diffusion

The conductivity of a UDC implies both thermal and electrical conductivity. Because all of the conductivity problems are governed by the similar equations, the results obtained also apply to dielectric and magnetic properties and to steady-state moisture diffusion. The various equivalent physical quantities in these different areas are listed in Table 2. The language of thermal conductivity will be used in the following discussion.

Table 2 Equivalent physical quantities

Physical subject	T	$H=-\Delta T$	D	μ_{ij}	ξ_{ij}
Thermal	Temperature	Temperature	Heat flux	Heat conductivities	**Resistivities**

conduction		gradient			
Electric conduction	Electric potential	Electric field intensity	Current density	Electric conductivities	**Resistivities**
Electrostatics	Electric potential	Electric field intensity	Electric induction, electric displacement	Dielectric constants, permittivities	
Magnetostatics	Magnetic potential	Magnetic field intensity	Magnetic induction	Magnetic permeabilities	
Moisture diffusion	**Concentration**	**Moisture gradient**	**Moisture flux**	**Diffusivities**	

Let $T(x)$ be a steady-state temperature field in a homogeneous body. The temperature gradient is given by:

$$H_i = \frac{\partial T}{-\partial x_i} \qquad \text{(Eq 35)}$$

and the heat flux vector by:

$$D_i = \mu_{ij} H_j \qquad \text{(Eq 36)}$$

where μ_{ij} is the conductivity tensor. The inverse of Eq 36 is:

$$H_i = \xi_{ij} D_j \qquad \text{(Eq 37)}$$

where ξ_{ij} is the resistivity tensor. In an isotropic material:

$$D_i = \mu H_i$$
$$H_i = \xi D_i \qquad \text{(Eq 38)}$$
$$\xi = 1/\mu$$

For a transversely isotropic material, such as carbon and graphite fibers with x_1, the axis of transverse isotropy (fiber axis):

$$D_1 = \mu_L H_1$$
$$D_2 = \mu_T H_2 \qquad \text{(Eq 39)}$$
$$D_3 = \mu_T H_3$$

where μ_L is longitudinal conductivity and μ_T is transverse conductivity.

A simple, common example is heat conduction through a slab whose faces are maintained at different temperatures, T and $T+\Delta T$. Then:

$$H_1 = -\frac{\Delta T}{h}$$
$$D_1 = \mu_{11} H_1$$

where h is the slab thickness and μ_{11} is the conductivity coefficient normal to the faces of the slab.

Because a UDC is statistically transversely isotropic, it has two different effective conductivities, μ^*_L in the fiber direction and μ^*_T transverse to the fibers. The effective constituent relations are analogous to Eq 39:

$$\overline{D}_1 = \mu^*_L \overline{H}_1$$
$$\overline{D}_2 = \mu^*_T \overline{H}_2 \qquad \text{(Eq 40)}$$
$$\overline{D}_3 = \mu^*_T \overline{H}_3$$

where overbars denote averages over the representative volume element (RVE).

It can be shown (Ref 2) that for isotropic matrix and fibers, the axial conductivity μ^*_L is given by:

$$\mu^*_L = \mu_m V_m + \mu_f V_f \qquad \text{(Eq 41)}$$

and for transversely isotropic fibers:

$$\mu_L^* = \mu_m V_m + \mu_{Lf} V_f \quad \text{(Eq 42)}$$

where μ_{Lf} is the longitudinal conductivity of the fibers. The results (Eq 41 and 42) are valid for any fiber distribution and any fiber cross section.

The problem of transverse conductivity is mathematically analogous to the problem of longitudinal shearing (Ref 2). It follows that all results for the effective longitudinal shear modulus, G_L^*, can be interpreted as results for transverse effective conductivity, μ_T^*. In particular, for the CCA model:

$$\mu_T^* = \mu_m \left[\frac{\mu_m V_m + \mu_f (1 + V_f)}{\mu_m (1 + V_f) + \mu_f V_m} \right] = \mu_m + \frac{V_f}{1/(\mu_f - \mu_m) + V_m / 2V_m} \quad \text{(Eq 43)}$$

These results are for isotropic fibers. For carbon and graphite fibers, μ_f should be replaced by the transverse conductivity of the fibers, μ_{Tf} (Ref 9).

As in the elastic case, there is reason to believe that Eq 43 represents with great accuracy all cases of circular fibers that are randomly distributed and are not in contact. The reason, again, is the numerical coincidence of hexagonal-array numerical analysis results with the number predicted by Eq 43.

To interpret the results for moisture diffusion, the quantity μ_m is interpreted as the diffusivity of the matrix. Because moisture absorption of fibers is negligible, μ_f is set equal to zero. The results are then:

$$\mu_L^* = \mu_m V_m$$
$$\mu_T^* = \mu_m \frac{V_m}{1 + V_f} \quad \text{(Eq 44)}$$

that leads to the interesting relation:

$$\mu_L^* / \mu_T^* = 1 + V_f \quad \text{(Eq 45)}$$

Macromechanics Analysis of Laminate Properties

Introduction

THE PROPERTIES of unidirectional composite (UDC) materials are quite different from those of conventional, metallic materials. The primary difference, from an analytical viewpoint, results from the material anisotropy. The UDC materials typically have exceptional properties in the direction of the reinforcing fibers but poor to mediocre properties perpendicular (transverse) to the fibers. Thus, with the exception of one-dimensionally loaded members (for example, truss members), UDC materials would be expected to perform poorly compared to conventional materials. The problem then is how to obtain maximum advantage from the exceptional fiber directional properties while minimizing the effects of the low transverse properties. One obvious solution is to use the approach taken in the manufacture of plywood.

Plywood consists of layers, or plies, of wood bonded together, with the wood grain in each ply oriented perpendicular to the adjacent plies. With this orientation of the plies of wood, the lesser properties of the wood perpendicular to the grain are augmented by the superior properties in the direction of the wood grain. At the same time, however, the superior properties in the grain direction cannot be fully utilized because of the perpendicular plies.

The bonding of individual UDC plies is used to form laminates. The plies, or laminae, are oriented such that the effective properties of the laminate match the loading environment. Laminate effective material properties are tailored to meet performance requirements through the use of lamination theory.

Lamination theory can be considered a form of structural analysis but can also be used when a structural material is being designed. This adds another level of effort to the design process but allows the structural material to be tailored to match the loadings. Thus, if a 2-to-1 biaxial loading environment is prescribed, the structural laminate can be designed for a 2-to-1 strength. The amount of material is thereby minimized in a way that is not possible with conventional materials.

This article first presents a treatment of UDC stress-strain relations in the forms appropriate for analysis of thin plies of material. The analysis is then developed for an assemblage of plies (laminate), and finally the stress-strain relations for a thin, laminated plate are developed for the case of plate membrane forces and bending moments.

For purposes of structural analysis, it is desirable to represent a laminate by a set of effective stiffnesses, just as a homogeneous plate is defined by its extensional and bending stiffnesses. Accordingly, the calculation of these laminate mechanical properties is defined and illustrated in this article. Also, the analysis is expanded to include treatment of laminate expansion resulting from temperature and moisture changes.

Next, calculations of temperature and moisture distributions through the thickness of a laminate are discussed. With this information and the definition of applied loads or deformations, the stresses in each ply can be calculated. Procedures for doing this are presented.

The sections just described deal with what may be classified as the nondestructive response of the laminate to external load and environment. The next sections address laminate failure resulting from static, cyclic, and impact loading conditions. The final section describes intra- and interlaminar cracking behavior.

Lamina Stress-Strain Relations

A laminate is composed of unidirectionally reinforced laminae oriented in various directions. The elastic stress-strain relations of the lamina are expressed in this article in matrix form using a different notation for elastic properties. With x_1 in the fiber direction, x_2 transverse to the fibers in the plane of the lamina, and x_3 normal to the plane of the lamina, these material properties define the lamina properties:

$$\begin{array}{lllllll} E_1 & = & E_L^* & & \nu_{12} & = & \nu_L^* \\ E_2 & = & E_3 & = E_T^* & \nu_{23} & = & \nu_T^* \\ G_{12} & = & G_L^* & & G_{23} & = & G_T^* \end{array} \qquad \text{(Eq 1)}$$

where E represents Young's modulus of elasticity, ν is Poisson's ratio, G is shear modulus, L is longitudinal, T is transverse, and * represents the effective properties.

Furthermore, the laminae, at this point, are treated as effective, homogeneous, transversely isotropic materials, and the strains are written without overbars. Thus,

$$\begin{Bmatrix} \varepsilon_{11} \\ \varepsilon_{22} \\ \varepsilon_{33} \\ 2\varepsilon_{23} \\ 2\varepsilon_{13} \\ 2\varepsilon_{12} \end{Bmatrix} = \begin{bmatrix} \frac{1}{E_1} & \frac{-\nu_{12}}{E_1} & \frac{-\nu_{12}}{E_1} & 0 & 0 & 0 \\ \frac{-\nu_{12}}{E_1} & \frac{1}{E_2} & \frac{-\nu_{23}}{E_2} & 0 & 0 & 0 \\ \frac{-\nu_{12}}{E_1} & \frac{-\nu_{23}}{E_2} & \frac{1}{E_2} & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{1}{G_{23}} & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{1}{G_{12}} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{1}{G_{12}} \end{bmatrix} \begin{Bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \sigma_{23} \\ \sigma_{13} \\ \sigma_{12} \end{Bmatrix} \qquad \text{(Eq 2)}$$

where ϵ is strain and σ is stress. Account has been taken of the symmetry relations:

$$\frac{\nu_{21}}{E_2} = \frac{\nu_{12}}{E_1} = \frac{\nu_{31}}{E_3} = \frac{\nu_{13}}{E_1} \quad \frac{\nu_{23}}{E_2} = \frac{\nu_{32}}{E_3}$$

It has been common practice in the analysis of laminates to use engineering shear strains rather than tensor shear strains. Thus, the factor of 2 has been introduced into the stress-strain relations of Eq 2.

The most important state of stress in a lamina is plane, that is:

$$\sigma_{13}=\sigma_{23}=\sigma_{33}= 0 \qquad \text{(Eq 3)}$$

because it occurs for both in-plane loading and bending at a sufficient distance from the laminate edges. In this case, Eq 2 reduces to:

$$\begin{Bmatrix} \varepsilon_{11} \\ \varepsilon_{22} \\ 2\varepsilon_{12} \end{Bmatrix} = \begin{bmatrix} \frac{1}{E_1} & \frac{-\nu_{12}}{E_1} & 0 \\ \frac{-\nu_{12}}{E_1} & \frac{1}{E_2} & 0 \\ 0 & 0 & \frac{1}{G_{12}} \end{bmatrix} \begin{Bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{12} \end{Bmatrix} \qquad \text{(Eq 4)}$$

which may be written:

$$\{\varepsilon_\ell\} = [S]\{\sigma_\ell\}$$

where ℓ identifies lamina coordinates, and [S], the compliance matrix, relates the stress and strain components in the principal material directions.

The three relations in Eq 4 relate the in-plane strain components to the three in-plane stress components. For this plane stress state, the three additional strains can be found to be:

$$\varepsilon_{23} = \varepsilon_{13} = 0$$

$$\varepsilon_{33} = -\sigma_{11}\frac{\nu_{13}}{E_1} - \sigma_{22}\frac{\nu_{23}}{E_2}$$

and thus the complete state of stress and strain is determined.

The relations in Eq 4 can be inverted to yield:

$$\{\sigma_\ell\} = [S]^{-1}\{\varepsilon_\ell\} \qquad \text{(Eq 5)}$$

or

$$\{\sigma_\ell\} = [Q]\{\varepsilon_\ell\}$$

where the matrix [Q] is defined as the inverse of the compliance matrix and is known as the reduced lamina stiffness matrix. Its terms can be shown to be given by:

$$[Q] = \begin{bmatrix} Q_{11} & Q_{12} & 0 \\ Q_{12} & Q_{22} & 0 \\ 0 & 0 & Q_{66} \end{bmatrix}$$

$$Q_{11} = \frac{E_1}{\dfrac{E_1 - \nu_{12}^2 E_2}{E_1}}$$

$$Q_{22} = \frac{E_2}{\dfrac{E_1 - \nu_{12}^2 E_2}{E_1}} \qquad \text{(Eq 6)}$$

$$Q_{12} = \frac{\nu_{12} E_2}{\dfrac{E_1 - \nu_{12}^2 E_2}{E_1}}$$

$$Q_{66} = G_{12}$$

The notation used for the [Q] matrix follows from the simplified engineering representation of the fourth-rank stiffness tensor. Each pair of subscripts of the stiffness components is replaced by a single subscript according to the scheme:

11 → 1 22 → 2 33 → 3

23 → 4 31 → 5 12 → 6

The reduced stiffness and compliance matrices, Eq 6 and 4, relate stresses and strains in the principal material directions of the material. To define the material response in directions other than these material coordinates, transformation relations must be developed for the material stiffnesses.

In Fig. 1, two sets of coordinate systems are shown. The 1-2 coordinate system corresponds to the principal material directions for a lamina, while the *x*-*y* coordinates are arbitrary and are related to the 1-2 coordinates through a rotation about the axis out of the plane of the figure. The angle, θ, is defined as the rotation from the arbitrary *x*-*y* system to the material 1-2 system (θ is positive for a counterclockwise rotation).

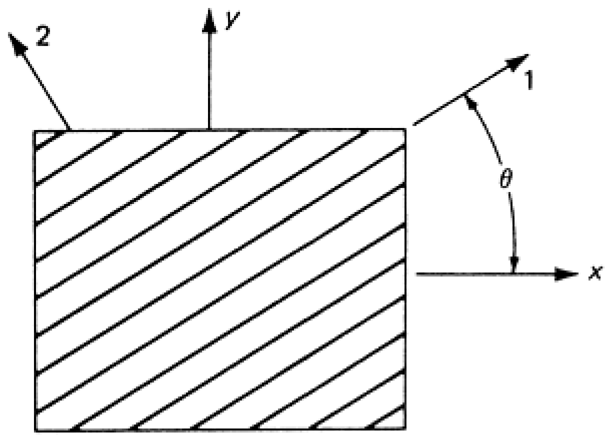

Fig. 1 Coordinate systems; 1, 2, principal material coordinates; *x*, *y*, laminate or arbitrary coordinates

The transformation of stresses from the 1-2 system to the *x*-*y* system follows the rules for transformation of tensor components. Thus:

$$\begin{Bmatrix}\sigma_{xx}\\ \sigma_{yy}\\ \sigma_{xy}\end{Bmatrix}=\begin{bmatrix}m^2 & n^2 & -2mn\\ n^2 & m^2 & 2mn\\ mn & -mn & m^2-n^2\end{bmatrix}\begin{Bmatrix}\sigma_{11}\\ \sigma_{22}\\ \sigma_{12}\end{Bmatrix} \quad \text{(Eq 7)}$$

or

$$\{\sigma_x\}=[\theta]\{\sigma_\ell\}$$

where m= cos θ and n= sin θ. In these relations, the subscript x is used to refer to the laminate coordinate system.

The same transformation matrix [θ] can also be used for the tensor strain components. However, since the engineering shear strains have been used, a different transformation matrix is required. Thus:

$$\begin{Bmatrix}\varepsilon_{xx}\\ \varepsilon_{yy}\\ 2\varepsilon_{xy}\end{Bmatrix}=\begin{bmatrix}m^2 & n^2 & -mn\\ n^2 & m^2 & mn\\ 2mn & -2mn & m^2-n^2\end{bmatrix}\begin{Bmatrix}\varepsilon_{11}\\ \varepsilon_{22}\\ 2\varepsilon_{12}\end{Bmatrix} \quad \text{(Eq 8)}$$

or

$$\{\varepsilon_x\}=[\psi]\{\varepsilon_\ell\}$$

where [ψ] is now the transformation matrix.

Given the transformations for stress and strain to arbitrary coordinate systems, the relations between stress and strain in the laminate system can be determined. Substituting Eq 7 and 8 into Eq 5 yields:

$$\{\sigma_x\}=[\bar{Q}]\{\varepsilon_x\} \quad \text{(Eq 9)}$$

The reduced-stiffness matrix, [$\overline{Q}$], relates the stress and strain components in the laminate coordinate system. Here:

$$\left[\bar{Q}\right]=[\theta][Q][\psi]^{-1} \quad \text{(Eq 10)}$$

The terms within [$\overline{Q}$] are defined by the appropriate matrix multiplication to be:

$$
\begin{aligned}
\bar{Q}_{11} &= Q_{11}m^4 + Q_{22}n^4 + 2m^2n^2(Q_{12} + 2Q_{66}) \\
\bar{Q}_{12} &= m^2n^2(Q_{11} + Q_{22} - 4Q_{66}) + (m^4 + n^4)Q_{12} \\
\bar{Q}_{16} &= [Q_{11}m^2 - Q_{22}n^2 - (Q_{12} + 2Q_{66})(m^2 - n^2)]mn \\
\bar{Q}_{22} &= Q_{11}n^4 + Q_{22}m^4 + 2m^2n^2(Q_{12} + 2Q_{66}) \\
\bar{Q}_{26} &= [Q_{11}n^2 - Q_{22}m^2 + (Q_{12} + 2Q_{66})(m^2 - n^2)]mn \\
\bar{Q}_{66} &= (Q_{11} + Q_{22} - 2Q_{12})m^2n^2 + Q_{66}(m^2 - n^2)^2 \\
\bar{Q}_{21} &= \bar{Q}_{12} \\
\bar{Q}_{61} &= \bar{Q}_{16}\bar{Q}_{62} = \bar{Q}_{26}
\end{aligned}
\qquad \text{(Eq 11)}
$$

where the subscript 6 has been retained in keeping with the discussion following Eq 6. Thus:

$$
[\bar{Q}] = \begin{bmatrix} \bar{Q}_{11} & \bar{Q}_{12} & \bar{Q}_{16} \\ \bar{Q}_{21} & \bar{Q}_{22} & \bar{Q}_{26} \\ \bar{Q}_{16} & \bar{Q}_{26} & \bar{Q}_{66} \end{bmatrix} \qquad \text{(Eq 12)}
$$

A feature of the [$\bar{Q}$] matrix that is immediately noticed as being dissimilar to previous constitutive relations is that [$\bar{Q}$] is fully populated. The additional terms that have appeared in [$\bar{Q}$], namely, $\bar{Q}_{16}$ and $\bar{Q}_{26}$, relate shear strains to extensional loading and vice versa. This effect of a shear strain resulting from an extensional stress is shown in Fig. 2.

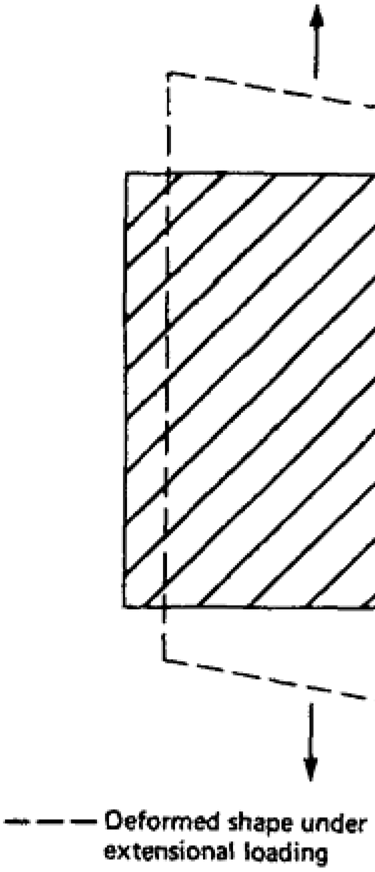

Fig. 2 Extensional-shear coupling

Referring to Eq 11, each of the extensional- shear coupling terms can be seen to contain a sine-cosine multiplier term. Obviously, if either sin θ or cos θ is zero, the extensional-shear coupling terms are zero. For the product sin θ cos θ to be zero, the angle θ must be 0° or 90°. Physically, this means that the fibers are either parallel or

perpendicular to the loading direction. For this case, extensional shear coupling does not occur in an orthotropic material, because the loadings are in the principal material directions (Eq 4).

The procedure used to develop the transformed stiffness matrix can also be used to find a transformed compliance matrix. Thus:

$$\{\varepsilon_\ell\} = [S]\{\sigma_\ell\}$$
$$\{\varepsilon_x\} = [\psi][S][\theta]^{-1}\{\sigma_x\} \qquad \text{(Eq 13)}$$
$$\{\varepsilon_x\} = [\bar{S}]\{\sigma_x\}$$

The relations between the terms in [$\bar{S}$] and [S] are developed by a procedure identical to that for the relations between [$\bar{Q}$] and [Q].

With the stress-strain relations now defined in the laminate coordinate system, lamina stiffnesses can also be defined in this system. Thus, expanding the last of Eq 13 yields:

$$\begin{Bmatrix} \varepsilon_{xx} \\ \varepsilon_{yy} \\ 2\varepsilon_{xy} \end{Bmatrix} = \begin{bmatrix} \bar{S}_{11} & \bar{S}_{12} & \bar{S}_{16} \\ \bar{S}_{21} & \bar{S}_{22} & \bar{S}_{26} \\ \bar{S}_{16} & \bar{S}_{26} & \bar{S}_{66} \end{bmatrix} \begin{Bmatrix} \sigma_{xx} \\ \sigma_{yy} \\ \sigma_{xy} \end{Bmatrix}$$

The engineering constants for the material can be defined by specifying the conditions for an experiment. Thus, the ratio $\sigma_{xx}/\epsilon_{xx}$, for $\sigma_{yy}=\sigma_{xy}= 0$, is the Young's modulus in the x direction. For this same stress state, $-\epsilon_{yy}/\epsilon_{xx}$ is Poisson's ratio. In this way, the lamina stiffnesses in the coordinate system of Eq 13 are found to be:

$$E_x = \frac{1}{\bar{S}_{11}}$$
$$E_y = \frac{1}{\bar{S}_{22}}$$
$$G_{xy} = \frac{1}{\bar{S}_{66}} \qquad \text{(Eq 14)}$$
$$\nu_{xy} = -\frac{\bar{S}_{21}}{\bar{S}_{11}} = -\frac{\bar{S}_{12}}{\bar{S}_{11}}$$

It is sometimes desirable to obtain elastic constants directly from the reduced stiffnesses, [$\bar{Q}$], by utilizing Eq 9. In the general case where the $\bar{Q}_{ij}$ matrix is fully populated, this can be accomplished by using Eq 14 and the solution for $\bar{S}_{ij}$ as functions of $\bar{Q}_{ij}$ obtained from the inverse relationship of the two matrices. Another approach is to evaluate extensional properties for the case of zero shear strain, $\epsilon_{xy}= 0$, as opposed to the previous case of zero shear stress, $\sigma_{xy}= 0$. For single stress states and zero shear strain it is found that, in terms of the transformed stiffness matrix terms (Eq 12), the elastic constants are:

$$E_x = \bar{Q}_{11} - \frac{\bar{Q}_{12}^2}{\bar{Q}_{22}}$$
$$E_y = \bar{Q}_{22} - \frac{\bar{Q}_{12}^2}{\bar{Q}_{11}} \qquad \text{(Eq 15)}$$
$$\nu_{xy} = \frac{\bar{Q}_{12}}{\bar{Q}_{22}} = \frac{\bar{Q}_{21}}{\bar{Q}_{22}}$$

Also:

$$G_{xy} = \bar{Q}_{66}$$

Referring to the terms in the [$\overline{Q}$] matrix (Eq 11) and the stiffness relations (Eq 15), it can be seen that, in general, the elastic constants in an arbitrary coordinate system are functions of all of the elastic constants in the principal material directions as well as the angle of rotation.

The variation of elastic modulus E_x with angle of rotation is shown in Fig. 3 for a typical graphite-epoxy material. For demonstration purposes, two different shear moduli have been used in generating the figure. The differences between the two curves demonstrate the effect of the principal material shear modulus on the transformed extensional stiffness. The two curves are identical at θ= 0° and θ= 90°. This is to be expected, because at these angles, the extensional stiffness, E_x, is simply E_1 or E_2. Between the two end points, substantial differences exist. For the smaller shear modulus, from approximately 50° to just less than 90°, the extensional stiffness is less than the E_2 value. This is a most interesting result, indicating that for these angles, the material stiffness is governed more strongly by the principal material shear modulus than by the transverse extensional stiffness.

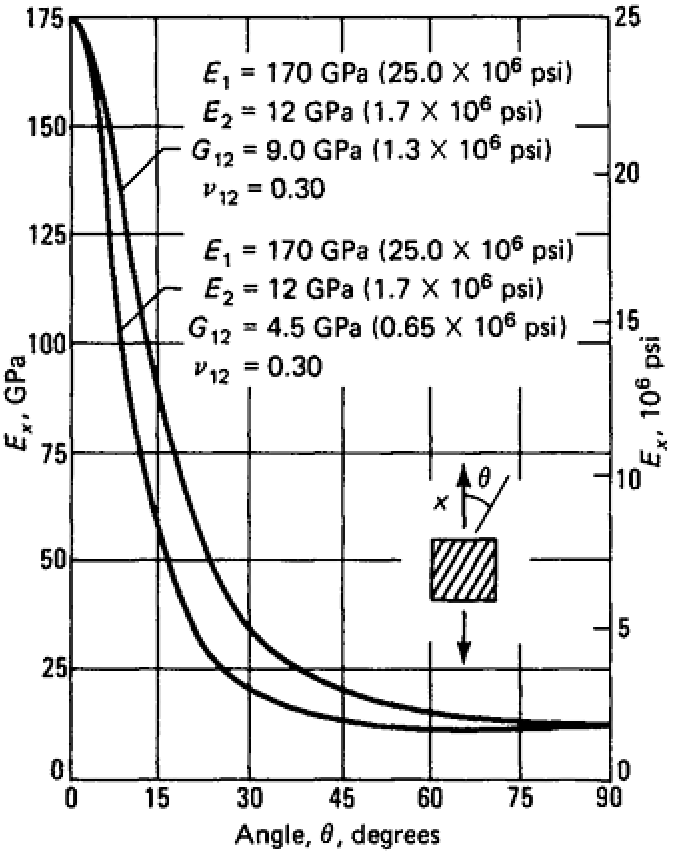

Fig. 3 Variation of E_x with angle of rotation and G_{12} for typical graphite-epoxy materials

The curves of Fig. 3 can also be used to determine the modulus E_y, simply by reversing the angle scale. Thus, the values shown at 0° correspond to E_y at 90° and the values at 90° correspond to E_y at 0°.

With the transformed stress-strain relations, it is now possible to develop an analysis for an assemblage of plies, that is, a laminate.

Macromechanics Analysis of Laminate Properties

Lamination Theory

The development of procedures to evaluate stresses and deformations of laminates is crucially dependent on the fact that the thickness of laminates is so much smaller than the in-plane dimensions. Typical thickness values for individual plies range between 0.15 and 0.25 mm (0.005 and 0.010 in.). Consequently, aerospace laminates

using from 8 to 50 plies are generally still thin plates and therefore can be analyzed on the basis of the usual simplifications of thin-plate theory.

Analysis of isotropic thin plates is an old, established field in which in-plane loading and bending are usually analyzed separately. The former is described by plane stress elastic theory, and the latter is described by classical plate- bending theory. This separation is possible because the two loadings are uncoupled; when both occur, the result is given by superposition. In the case of anisotropic laminates, in-plane loading and bending are generally coupled and must be treated together. It is only for symmetric laminae stacking sequences that uncoupling occurs. Consequently, lamination theory will be developed first for the general case, and simplifications will then be introduced.

The classical assumptions of thin-plate theory are:

- The thickness of the plate is much smaller than the in-plane dimensions.
- The strains in the deformed plate are small compared to unity.
- Normals to the undeformed plate surface remain normal to the deformed plate surface.
- Vertical deflection does not vary through the thickness.
- Stress normal to the plate surface is negligible.

On the basis of the second, third, and fourth assumptions, the displacement field in the plate, *u*, can be expressed as:

$$u_z = u_z^0(x, y)$$
$$u_x = u_x^0(x, y) - z\frac{\partial u_z}{\partial x} \qquad \text{(Eq 16)}$$
$$u_y = u_y^0(x, y) - z\frac{\partial u_z}{\partial y}$$

with the *x*-*y*-*z* coordinate system defined as in Fig. 4. These relations (Eq 16) indicate that the in-plane displacements consist of a midsurface displacement, designated by the superscript 0, plus a linear variation through the thickness. The two partial derivatives are simply bending rotations of the midsurface. The use of the fourth assumption prescribes that u_z not vary through the thickness. The *z* coordinate is measured from the midsurface of the plate. This is a natural convention for a laminate that is symmetrically stacked with reference to the midsurface but an arbitrary one when this is not the case.

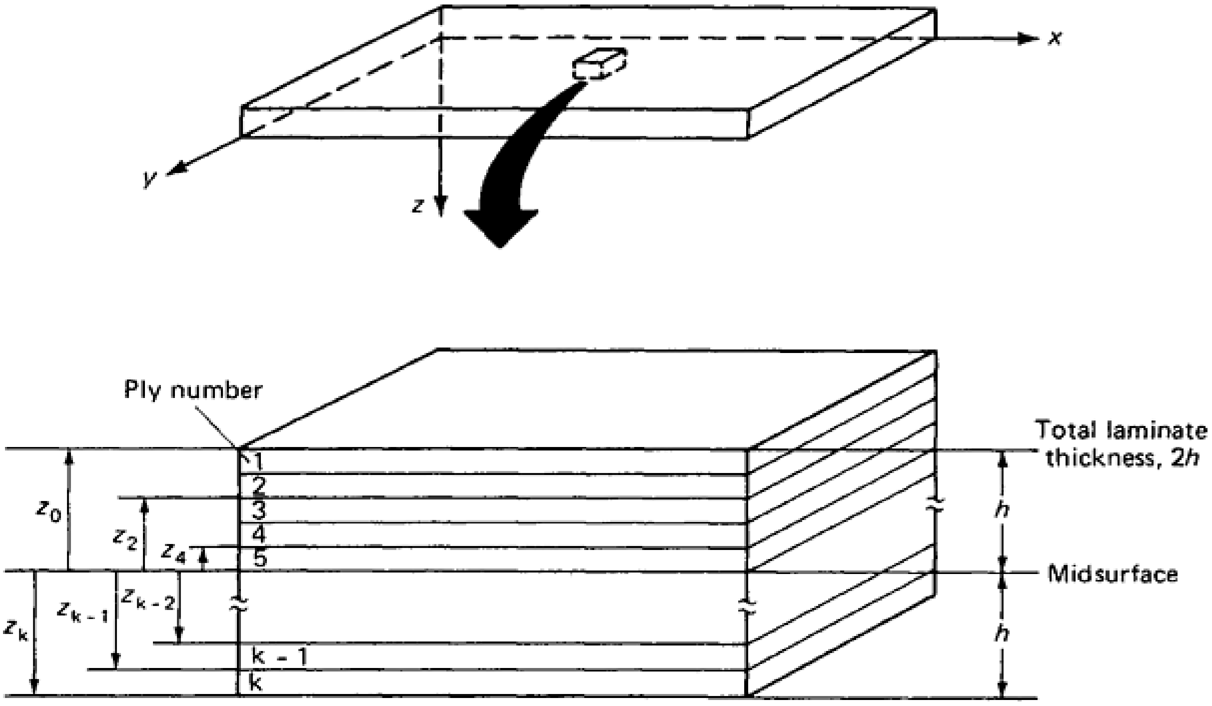

Fig. 4 Laminate construction

The linear strain displacement relations are:

$$\varepsilon_{xx} = \frac{\partial u_x}{\partial x}$$
$$\varepsilon_{yy} = \frac{\partial u_y}{\partial y} \qquad \text{(Eq 17)}$$
$$\varepsilon_{xy} = \frac{1}{2}\left(\frac{\partial u_x}{\partial y} + \frac{\partial u_y}{\partial x}\right)$$

Performing the required partial differentiations yields:

$$\varepsilon_{xx} = \varepsilon^{\mathbf{0}}_{xx} + z\kappa_{xx}$$
$$\varepsilon_{yy} = \varepsilon^{\mathbf{0}}_{yy} + z\kappa_{yy} \qquad \text{(Eq 18)}$$
$$2\varepsilon_{xy} = 2\varepsilon^{\mathbf{0}}_{xy} + 2z\kappa_{xy}$$

or

$$\{\varepsilon_x\} = \{\varepsilon^0\} + z\{\kappa\}$$

where

$$\{\varepsilon^0\} = \begin{Bmatrix} \dfrac{\partial u_x^0}{\partial x} \\ \dfrac{\partial u_y^o}{\partial_y} \\ \left(\dfrac{\partial y_x^o}{\partial y} + \dfrac{\partial u_y^0}{\partial x}\right) \end{Bmatrix} \qquad \text{(Eq 19)}$$

and

$$\{\kappa\} \equiv \begin{Bmatrix} \kappa_{xx} \\ \kappa_{yy} \\ 2\kappa_{xy} \end{Bmatrix} = \begin{Bmatrix} -\dfrac{\partial^2 u_z}{\partial x^2} \\ -\dfrac{\partial^2 u_z}{\partial y^2} \\ -2\dfrac{\partial^2 u_z}{\partial x \partial y} \end{Bmatrix} \qquad \text{(Eq 20)}$$

Thus, the strain at any point in the plate is defined as the sum of a midsurface strain, $\{\epsilon^0\}$, and a curvature, $\{\kappa\}$, multiplied by the distance from the midsurface.

For convenience, as is usual in plate theory, stress and moment resultants will be used rather than stresses for the remainder of the development (Fig. 5). The stress resultants, *N*, are defined as:

$$\{N\} = \begin{Bmatrix} N_{xx} \\ N_{yy} \\ N_{xy} \end{Bmatrix} = \int_{-h}^{h} \{\sigma_x\} dz \qquad \text{(Eq 21)}$$

and the moment resultants, *M*, are defined as:

$$\{M\} = \begin{Bmatrix} M_{xx} \\ M_{yy} \\ M_{xy} \end{Bmatrix} = \int_{-h}^{h} \{\sigma_x\} z\mathrm{d}z \qquad \text{(Eq 22)}$$

where the integrations are carried out over the plate thickness, 2*h*.

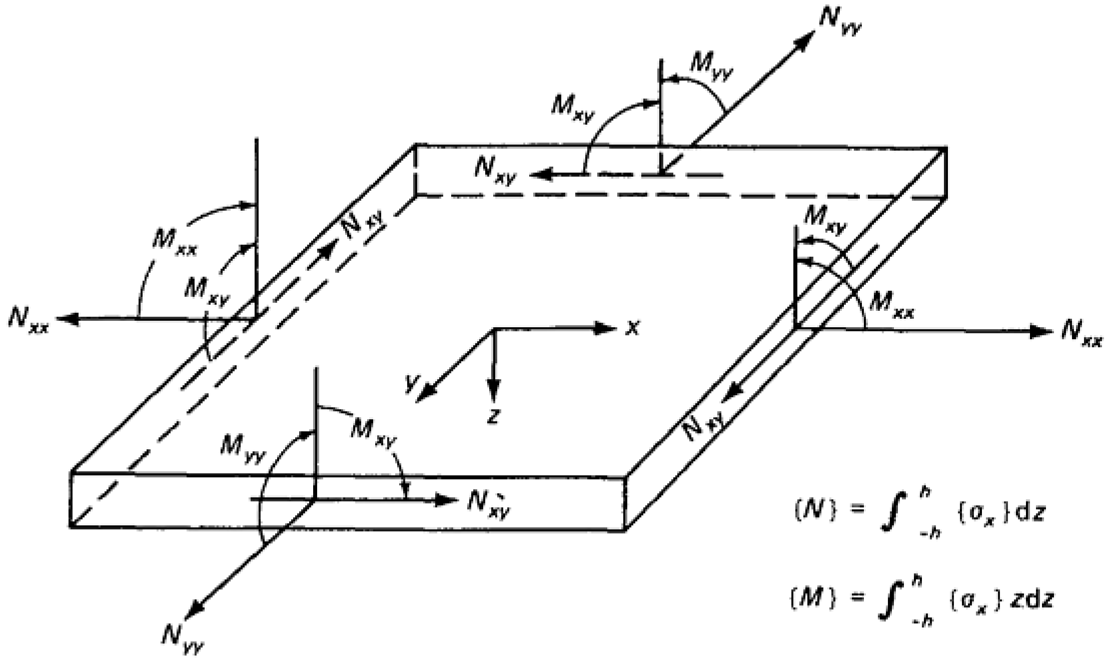

Fig. 5 Stress and moment resultants

Noting Eq 9 and 18, relations between the stress and moment resultants and the midplane strains and curvatures can be written as:

$$\{N\} = \int_{-h}^{h} \{\sigma_x\}\mathrm{d}z = \int_{-h}^{h} \left[\bar{Q}\right](\{\varepsilon^0\} + z\{\kappa\})\mathrm{d}z \qquad \text{(Eq 23)}$$

$$\{M\} = \int_{-h}^{h} \{\sigma_x\}z\mathrm{d}z = \int_{-h}^{h} \left[\bar{Q}\right](\{\varepsilon^0\} + z\{\kappa\})z\mathrm{d}z \qquad \text{(Eq 24)}$$

Since the transformed lamina stiffness matrices are constant within each lamina and the midplane strains and curvatures are constant with respect to the *z* coordinate, the integrals in Eq 23 and 24 can be replaced by summations, Σ, over the total number of plies.

Introducing three matrices equivalent to the needed summations, the relations can be written as:

$$\{N\}=[A]\{\epsilon^0\}+[B]\{\kappa\}$$

$$\{M\}=[B]\{\epsilon^0\}+[D]\{\kappa\}$$

or

$$\left\{\frac{N}{M}\right\} = \begin{bmatrix} A & B \\ B & D \end{bmatrix} \left\{\frac{\varepsilon^0}{\kappa}\right\} \qquad \text{(Eq 25)}$$

where the stiffness matrix is composed of the following 3 by 3 matrices:

$$[A]=\sum_{i=1}^{K}\left[\bar{Q}\right]^{i}(z_i - z_{i-1})$$

$$[B]=\frac{1}{2}\sum_{i=1}^{K}\left[\bar{Q}\right]^{i}(z_i^2 - z_{i-1}^2) \quad \text{(Eq 26)}$$

$$[D]=\frac{1}{3}\sum_{i=1}^{K}\left[\bar{Q}\right]^{i}(z_i^3 - z_{i-1}^3)$$

where K is the total number of plies, z_i is defined as in Fig. 4, and superscript i denotes a property of the ith ply. Note that $z_i - z_{i-1}$ is equal to the ply thickness. Here the reduced lamina stiffnesses for the ith ply are found from Eq 11 using the principal ply properties and orientation angle of each ply in turn. Thus, the constitutive relations for a laminate in terms of stress and moment resultants have been developed.

In examining the relations (Eq 25), the first interesting feature revealed is a coupling between bending and extension. The [*B*] matrices relate stress resultants to bending curvatures and moment resultants to midplane strains. Thus, for a general laminate, the application of a stress resultant produces curvatures, and application of a bending moment produces extensional strain. The feature is known as bending-extensional coupling.

In typical structural laminates, bending-extensional coupling is eliminated by proper specification of the stacking sequence. Stacking sequence refers to the order in which the various plies are put together. From the relations for computing the [*B*] matrix (Eq 26), it can be seen that if the plies are arranged in an even z function (symmetric about the midplane), the [*B*] matrix is eliminated. Thus, if the laminate is designed with identically oriented plies at equal distances from the midsurface, bending-extensional coupling is eliminated.

Other forms of coupling are inherent in the relations (Eq 25). To examine these couplings, it is necessary to evaluate individual terms in the [*A*], [*B*], and [*D*] matrices. The most general form of these matrices, combined as in Eq 25, is:

$$\begin{bmatrix} A_{11} & A_{12} & A_{16} & B_{11} & B_{12} & B_{16} \\ A_{21} & A_{22} & A_{26} & B_{21} & B_{22} & B_{26} \\ A_{16} & A_{26} & A_{66} & B_{16} & B_{26} & B_{66} \\ B_{11} & B_{12} & B_{16} & D_{11} & D_{12} & D_{16} \\ B_{21} & B_{22} & B_{26} & D_{21} & D_{22} & D_{26} \\ B_{16} & B_{26} & B_{66} & D_{16} & D_{26} & D_{66} \end{bmatrix}$$

In general, the [*A*], [*B*], and [*D*] matrices are fully populated. Thus, there is coupling between membrane extension and membrane shear (A_{16}, A_{26}) and between bending and twisting (D_{16}, D_{26}). Both of these forms of coupling can be eliminated by judicious ply orientation and stacking sequence selection, but in some cases this selection may be impractical. Extensional- shear coupling can be eliminated by specifying a balanced construction. Balance indicates that for every +θ ply, there is a–θ ply. These plies do not have to be adjacent to satisfy this requirement.

When bending-twisting coupling is undesirable, it can be eliminated, but only by using a unidirectional or cross-ply construction. Unidirectional construction implies that all layers have the same orientation, which is aligned with the loading direction. A cross-ply laminate has plies oriented at 0° and 90° only, again oriented with the loading direction. It is also possible to limit the effect of bending-twisting coupling by other means. If a symmetric laminate is constructed with many plies, and plies with the same angular orientation are not grouped together, the magnitude of the D_{16} and D_{26} terms will be reduced with respect to the other terms in the [*D*] matrix. Thus, while the bending-twisting coupling is not eliminated, its effect is reduced. In certain applications, such coupling may be desirable.

Laminate Properties

The previous section presented the development of the relations between midsurface strains and curvatures and membrane stress and moment resultants. The elastic stiffnesses in these relationships are functions of the ply elastic constants and the ply orientations and arrangement or stacking sequence. In the present section, these results will be used to calculate plate bending and extensional stiffnesses suitable for use in structural analysis. The effects of orientation variables on plate properties are also discussed.
For practical structures it is necessary to understand not only the mechanical loading conditions but also the effects of temperature changes on laminate behavior. Thus, the thermal expansion characteristics of laminates will be presented. Further, for polymeric matrix composites, high moisture content has been found to cause dimensional changes. This effect is treated in this section to define effective swelling coefficients.
In general, as shown previously, laminates exhibit coupling between bending and extension. Elimination of this coupling was shown to be possible through the specification of midplane symmetric construction. This leads to a natural division of laminates into symmetric and nonsymmetric categories.
Before these two laminate categories are discussed, typical laminate notation is described. A shorthand notation has been devised and is in common use. The basis for the notation comes from the fact that structural laminates typically have repeating groups of plies and pairs of plies at +θ and–θ angles. Using these groupings, the laminate construction

[0°/0°/45°/–45°/90°90°/–45°45°0°0°]

can be specified as:

$$[45°/-45°/0°/0°/90°/0°/0°/-45°/45°]$$

The numerical subscript indicates the number of adjacent identical plies. Adjacent balanced angle plies are lumped together, and the subscript s indicates that the pattern is repeated in reverse order, forming a symmetric laminate. A multiplier subscript is also used to denote multiple groups of plies. Thus, the laminate

[45°/–45°/0°/0°/45°/–45°/0°/0°/0°/0°/

–45°/45°/0°/0°/–45°/45°]

is specified as:

$$\left[\pm 45°/0_2^{\circ}\right]_{2s}$$

When the central ply of a symmetric laminate is not repeated, this is denoted by an overbar. Thus the laminate

[45°/–45°/0°/0°/90°/0°/0°/–45°/45°]

is specified as:

$$\left[\pm 45°/0_2^{\circ}/\overline{90}°\right]_s$$

Additional conventions can be designated, but those shown here are usually sufficient.
Symmetric Laminates. Because a symmetric laminate does not exhibit coupling between extension and bending, the design of composites is considerably simplified because symmetric constructions behave somewhat similarly to conventional materials. Recalling Eq 25 and noting that for this case the [B] matrix is zero, the relations can be rewritten as:

$$\begin{Bmatrix} N_{xx} \\ N_{yy} \\ N_{xy} \end{Bmatrix} = \begin{bmatrix} A_{11} & A_{12} & A_{16} \\ A_{12} & A_{22} & A_{26} \\ A_{16} & A_{26} & A_{66} \end{bmatrix} \begin{Bmatrix} \varepsilon_{xx}^0 \\ \varepsilon_{yy}^0 \\ 2\varepsilon_{xy}^0 \end{Bmatrix} \qquad \text{(Eq 27)}$$

and

$$\begin{Bmatrix} M_{xx} \\ M_{yy} \\ M_{xy} \end{Bmatrix} = \begin{bmatrix} D_{11} & D_{12} & D_{16} \\ D_{12} & D_{22} & D_{26} \\ D_{16} & D_{26} & D_{66} \end{bmatrix} \begin{Bmatrix} \kappa_{xx} \\ \kappa_{yy} \\ 2\kappa_{xy} \end{Bmatrix}$$

Since the extensional and bending behavior are uncoupled, effective laminate elastic constants can be readily determined. Inverting the stress resultant midplane strain relations yields:

$$\{\epsilon^0\}=[A]^{-1}\{N\}=[a]\{N\}$$

$[a]$ is called the elastic compliance matrix from which the laminate elastic constants are seen to be:

$$E_x = \frac{1}{2ha_{11}} \quad G_{xy} = \frac{1}{2ha_{66}}$$
$$E_y = \frac{1}{2ha_{22}} \quad \nu_{xy} = -\frac{a_{12}}{a_{11}} \qquad \text{(Eq 28)}$$

where the divisor $2h$ corresponds to the laminate thickness.

Noting that the $[A]$ matrix consists of $[Q]$ matrices from each layer in the laminate, it is obvious that the laminate elastic properties are functions of the angular orientation of the plies. This is illustrated in Fig. 6 for a typical high- modulus graphite-epoxy system. The lamina properties for this material are listed in Table 1. The laminae are oriented in ±θ pairs in a symmetric, balanced construction, creating what is called an angle-ply laminate.

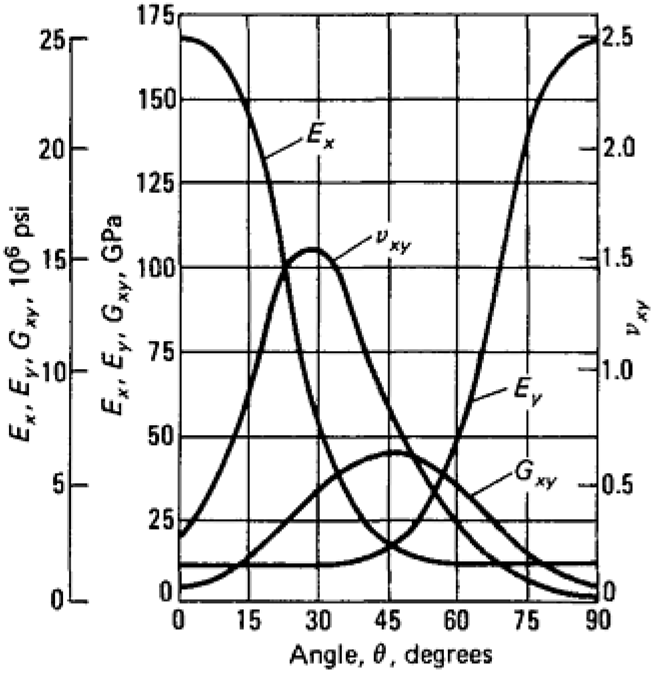

Fig. 6 Laminate elastic constants for high-modulus graphite-epoxy system, $[\pm\theta]_s$

Table 1 Properties of a high-modulus graphite-epoxy lamina

E_1= 170 GPa (25.0 × 10^6 psi)
E_2= 12 GPa (1.7 × 10^6 psi)
G_{12}= 4.5 GPa (0.65 × 10^6 psi)
ν_{12}= 0.30
ρ= 0.056
α_1=–0.54 × 10^{-6}/K
α_2= 35.1 × 10^{-6}/K
σ_L^{tu} = 758 MPa (110.0 ksi)
σ_T^{tu} = 28 MPa (4.0 ksi)
σ_L^{u}= 62 MPa (9.0 ksi)
σ_L^{cu} = 758 MPa (110.0 ksi)
σ_T^{cu} = 138 MPa (20.0 ksi)
V_f= 0.6

Note: Ply thickness, 0.13 mm (0.0052 in.)

Figure 6 indicates a variation in extensional modulus similar to that shown for the off-axis unidirectional material (Fig. 3). The differences between an off-axis material and an angle-ply laminate are due to the effects of extensional- shear coupling. In an off-axis material, extensional loadings produce shear deformations as well as extensional deformations. In an angle- ply laminate, the shear deformations are eliminated through internal constraints. Since the shear strains are eliminated, the material exhibits higher effective stiffnesses.

Two other features are noteworthy in Fig. 6, namely, the variation of shear modulus and Poisson's ratio. The shear modulus is equal to the unidirectional value for θ= 0° and θ= 90°; it rises sharply and reaches a maximum at θ= 45°. The peak at 45° can be explained by noting that shear is equivalent to a combined state of equal tension and compression loads oriented at 45°. Thus, the shear loading on a [±45°] laminate is equivalent to tensile and compressive loading on a $[0°/90°]_s$ laminate. Effectively, the fibers are aligned with the loading; hence, the large shear stiffness.

An even more interesting effect is seen in the variation of Poisson's ratio. The peak value in this example is greater than 1.5. In an isotropic material, this would be impossible. In an orthotropic material, the isotropic restrictions do not hold, and a Poisson's ratio greater than one is valid and realistic. In fact, large Poisson's ratios are typical for laminates constructed of UDC materials with the plies oriented at approximately ±30°.

This effect can readily be explained by referring to Fig. 7, which shows two separate loadings on a ±30° lamina. When a positive N_{xx} load is applied, the deformed shape contains a positive ϵ_{xx} and a negative ϵ_{xy}. In the $[\pm 30°]_s$ laminate, the shear strain is constrained by the presence of the–30° plies, causing an internal shear load, which eliminates the shear strain. The large Poisson's ratio is a result of this internal shear load. As shown in the second part of Fig. 7, a compressive N_{yy} load promotes a positive ϵ_{xy}. Because of material symmetries, the application of a positive N_{xy} would produce a compressive ϵ_{yy}. Therefore, the positive internal shear load required to constrain the shear strains developed by the positive N_{xx} in the first part of Fig. 7 produces a compressive ϵ_{yy}. Thus, the Poisson-induced strain is made up of two components: First, the applied tensile N_{xx} produces a compressive ϵ_{yy}, and, second, the induced positive N_{xy} produces a compressive ϵ_{yy}. Thus, the large Poisson's ratio is simply a function of extensional-shear coupling in the individual laminae.

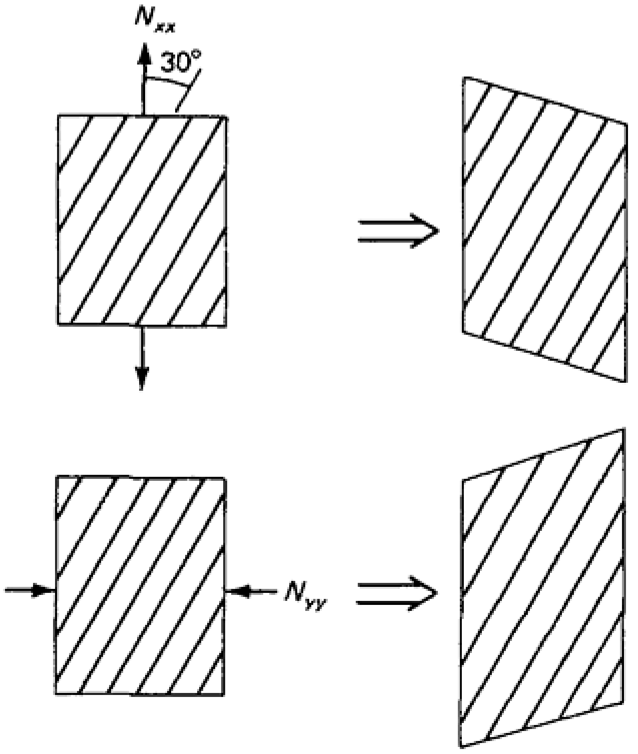

Fig. 7 Extensional-shear coupling and Poisson's ratio

Because of the infinite variability of the angular orientation of the individual laminae, presumably a laminate could be constructed having a stiffness which behaves isotropically in the plane of the laminate by using a large number of plies having small, equal differences in their orientation. It can be shown that a symmetric, quasi-isotropic laminate can also be constructed with as few as six plies, three plies above and three below the midplane. The simplest quasi- isotropic laminate is $[0°/\pm 60°]_s$. A general rule for describing a quasi-isotropic laminate states that the angles between plies are equal to π/N, where N is an integer greater than or equal to 3,

and the number of plies at each orientation is identical, in a symmetric laminate. For plies of a given material, all such quasi-isotropic laminates will have the same elastic properties, regardless of the value of *N*.
As was stated, a quasi-isotropic laminate has in-plane stiffnesses which follow isotropic relationships. Thus:

$$E_x=E_y=E_\theta$$

where the subscript θ indicates any arbitrary angle. Additionally,

$$G_{xy}=\frac{E_x}{2(1+\nu_{xy})}$$

There are two items which must be remembered with respect to quasi-isotropic laminates. First and foremost, only the elastic in-plane properties are isotropic; the strength properties, in general, will vary with direction. The second item is that two equal moduli, $E_x=E_y$, do not necessarily indicate quasi-isotropy. This second item is graphically demonstrated in Table 2 where three laminates each have identical E_x and E_y moduli.

Table 2 Elastic properties of laminates

	E_x E_y		ν_{xy}	G_{xy}	
	GPa	**10^6 psi**		**GPa**	10^6 psi
$[0°/90°]_s$	92.46	13.41	0.038	4.5	**0.65**
$[\pm45°]_s$	16.4	2.38	0.829	44.5	**6.46**
$[0°/90°/+45°/-45°/90°/0°]_s$	**75.64**	**10.97**	**0.213**	**17.9**	**2.59**

Note: See Table 1 for lamina properties.
The first two laminates in Table 2 are actually the same. If one rotates the $[0°/90°]_s$ laminate 45°, it is easily seen that it becomes a $[\pm45°]_s$ laminate. Note that the extensional moduli of these laminates are not the same and that the shear modulus in each laminate is not related to the extensional moduli and Poisson's ratio. For these laminates, the π/N relation has not been satisfied and they are not quasi-isotropic.
The third laminate has plies oriented at 45° to each other, but there are not equal numbers of plies at each angle. This laminate is also not quasi-isotropic. This can be verified by computing a shear modulus using the isotropic relation.
The discussion of symmetric laminates has thus far centered on membrane behavior. It has been shown that symmetric laminates can be constructed that are very well behaved in the membrane sense. The bending behavior of symmetric laminates is considerably more complex, primarily due to the arrangement of the plies throughout the thickness of the laminate.
Unsymmetric Laminates. The use of laminates that are not midplane symmetric introduces some fundamental difficulties for the designer and analyst, the most important being how one defines the membrane and bending stiffnesses of such a material. Because this type of laminate bends when subjected to membrane loading, how is an extensional modulus defined? Conversely, since the material extends when subjected to a bending load, how is a bending stiffness defined?
Basically, there are two approaches to defining these elastic constants. A membrane stiffness can be derived either with zero curvatures or with zero bending moments, and a bending stiffness can be defined with either zero membrane strains or zero membrane forces. In both cases, the stiffness defined will be greater when the bending-extensional coupling is restrained. The nature of the problem can sometimes help the designer determine which approach to use.
In order to define stiffnesses of unsymmetric laminates with constrained bending-extensional coupling, it is necessary to use zero curvatures for extension and zero midplane strains for bending. Writing the full constitutive relations:

$$\{N\}=[A]\{\epsilon^0\}+[B]\{\kappa\}$$
$$\{M\}=[B]\{\epsilon^0\}+[D]\{\kappa\} \qquad \text{(Eq 29)}$$

the extensional stiffness can be found by substituting κ= 0; thus:

$$\{N\}=[A]\{\epsilon^0\} \qquad \text{(Eq 30)}$$

and bending stiffness can be found by substituting $\{\epsilon^0\}=0$.

$$\{M\}=[D]\{\kappa\} \qquad \text{(Eq 31)}$$

The relations shown in Eq 30 and 31 are identical to those used in symmetric laminates; therefore, the constrained stiffnesses are identical to those of symmetric laminates. However, moment resultants are required to develop the zero curvatures in Eq 30, and stress resultants are required to develop the zero midplane strains in Eq 31.

The moment resultants that are developed because of the prescribed zero curvatures can easily be determined. Solving Eq 30 for the resulting midplane strains yields:

$$\{\epsilon^0\}=[A]^{-1}\{N\} \qquad \text{(Eq 32)}$$

Substituting these into Eq 29, while noting that the curvatures are zero, yields:

$$\{M\}=[B]\{\epsilon^0\}$$

or

$$\{M\}=[B][A]^{-1}\{N\} \qquad \text{(Eq 33)}$$

Stress resultants developed because of curvature restraint can be found similarly. Thus:

$$\{\kappa\}=[D]^{-1}\{M\}$$

$$\{\mathrm{N}\}=[\mathrm{B}]\{\kappa\} \qquad \text{(Eq 34)}$$

or

$$\{N\}=[B][D]^{-1}\{\kappa\} \qquad \text{(Eq 35)}$$

Defining stiffnesses without constraining the bending-extensional coupling requires more effort. Referring to Eq 29, the extensional stiffnesses can be found by specifying that $\{M\}= 0$. Therefore:

$$\{0\}=[B]\{\epsilon^0\}+[\mathrm{D}]\{\kappa\} \qquad \text{(Eq 36)}$$

The curvatures can then be found to be:

$$\{\kappa\}=-[D]^{-1}[B]\{\epsilon^0\} \qquad \text{(Eq 37)}$$

Substituting these into the first set of relations in Eq 29 yields:

$$\{N\}=[A]\{\epsilon^0\}+[B](-[D]^{-1}[B]\{\epsilon^0\}$$

or

$$\{N\}= ([A]-[B][D]^{-1}[B])\{\epsilon^0\}$$

or

$$\{N\}=[A^*]\{\epsilon^0\} \qquad \text{(Eq 38)}$$

The effective laminate extensional stiffnesses can now be found using the relations in Eq 28 and the effective stiffness matrix $[A^*]$.

An effective bending stiffness matrix can be determined similarly by specifying $\{N\}= 0$. Thus:

$$\{0\}=[A]\{\epsilon^0\}+[B]\{\kappa\} \qquad \text{(Eq 39)}$$

Now the midplane strains are seen to be:

$$\{\epsilon^0\}=-[A]^{-1}[B]\{\kappa\} \qquad \text{(Eq 40)}$$

and the second of relations in Eq 29 is rewritten as:

$$\{M\}= (-[B][A]^{-1}[B]+[D])\{\kappa\}$$

or

$$\{M\}=[D^*]\{\kappa\} \qquad \text{(Eq 41)}$$

yielding an effective bending stiffness matrix, $[D^*]$.

Thermal Expansion. As the use of composite materials becomes more common, they are subjected to mechanical and environmental loading conditions that are increasingly severe, and with the advent of high-temperature resin systems, the range of temperatures over which the composite system can be used has increased. Thus, it is necessary to understand the response of laminates to temperature and moisture, as well as to applied loads. Previously, laminate extensional and bending stiffnesses were determined; in this section, laminate conductivities and expansivities will be defined.

The presence of stresses induced by free thermal expansion is new to the designer and analyst of conventional materials. The mechanism that produces such stresses is qualitatively described in Fig. 8, which shows that free laminae and bonded laminae (laminate) expand differently. In the direction shown, the 0° plies will develop tensile stress, while the 90° ply will develop compressive stress because of the differences between the laminae and laminate thermal expansion coefficients. This effect is similar to heating a conventional material and providing constraints such that thermal expansion strains cannot develop.

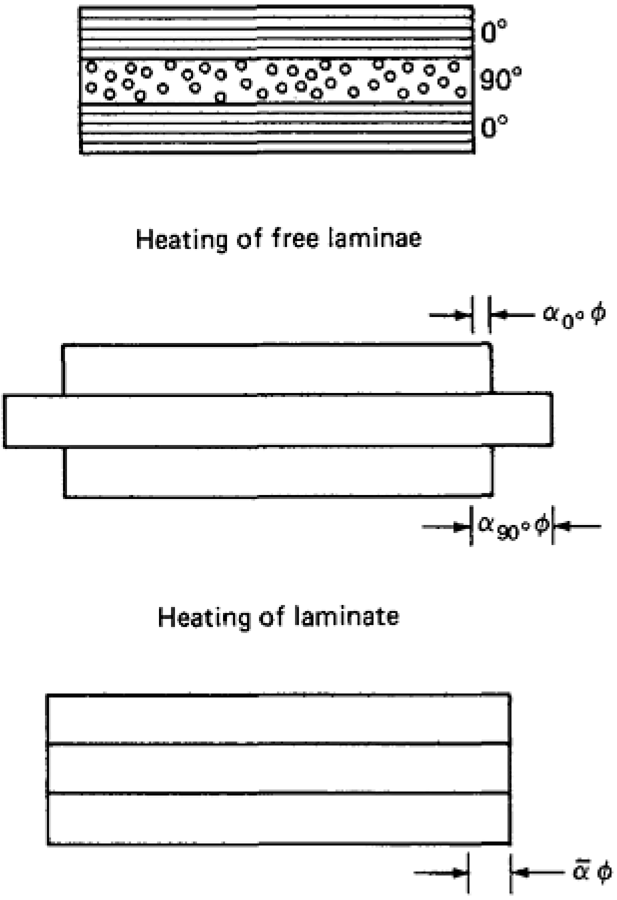

Fig. 8 Thermally induced loads

To determine quantitatively the laminate thermal expansion coefficients and thermally induced stresses, it is necessary to begin at the ply level. The thermoelastic relations for strain in the principal material directions are:

$$\{\varepsilon_\ell\} = \{\varepsilon_\ell^M\} + \{\alpha_\ell\}\Delta T$$

or

$$\{\varepsilon_\ell\} = \{\varepsilon_\ell^M\} + \varepsilon_\ell^T \qquad \text{(Eq 42)}$$

The vector $\{\alpha_\ell\}$ represents the free thermal expansion coefficients of a ply. The individual components are:

$$\{\alpha_\ell\} = \begin{Bmatrix} \alpha_1 \\ \alpha_2 \\ 0 \end{Bmatrix} \qquad \text{(Eq 43)}$$

and ΔT represents a change in temperature. The thermal strains, $\{\alpha_\ell\}\Delta T$, are the lamina free thermal expansions. They produce no stress in an unconstrained lamina. The thermal expansion coefficients, α_1 and α_2, are the effective thermal expansion coefficients α_L^* and α_T^*, respectively, of the unidirectional composite. Substituting for mechanical strain terms in Eq 42 and inverting, yields:

$$\{\sigma_\ell\} = [Q]\{\varepsilon_\ell\} - \{\Gamma_\ell\}\Delta T \qquad \text{(Eq 44)}$$

where

$$\{\Gamma_\ell\} = [Q]\{\alpha_\ell\}$$

The components in the thermal stress coefficient vector, $\{\Gamma_\ell\}$, can be shown, by carrying out the indicated multiplication, to be:

$$\{\Gamma_\ell\} = \begin{Bmatrix} \dfrac{E_1\alpha_1 + \nu_{12}E_2\alpha_2}{\Delta} \\ \dfrac{E_2\alpha_2 + \nu_{12}E_1\alpha_1}{\Delta} \\ 0 \end{Bmatrix} \quad \text{(Eq 45)}$$

where

$$\Delta = 1 - \frac{E_2}{E_1}\nu_{12}^2$$

The vector $\{\Gamma_\ell\}\Delta T$ physically represents a correction to the stress vector, which results from the full constraint of the free thermal strains in a lamina.

Both the thermal expansion vector, $\{\alpha_\ell\}\Delta T$, and thermal stress vector, $\{\Gamma_\ell\}\Delta T$, can be transformed to an arbitrary coordinate system using the relations developed for stress and strain transformation (Eq 7 and 8).

With transformed thermal expansion and stress vectors, it is possible to develop thermoelastic laminate relations. Following directly the development of Eq 21 to 25, the membrane relations are:

$$\{N\}=[A]\{\epsilon^0\}+[B]\{\kappa\}+\{N^T\} \quad \text{(Eq 46)}$$

where

$$\{N^T\} = -\int_{-h}^{h} \{\Gamma_x\}\Delta T \, dz \quad \text{(Eq 47)}$$

Similarly, the bending relations are

$$\{M\}=[B]\{\epsilon^0\}+[D]\{\kappa\}+\{M^T\} \quad \text{(Eq 48)}$$

where

$$\{M^T\} = \int_{-h}^{h} \{\Gamma_x\}\Delta T \, z\,dz$$

The integral relations for the thermal stress resultant vector, $\{N^T\}$, and thermal moment resultant vector, $\{M^T\}$, can be evaluated only when the change in temperature variation through the thickness of the laminate is known. For uniform temperature change through the thickness, the term ΔT is constant and can be factored out of the integration, yielding:

$$\{N^T\} = \Delta T \sum_{i=1}^{K} \{\Gamma_x\}^i (z_i - z_{i-1})$$
$$\{M^T\} = \frac{1}{2}\Delta T \sum_{i=1}^{K} \{\Gamma_x\}^i (z_i^2 - z_{i-1}^2) \quad \text{(Eq 49)}$$

With the relations in Eq 46 and 48, it is possible to determine effective laminate coefficients of thermal expansion and thermal curvature. These quantities are the extension and curvature changes resulting from a uniform temperature distribution.

Noting that for free thermal effects $\{N\}=\{M\}= 0$, and defining a free thermal expansion vector as

$$\{\alpha_x\} = \{\epsilon^0\}\frac{1}{\Delta T} \quad \text{(Eq 50)}$$

and a free thermal curvature vector as

$$\{\delta_x\} = \{\kappa\}\frac{1}{\Delta T} \quad \text{(Eq 51)}$$

the relations in Eq 46 and 48 can be solved. After suitable matrix manipulations, the following expressions for thermal expansion, $\{\alpha_x\}$, and thermal curvature, $\{\delta_x\}$, are found:

$$\{\alpha_x\} = \frac{1}{\Delta T}[L_1]^{-1}\left([B][D]^{-1}\{M^T\} - \{N^T\}\right) \quad \text{(Eq 52)}$$

$$\{\delta_x\} = \frac{1}{\Delta T}[L_2]^{-1}\left([B][A]^{-1}\{N^T\} - \{M^T\}\right) \quad \text{(Eq 53)}$$

where

$$[L_1]=[A]-[B][D]^{-1}[B]$$

$$[L_2]=[D]-[B][A]^{-1}[B]$$

The relations in Eq 52 and 53 are complicated expressions containing the $[A]$, $[B]$, and $[D]$ matrices. In many practical cases, the laminates of interest are symmetric, which simplifies the expressions considerably. For symmetric laminates, the bending-extensional coupling vanishes (that is, $[B]= 0$), and the relations are reduced to the form:

$$\{\alpha_x\} = -\frac{1}{\Delta T}[A]^{-1}\{N^T\}$$
$$\{\delta_x\} = -\frac{1}{\Delta T}[D]^{-1}\{M^T\} \quad \text{(Eq 54)}$$

Examination of the relations for $\{M^T\}$, Eq 49, shows that the symmetry that eliminates the $[B]$ matrix also eliminates the $\{M^T\}$ vector. Thus:

$$\{\delta_x\}=\{0\} \quad \text{(Eq 55)}$$

and no curvatures occur because of uniform temperature changes in symmetric laminates.

The variation of the longitudinal thermal expansion coefficient for a symmetric angle-ply laminate is shown in Fig. 9 to illustrate the effect of laminae orientation. At $\theta= 0°$, the term α_x is simply the axial lamina coefficient of thermal expansion; at $\theta= 90°$, α_x equals the lamina transverse thermal expansion coefficient. An interesting feature of the curve is the large negative value of α_x in the region of 30°. In Fig. 6, the value of Poisson's ratio also behaves peculiarly in the region around 30°. The odd variation of both the coefficient of thermal expansion and Poisson's ratio stems from the magnitude and sign of the shear-extensional coupling in the individual lamina.

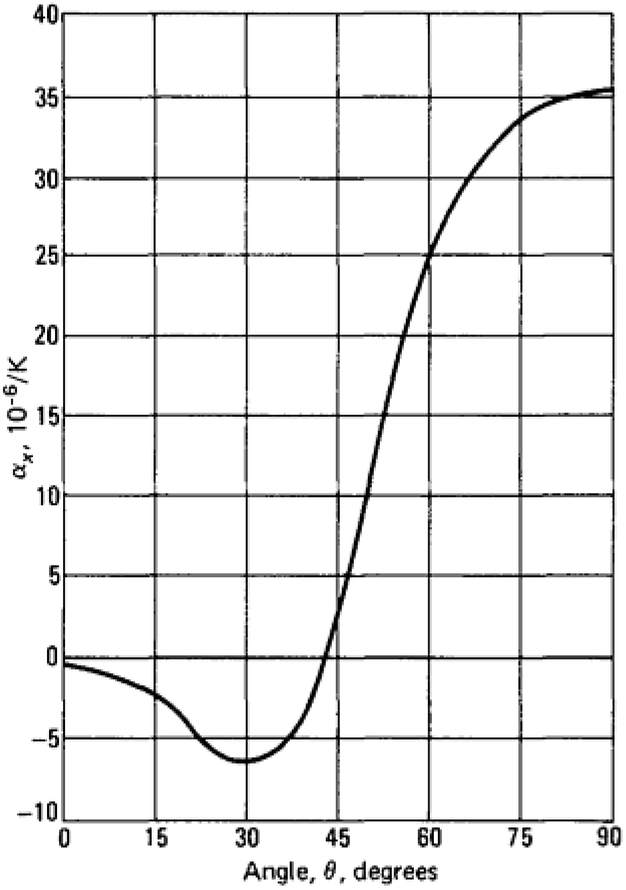

Fig. 9 Thermal expansion coefficients for high-modulus graphite-epoxy system, $[\pm\theta]_s$

Previously, classes of laminates were shown to have isotropic stiffnesses in the plane of the laminate. Similarly, laminates that are isotropic in thermal expansion within the plane of the laminate can be specified. The requirements for thermal expansion isotropy are considerably less restrictive than those for elastic constants. In fact, any laminate that has two identical, orthogonal thermal expansion coefficients and a zero-shear thermal expansion coefficient is isotropic in thermal expansion. Thus, $[0°/90°]_s$ and $[\pm 45°]_s$ laminates are isotropic in thermal expansion even though they are not quasi-isotropic for elastic stiffnesses.

Laminates that are isotropic in thermal expansion have thermal expansions of the form:

$$\{\alpha_x\} = \begin{Bmatrix} \alpha_x \\ \alpha_y \\ \alpha_{xy} \end{Bmatrix} = \begin{Bmatrix} \alpha^* \\ \alpha^* \\ 0 \end{Bmatrix} \quad \text{(Eq 56)}$$

where the term α* can be shown to be a function of lamina properties only, as follows:

$$\alpha^* = \alpha_1 + \frac{(\alpha_2 - \alpha_1)(1 + \nu_{12})}{1 + 2\nu_{12} + \dfrac{E_1}{E_2}}$$

Thus, for a given ply material, all laminates that are isotropic in thermal expansion have identical expansion coefficients.

Moisture Expansion. Resin matrix composites are said to be hygroelastic when the matrix absorbs and desorbs moisture from and to the environment. The primary effect of moisture sorption is a volumetric change in the laminae. When a lamina absorbs moisture, it expands; when moisture is lost, the lamina contracts. Thus, the effect is similar to thermal expansion.

In a lamina, a free moisture expansion coefficient vector can be defined as:

$$\{\varepsilon_\ell\} = \{\beta_\ell\}\Delta M \quad \text{(Eq 57)}$$

where

$$\{\beta_\ell\} = \begin{Bmatrix} \beta_1 \\ \beta_2 \\ 0 \end{Bmatrix}$$

and ΔM is moisture change by weight. Noting that the relations in Eq 57 are identical to those of thermal expansion, with $\{\beta_\ell\}$ substituted for $\{\alpha_\ell\}$ and ΔM substituted for ΔT, it can easily be seen that all of the relations developed for thermal effects can be used for moisture effects, as long as the substitutions mentioned are performed.

The procedure required to determine moisture gains or losses are described in the section "Stresses Due to Temperature and Moisture" subsequently in this article. The analytical procedures detailed here allow for the prediction of moisture-induced stresses when the percent moisture change is known for the laminate. As with the thermoelastic analysis, only elastic effects have been treated.

Conductivity. The conductivity (thermal or moisture) of a laminate in the direction normal to the surface is equal to the transverse conductivity of a unidirectional fiber composite. This follows from the fact that normal conductivity for all plies is identical and unaffected by ply orientation.

The in-plane conductivities will be required for certain problems involving spatial variations of temperature and moisture. For a given uniform state of moisture in a laminate, the effective thermal conductivities in the x and y directions can be obtained by methods entirely analogous to those used previously for stiffnesses:

$$\mu_x = \frac{1}{2h}\sum_{i=1}^{K}(\mu_1 m^2 + \mu_2 n^2)t^i_{\text{ply}} \qquad \text{(Eq 58)}$$

$$\mu_y = \frac{1}{2h}\sum_{i=1}^{K}(\mu_1 n^2 + \mu_2 m^2)t^i_{\text{ply}} \qquad \text{(Eq 59)}$$

where μ_1 is the conductivity in the fiber direction, μ_2 is the conductivity transverse to the fibers, m is $\cos\theta^i$, n is $\sin\theta^i$, θ^i is the orientation of ply i, t_{ply} is the thickness of ply i, K is the total number of plies, and $2h$ is the laminate thickness. The results apply to symmetric as well as to asymmetric laminates. The results for moisture conductivity are identical.

Thermal and Hygroscopic Analysis

This section is concerned with the distribution of temperature and moisture through the thickness of a laminate. The mathematical descriptions of these two phenomena are identical, and the physical effects are similar. Some of these aspects have already been discussed.

A free lamina undergoes stress-free deformation due to temperature change or moisture swelling. In a laminate, stress-free deformation is constrained by adjacent layers, producing internal stresses. In addition to the swelling-induced stresses, temperature and moisture content also affect the properties of the material. These effects are primarily related to matrix-dominated strength properties. Figure 10 (Ref 1) indicates that for the typical graphite-epoxy system, moisture has little or no effect on stiffness. Figures 11 and 12 (Ref 1) show a large variation in strength, with the exception of axial tension. In each of these figures, the presence of moisture is seen to decrease the elevated-temperature strengths of the material while neither detrimentally affecting nor increasing the lower-temperature strengths.

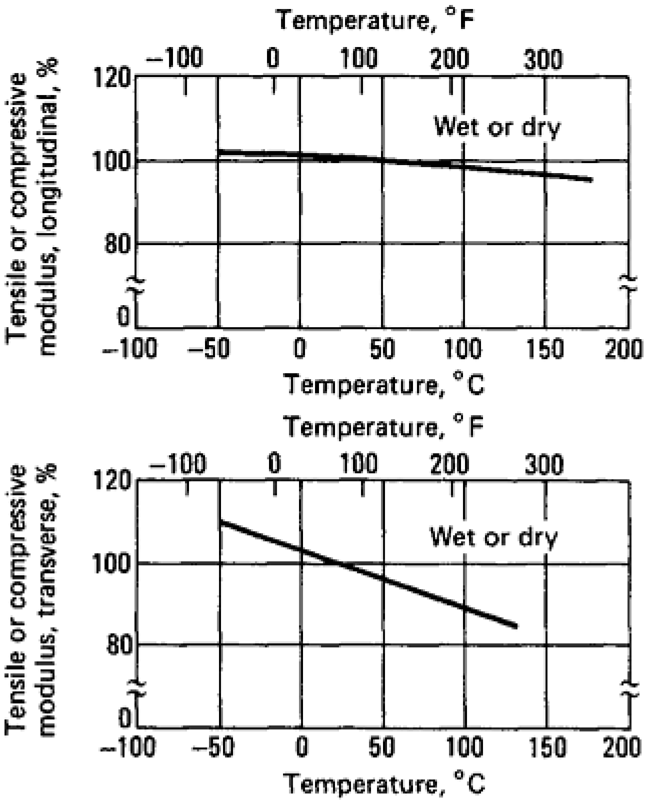

Fig. 10 Effects of moisture and temperature on lamina stiffness measured at room temperature

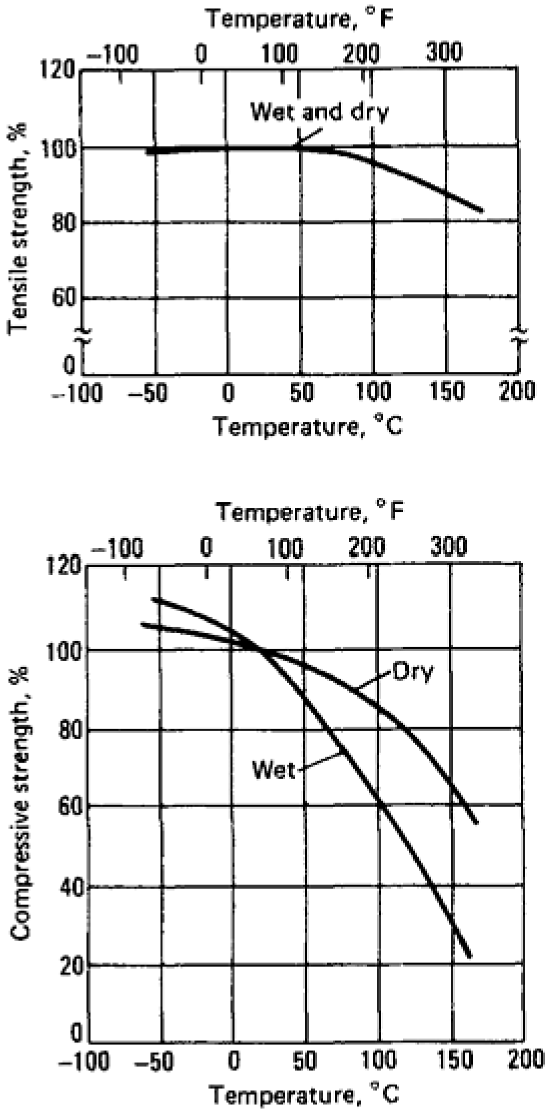

Fig. 11 Effects of moisture and temperature on lamina longitudinal strength, measured at room temperature

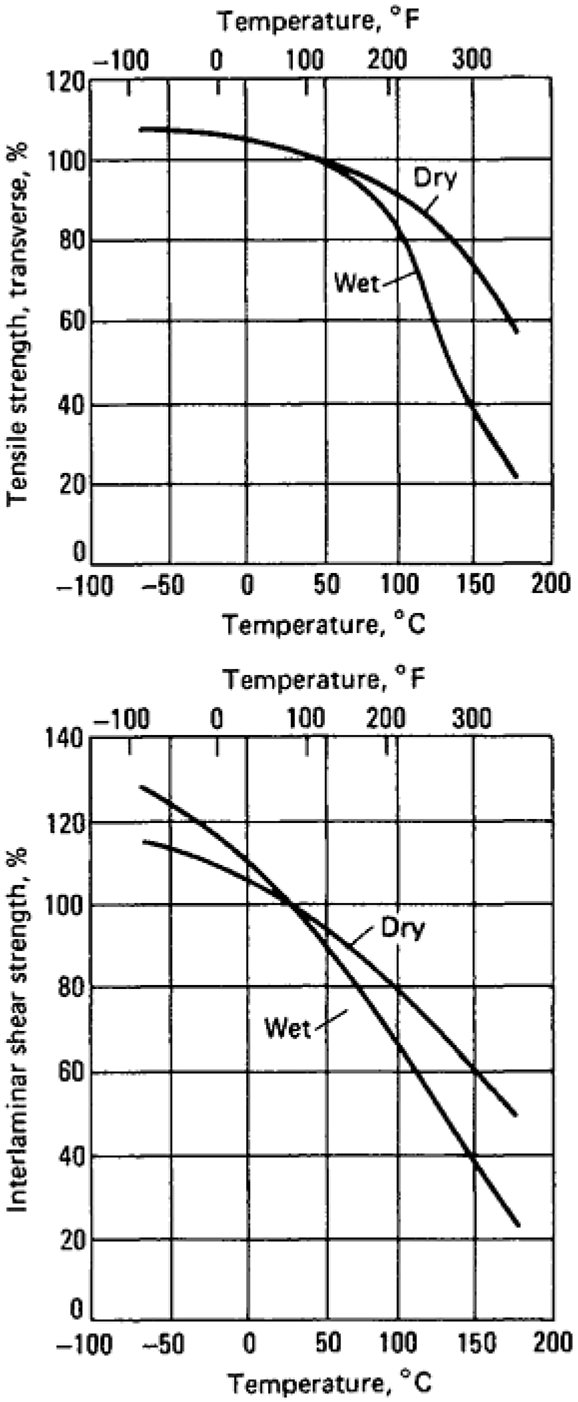

Fig. 12 Effects of moisture and temperature on lamina matrix-dominated strengths measured at room temperature

The principal strength-degrading effect is related to a change in the glass transition temperature of the matrix material. As moisture is absorbed, the temperature at which the matrix changes from a glassy state to a viscous state decreases. Thus, the elevated-temperature strength properties decrease with increasing moisture. Limited data suggest, however, that this process is reversible. When the moisture content of the composite is decreased, the glass transition temperature increases and the original strength properties return.

In Fig. 10, 11, and 12, the term *wet* indicates that the material is fully saturated. This condition corresponds to a state of equilibrium with the environment at which the relative humidity is nearly 100%. The equilibrium moisture content at full saturation for typical epoxy composite systems ranges from about 1.0 to 2.5% weight gain.

All of these considerations also apply in the case of temperature rise in the sense that the matrix and therefore the laminae lose stiffness and strength when the temperature rises. Therefore, this effect is primarily important for matrix-dominated properties.

The differential equation governing time-dependent moisture sorption of an orthotropic homogeneous material is given by:

$$D_1 \frac{\partial^2 c}{\partial x_1^2} + D_2 \frac{\partial^2 c}{\partial x_2^2} + D_3 \frac{\partial^2 c}{\partial x_3^2} = \frac{\partial c}{\partial t} \quad \text{(Eq 60)}$$

where t is time, x_1, x_2, x_3 are coordinates in principal material directions, c is the specific moisture concentration, and D_1, D_2, and D_3 are moisture diffusivity coefficients. Equation 60 is based on Fick's law of moisture diffusion and is entirely analogous to the equation governing time- dependent heat conduction, with temperature, φ, replacing concentration, c, and thermal conductivities, μ_1, μ_2, and μ_3 replacing the moisture diffusivities. For a transversely isotropic lamina, with x_1 in the fiber direction, x_2 in the transverse direction, and $x_3=z$ in the direction normal to the lamina:

$$D_1=D_L$$

$$D_2=D_3=D_T \quad \text{(Eq 61)}$$

These quantities are analogous to the thermal conductivities of a UDC.

An important special case is one-dimensional diffusion or conduction through the thickness of a lamina. In this case, Eq 60 reduces to:

$$D_T \frac{\partial^2 c}{\partial z^2} = \frac{\partial c}{\partial t} \quad \text{(Eq 62)}$$

This equation also applies to moisture diffusion or thermal conduction through a laminate, in the direction normal to its laminae planes, since all laminae are homogeneous in the z-direction with equal diffusion coefficients, $D_T=D_z$.

Equation 62 is applicable to the important problem of time-dependent moisture diffusion through a laminate where the two faces are in different moisture environments. After enough time has elapsed, the concentration settles down to a time-independent (so-called stationary) state. In this state, since c is no longer time-dependent, Eq 62 simplifies to:

$$\frac{d^2 c}{dz^2} = 0$$

Thus, c is a linear function of z, and if the laminate faces are in environments with constant saturation concentrations, c_1 and c_2, then:

$$c = \frac{1}{2}\left[(c_2 - c_1)z/h + c_2 + c_1\right] \quad \text{(Eq 63)}$$

where the laminate thickness is $2h$, and z originates in the middle surface. In the important case where $c_2=c_1$, Eq 63 reduces to:

$$c=c_1= \text{constant} \quad \text{(Eq 64)}$$

The foregoing discussion of moisture also applies to heat conduction.

Solutions to the time-dependent problem, Eq 62, are readily available, and considerable work has been performed in the area of moisture absorption (Ref 2). The most interesting feature of the solutions to Eq 62 relates to the magnitude of the coefficient D_z, which is a measure of the speed of moisture diffusion. In typical epoxy matrix systems, D is of the order of 645 × 10^{-8} mm^2/s (1 × 10^{-8} $in.^2/s$) to 645 × 10^{-10} mm^2/s (1 × 10^{-10} $in.^2/s$). The diffusion coefficient is sufficiently small that full saturation of a resin matrix composite may require months or years, even when subjected to 100% relative humidity.

The approach typically taken for design purposes is to assume a worst-case scenario. If the material is assumed to be fully saturated, reduced allowable strengths can be computed. This is a conservative approach, because typical service environments do not generate full saturation. It is used because it allows for inclusion of the effects of moisture in a relatively simple fashion. Design databases are growing and analytical methods are maturing, so that the worst- case combinations of environment factors can be considered for the specific materials and loading being studied. In the cases where moisture absorption is detrimental, full saturation can be assumed.

In the case of heat conduction, the time required to achieve the stationary state, the analogue of saturation, is extremely rapid. Thus, the transient time-dependent state is generally of little practical importance for laminates.

Laminate Stress Analysis

The physical properties defined in the section "Laminate Properties" in this article enable any laminate to be represented by an equivalent homogeneous anisotropic plate or shell element for the purpose of structural analysis. The results will be the definition of stress resultants, bending moments, temperature, and moisture at any point on the surface defining the plate. (Temperature and moisture distributions through the thickness of the plate will also be defined when they exist.) With this definition of the local values of the state variables, a laminate analysis is next performed to determine the state of stress in each lamina in order to assess margins for each critical design condition.

Stresses Due to Mechanical Loads. To determine stresses in the individual plies, the laminate midplane strain and curvature vectors must be used. Writing the laminate constitutive relations as:

$$\left\{\frac{N}{M}\right\} = \left[\frac{A}{B}\middle|\frac{B}{D}\right]\left\{\frac{\varepsilon^0}{\kappa}\right\} \quad \text{(Eq 65)}$$

shows that a simple inversion will yield the required relations for $\{\epsilon^0\}$ and $\{\kappa\}$. Thus:

$$\left\{\frac{\varepsilon^0}{\kappa}\right\} = \left[\frac{A}{B}\middle|\frac{B}{D}\right]^{-1}\left\{\frac{N}{M}\right\} \quad \text{(Eq 66)}$$

Given the strain and curvature vectors, the total strain in the laminate can be written as:

$$\{\epsilon_x\}=\{\epsilon^0\}+z\{\kappa\} \quad \text{(Eq 67)}$$

The strains at any point through the laminate thickness are now given as the superposition of the midplane strains and the curvatures multiplied by the distance from the midplane. Thus, the strain field at the center of ply *i* in a laminate can be seen to be:

$$\{\varepsilon_x\}^i = \{\varepsilon^0\} + \frac{1}{2}\{\kappa\}(z^i + z^{i+1}) \quad \text{(Eq 68)}$$

where the term

$$\frac{1}{2}(z^i + z^{i+1})$$

corresponds to the distance from the midplane to the center of ply *i*. Curvature-induced strains at a point through the laminate thickness can be defined simply by specifying the distance to the point in question from the midplane.

The strains defined in Eq 68 correspond to the arbitrary laminate coordinate system. These strains can be transformed into the principal material coordinates for this ply by using transformations developed previously. Thus:

$$\{\varepsilon_\ell\}^i = \left[\theta^i\right]^{-1} \{\varepsilon_x\}^i \quad \text{(Eq 69)}$$

where the superscript *i* indicates which ply and therefore which angle of orientation is to be used. Because the orientations of the various plies may differ, it is necessary to use the transformation matrix corresponding to the proper ply orientation.

With the strains in the principal material coordinates defined, stresses in these same coordinates are written using the lamina reduced stiffness matrix (Eq 5). Thus:

$$\{\sigma_\ell\}^i = \left[Q^i\right]\{\varepsilon_\ell\}^i \quad \text{(Eq 70)}$$

Again, it is important that the stiffness matrix used correspond to the correct ply, as each ply may be of a different material.

The stresses in the principal material coordinates can be determined without the use of principal material strains. Using the strains defined in the laminate coordinates (Eq 68) and the transformed lamina stiffness matrix (Eq 9, 11, 12), stresses in the laminate coordination system are written as:

$$\{\sigma_x\}^i = \left[\bar{Q}^i\right]\{\varepsilon_x\}^i \quad \text{(Eq 71)}$$

and these stresses are then transformed to the principal material coordinates. Thus:

$$\{\sigma_\ell\}^i = \left[\theta^i\right]^{-1} \{\sigma_x\}^i \quad \text{(Eq 72)}$$

Reviewing these relations, it can be seen that for the case of symmetric laminates and membrane loading, the curvature vector is zero. This implies that the laminate coordinate strains are identical in each ply and equal to the midplane strains. The differing angular orientation of the various plies will promote different stress and strain fields in the principal material coordinates of each ply.

Stresses Due to Temperature and Moisture. When the equations for the thermoelastic response of composite laminates were developed, it was indicated that thermal loading in laminates can cause stresses within the plies even when the laminate is allowed to expand freely. The stresses are induced because of a mismatch in thermal expansion coefficients between plies oriented in different directions. Either the mechanical stresses of the preceding section or the thermomechanical stresses to be calculated in this section can be used to evaluate laminate strength.

To determine the magnitude of thermally induced stresses, the thermoelastic constitutive relations (Eq 46, 48) are required. Since free thermal effects require that $\{N\}=\{M\}= 0$, these relations are written as:

$$\left\{\frac{0}{0}\right\} = \left[\frac{A}{B}\middle|\frac{B}{D}\right]\left\{\frac{\varepsilon^0}{\kappa}\right\} + \left\{\frac{N^T}{M^T}\right\} \quad \text{(Eq 73)}$$

Inverting these relations yields the free thermal strain and curvature vectors for the laminate:

$$-\left[\frac{A}{B}\middle|\frac{B}{D}\right]^{-1}\left\{\frac{N^T}{M^T}\right\}\left\{\frac{\varepsilon^0}{\kappa}\right\} \quad \text{(Eq 74)}$$

Proceeding as before, the strain field in any ply is written as:

$$\{\epsilon_x\}^i=\{\epsilon^0\}+z^i\{\kappa\} \quad \text{(Eq 75)}$$

Stresses in the laminate coordinates are written as:

$$\{\sigma_x\}^i = \left[\bar{Q}^i\right]\{\varepsilon_x\}^i - \{\Gamma_x\}^i \Delta T^i \quad \text{(Eq 76)}$$

which can then be transformed to the principal material coordinates. Thus:

$$\{\sigma_\ell\}^i = \left[\theta^i\right]^{-1} \{\sigma_x\}^i \quad \text{(Eq 77)}$$

As was shown for mechanically induced loadings, the stresses can be found in another fashion. Transforming the strains of Eq 75 directly yield

$$\{\varepsilon_\ell\}^i = \left[\theta^i\right]^{-1} \{\varepsilon_x\}^i \qquad \text{(Eq 78)}$$

Recalling Eq 44, stresses in the principal material coordinates are written as:

$$\{\sigma_\ell\}^i = \left[Q^i\right]\{\varepsilon_\ell\}^i + \{\Gamma_\ell\}^i \Delta T^i \qquad \text{(Eq 79)}$$

Some interesting physical interpretations can be obtained by restricting the discussion to uniform-temperature fields and symmetric laminates. In the presence of these restrictions, the coupling matrix, [B], and the thermal moment resultant vector, $\{M^T\}$, vanish, and:

$$\{\epsilon^0\}=\{\alpha_x\}\Delta T$$

and

$$\{\kappa\}=\{0\}$$

The strains in the laminate coordinates are identical in each ply. Thus:

$$\{\varepsilon_x\}^i = \{\varepsilon^0\} = \{\alpha_x\}\Delta T \qquad \text{(Eq 80)}$$

For this case, it can be shown that:

$$\{\sigma_x\}^i = \left[\bar{Q}^i\right](\{\alpha\} - \{\alpha_x\}^i)\Delta T \qquad \text{(Eq 81)}$$

These relations indicate that stresses induced by the free thermal expansion of a laminate are related to the differences between the laminate and the ply thermal expansion vectors. Thus, the stresses are proportional to the difference between the amount the ply would freely expand and the amount the laminate will allow it to expand.

A further simplification can be found if the laminate under investigation is isotropic in thermal expansion. It can be shown that if this class of laminates is subjected to a uniform temperature change, the stresses in the principal material coordinates are identical in every ply. The stress vector can be shown to be:

$$\{\sigma_\ell\} = \frac{E_{11}(\alpha_{22} - \alpha_{11})\Delta T}{1 + 2\nu_{12} + \dfrac{E_{11}}{E_{22}}} \begin{Bmatrix} 1 \\ -1 \\ 0 \end{Bmatrix} \qquad \text{(Eq 82)}$$

where the transverse direction stress is equal and opposite to the fiber direction stress. This is important because unidirectional transverse material strengths are typically an order of magnitude lower than fiber direction strengths.

A similar development can be generated for moisture-induced stresses. All of the results of this section apply when the moisture swelling coefficients, $\{\beta_1\}$, are substituted for the thermal expansion coefficients, $\{\alpha_1\}$.

Netting Analysis. Another approach to the calculation of ply stresses is sometimes used for membrane loading of laminates. This procedure, called netting analysis, treats the laminate as a net; that is, all loads are carried in the fibers while the matrix material is present only to hold the geometric position of the fibers.

Since only the fibers are assumed to be loaded in this analytical model, stress-strain relations in the principal material directions can be written as:

$$\sigma_{11}=E_1\epsilon_{11}$$

or

$$\varepsilon_{11} = \frac{1}{E_1}\sigma_{11} \qquad \text{(Eq 83)}$$

and

$$E_2=G_{12}=\sigma_{22}=\sigma_{12}= 0$$

The laminate stiffnesses predicted by means of a netting analysis will be smaller than those predicted using lamination theory, because of exclusion of the transverse and shear stiffnesses from the formulation. This effect is demonstrated in Table 3 for a quasi-isotropic laminate consisting of high-modulus graphite-epoxy. The stiffness properties predicted using a netting analysis are on the order of 10% smaller than those predicted using

lamination theory. Experimental work has consistently shown that lamination theory predictions are more realistic.

Table 3 Laminate elastic constants

Analysis	E_x		E_y		G_{xy}		ν_{xy}
	GPa	**10^6 psi**	**GPa**	**10^6 psi**	**GPa**	**10^6 psi**	
Lamination theory	64.9	9.42	64.9	9.42	24.5	3.55	**0.325**
Netting analysis	**57.4**	**8.33**	**57.4**	**8.33**	**21.6**	**3.13**	**0.333**

Note: Unit thickness: high-modulus graphite-epoxy

Although the stiffness predictions using netting analyses are of limited value, such an analysis can be used as an approximation of the response of a composite in which the matrix has been damaged. In this sense it may be considered a worst-case analysis and is frequently used to predict ultimate strengths of composite laminates.

Interlaminar Stresses. The analytical procedures that have been developed in this article can be used to predict stresses within each lamina in a laminate. The stresses predicted are planar because of the assumed state of plane stress. There are cases for which the assumption of plane stress is not valid and a three-dimensional stress analysis is required.

An example of such a case exists at certain free edges in laminates where stress-free boundary conditions must be imposed. When the laminate in Fig. 13 is subjected to a membrane loading in the *x* direction, Poisson's ratio mismatches between the 0° plies and the ±60° plies will introduce a stress in the *y* direction in each ply. Additionally, extensional-shear coupling effects will generate equal but opposite shear stresses in the 60° and–60° plies. In Fig. 13, all σ_y and σ_{xy} stresses must vanish at $y=\pm b$ to satisfy the stress-free boundary conditions. This cannot be accomplished with lamination theory; a three- dimensional analysis is required.

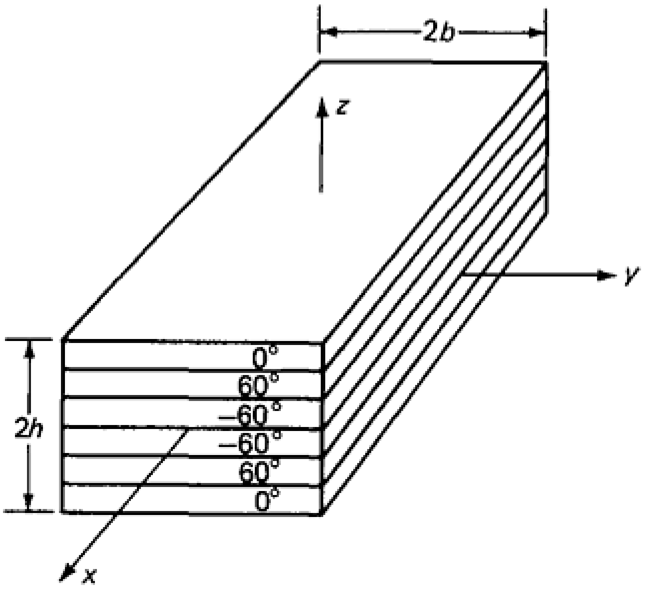

Fig. 13 Laminate construction (interlaminar stress example)

Using equilibrium and symmetry considerations, the other components of stress which arise at the free edge can be visualized. In Fig. 14, lamination theory stresses are shown for the uniaxial loading discussed previously; it can be seen that the laminate analysis satisfies equilibrium in the *y* direction but not the conditions at the free boundary. Thus, additional forces are required to satisfy the boundary conditions. For example, in the 0° plies, a compressive σ_y is predicted using lamination theory. This does not satisfy the boundary condition locally. A second, self-equilibrating set of edge stresses may be regarded as a superposed stress field that brings the lamination theory stresses to the necessary boundary values. Thus, an interlaminar shear stress, σ_{yz}, develops between the 0° and 60° plies. This introduces an *x*-moment disequilibrium even though the *y*-direction force equilibrium has been satisfied. To achieve *x*-moment equilibrium, a couple is needed. The required couple develops as an interlaminar normal stress distribution which, in Fig. 15, is seen to be compressive at $y=b$. For a couple to develop, the normal stress must change sign as the distance from the free edge increases.

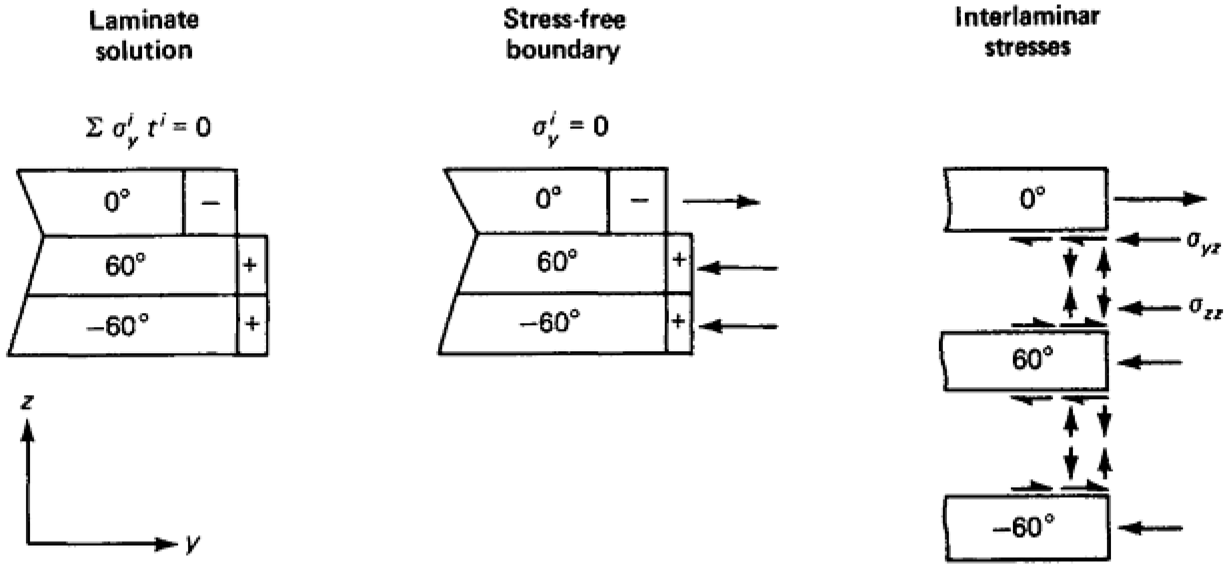

Fig. 14 Equilibrium and boundary conditions, *y* direction. t^i, thickness of *i*th ply

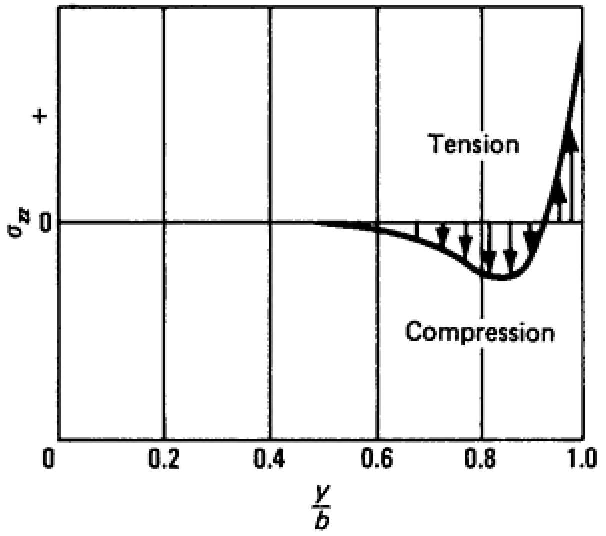

Fig. 15 Interlaminar normal stresses and moment equilibrium

In Fig. 16, a similar situation exists with respect to the in-plane shear stresses, σ_{xy}. At the free edge, $y=b$, these stresses must vanish. Therefore, the other component of interlaminar shear stress, σ_{xz}, develops, and the stress-free boundary conditions are satisfied. In each case it is seen that lamination theory satisfies strain compatibility and equilibrium, while the interlaminar stresses satisfy the stress-free boundary conditions.

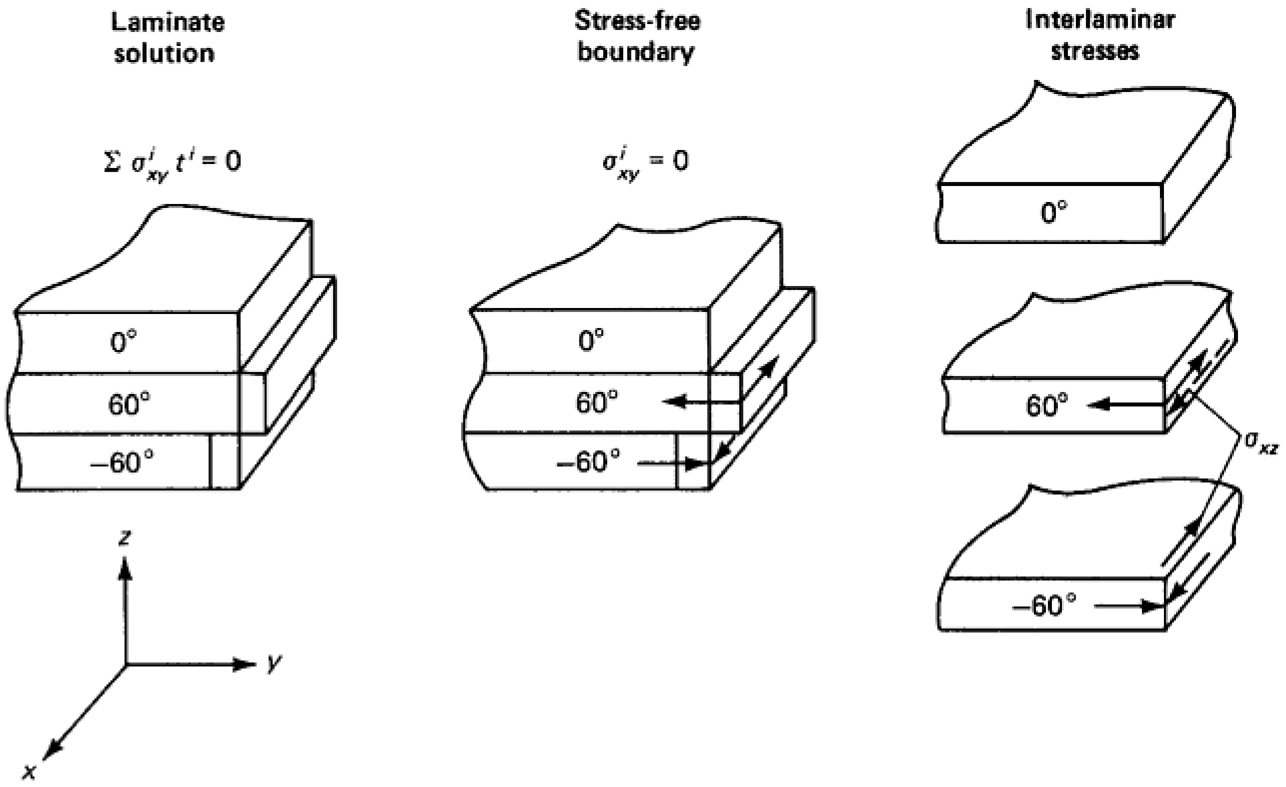

Fig. 16 Equilibrium and boundary conditions, *x* direction

The sign of the interlaminar normal stress at the free edge can be of great importance. As can be inferred from previous discussions, a large Poisson's ratio mismatch between plies produces large interlaminar normal stresses. If these stresses are tensile, the laminate may split between plies, or delaminate, under membrane loading. Obviously, if the laminate is designed such that expected loadings produce only compressive interlaminar normal stresses at the free edges, delamination will not occur.

The free-edge problem occurs wherever ply stresses must become zero to satisfy boundary conditions. Thus, any free edge, including holes, may introduce interlaminar stresses. The consequences of these stresses obviously need to be evaluated for structural applications, particularly where fatigue loadings are present. It can become extremely complex to provide quantitative analytical treatment of free-edge stresses in all but the most simple geometric shapes. In most cases, the possibility of delaminations due to the effects of free edge stresses is tested experimentally.

Nonlinear Stress Analysis. All of the preceding material in this article has related to laminae that behave in a linear elastic fashion. However, composites can behave in a nonlinear fashion because of such factors as internal damage or because of nonlinear stress-strain behavior of the polymeric matrix. Matrix nonlinearity (or microcracking) can result in laminae that have nonlinear stress-strain curves for transverse stress or axial shear stress. When this situation exists, the previously presented elastic laminate stress analysis must be replaced by a nonlinear analysis. A convenient procedure for doing this is found in Ref 3.

This subject is of importance primarily for such specialized applications as dimensionally stable space structures. Hence, further treatment is beyond the scope of this article.

Strength and Failure

Methods for stress analysis of laminates subjected to mechanical loads, temperature changes, and moisture absorption are described in the previous section. The main reason for performing a stress analysis is to determine or assess the strength of a laminate. The problem is of primary practical significance, because design without knowledge of strength characteristics is impossible. Such information for laminates cannot be obtained on a purely experimental basis, because the number of candidate laminates is immense, and each of them is an anisotropic structural element. Thus, in each case it would be necessary to determine a set of strengths and to incorporate them into a failure criterion for a laminate under combined load. The situation is much more complex than for a UDC where the one-dimensional strengths can be obtained experimentally and only one failure criterion under combined stress is needed. In the present case, however, the one- dimensional strengths of a laminate are by themselves of great variety, because they depend on stacking sequence and layer orientations. To complicate matters further, both in-plane and bending loads must be considered.

This situation clearly requires analytical criteria for strengths of laminates, which, unfortunately, are not yet available. Consequently, the approaches and methods discussed will be both quantitative and qualitative.

The case of a perfect laminate, which does not contain defects of any kind, is considered first. When such a laminate is loaded in its plane, a simple stress distribution results, consisting of plane stress in each layer and a complex three- dimensional stress distribution at the edges that involves interlaminar normal and shear stress. Some of these stress components may become large at the edges; theoretically, they may become infinite. This at once indicates several modes of initial failure. Away from the edges, a laminate may fail either in what may be called a fiber mode, implying rupture or buckling of fibers, or in what may be called a matrix mode, implying longitudinal cracking parallel to the fibers. Since the state of stress is planar, there are no other failure modes. The advantage of the criteria to be developed for these modes is that they predict not only failure but also the mode. At the edges, the interlaminar stresses may produce delamination as the initial failure. The major difficulties of analytical strength definition are determining failures subsequent to the initial failure and providing a criterion for when these will produce ultimate failure of the laminate.

Initial Failure. For a laminate that is loaded by in-plane forces and/or bending moments, the stresses in the layers at a sufficient distance from the edges can be obtained by the methods developed in the previous section “Laminate Stress Analysis” in this article. If there is no external bending, if the membrane forces are constant along the edges, and if the laminate is balanced and symmetric, the stresses in the k^{th} layer are constant and planar. With reference to the material axes of the laminae, fiber direction x_1 and transverse direction x_2, they are written σ_{11}^k, σ_{22}^k, and σ_{12}^k. Failure will occur when either one of the following failure criteria is satisfied:

Fiber mode

$$\left(\frac{\sigma_{11}^k}{\sigma_L^u}\right)^2 + \left(\frac{\sigma_{12}^k}{\tau_L^u}\right)^2 = 1$$

Matrix mode

$$\left(\frac{\sigma_{22}^k}{\sigma_L^u}\right)^2 + \left(\frac{\sigma_{12}^k}{\tau_L^u}\right)^2 = 1 \qquad \text{(Eq 84)}$$

where σ_L^u is ultimate longitudinal stress and τ_L^u is ultimate longitudinal shear stress. It is necessary to distinguish between tensile (case a) and (case b) compressive normal stresses. Thus:

$$\sigma_L^u \begin{cases} \sigma_L^{tu} & \sigma_{11} > 0 \quad (a) \\ \sigma_L^{cu} & \sigma_{11} < 0 \quad (b) \end{cases} \qquad \text{(Eq 85)}$$

$$\sigma_T^u \begin{cases} \sigma_T^{tu} & \sigma_{22} > 0 \quad (a) \\ \sigma_T^{cu} & \sigma_{22} < 0 \quad (b) \end{cases} \qquad \text{(Eq 86)}$$

where σ_T^u is ultimate transverse stress, σ_L^{tu} and σ_T^{tu} are ultimate tensile stress, longitudinal and transverse; and σ_L^{cu} and σ_T^{cu} are ultimate compressive stress, longitudinal and transverse. Sometimes the simplistic maximum-

stress criterion is used to assess the initiation of failure. For the *k*th lamina, the maximum-stress criterion assumes the form:

$$-\sigma_L^{cu} \le \sigma_{11}^k \le \sigma_L^{tu}$$
$$-\sigma_T^{cu} \le \sigma_{22}^k \le \sigma_T^{tu} \qquad \text{(Eq 87)}$$
$$\left|\sigma_{12}\right|^k \le \tau_L^u$$

The maximum-stress criterion typically overestimates the strength of a lamina, because the interaction of stress components is neglected. Some stress interaction is obtained when the maximum-strain criterion is used. This involves replacing the stresses by ϵ_{11}, ϵ_{22}, and ϵ_{12} and replacing the ultimate stresses by the corresponding ultimate strains.

The failure criteria (Eq 84) must be used for each layer. The layer for which the criteria are satisfied by the lowest external load will define the load that produces the initial laminate failure, while also identifying the layer that fails and the nature of the failure (that is, fiber failure or cracking along fibers). This is called first-ply failure.

Bending occurs when there are external bending and/or twisting moments or when the laminate is not symmetric. In these cases, the stresses σ_{11}^k, σ_{22}^k, and σ_{12}^k in a layer are linear in x_3. Consequently, the stresses assume their maximum and minimum values at the layer interfaces; thus, the failure criteria (Eq 84) must be examined for each layer at these locations.

The situation is much more complicated for the edge stresses, where the state of stress is three-dimensional and must be obtained by numerical analysis in each case. The major problem is that there are edge stress singularities, that is, some interlaminar stresses become theoretically infinite. Numerical methods cannot uncover the nature of a singularity, but there are analytical treatments (Ref 4) that do this. The major problem is how to assess the implication for failure of such edge stress singularities, a problem as yet unresolved. The situation is reminiscent of fracture mechanics in the sense that stresses at a crack tip are theoretically infinite, thus singular. Fracture mechanics copes with this difficulty in terms of a criterion for crack propagation that is based either on the amount of energy required to open a crack or, equivalently, on the value of the stress intensity factor. Similar considerations seem to apply for edge singularities, but the situation is much more complicated, since a crack initiating at the edge will propagate between anisotropic layers. It appears, therefore, that the problem of edge failure must be relegated to experimentation for the time being.

Subsequent Failures. In many cases, laminates have considerable strength remaining after first-ply failure; the difficult and important problem arises of analytically determining subsequent failures. As noted, this problem is far from resolved and an active area of research in composite materials. A simplistic, well known approach to this problem is as follows: when initial failure takes place, the failure may occur in the fiber or in the matrix mode. In the first case, the stiffness in the fiber direction, E_L, is reduced; in the second case, the elastic properties, E_T and G_L, are reduced. These elastic properties are not reduced to zero, because the initial failure produces cracks in the layer and the uncracked regions remain bonded to adjacent layers. Although a precise estimate of these stiffness reductions is not yet available, the simplest (but drastic) assumption is that E_L reduces to zero in the fiber mode and that E_T and G_L reduce to zero in the matrix mode. Since a laminate will usually not survive a fiber-mode failure, the progressive- failure cases of interest are initial and subsequent failures in the matrix mode. If it is assumed that, for failure of a lamina group in the matrix mode, E_T and G_L of that group can be set equal to zero, eventually the basic assumptions of netting analysis result. For netting analysis, the ultimate load is defined by the state at which E_T and G_L vanish in all laminae.

To demonstrate these effects, some specific examples of membrane loadings will be considered. The unidirectional lamina properties used in the examples are listed in Table 1.

The predicted load-strain response of a $(0°/\pm45°)_s$ laminate subjected to three different membrane-loading environments is shown in Fig. 17, 18, and 19. For simplicity, failure analyses for these examples have been performed using the maximum-stress failure criterion.

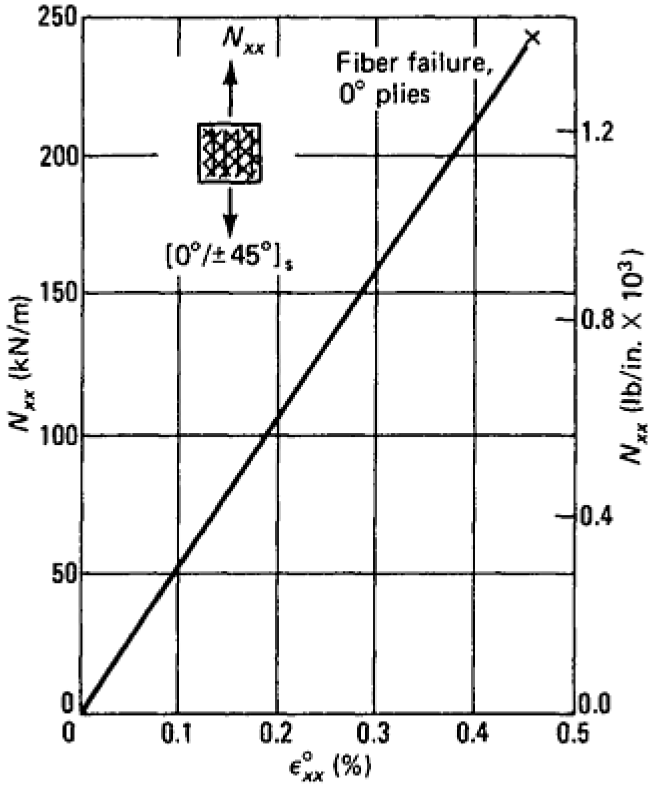

Fig. 17 Load-strain response, tensile N_{xx} loading

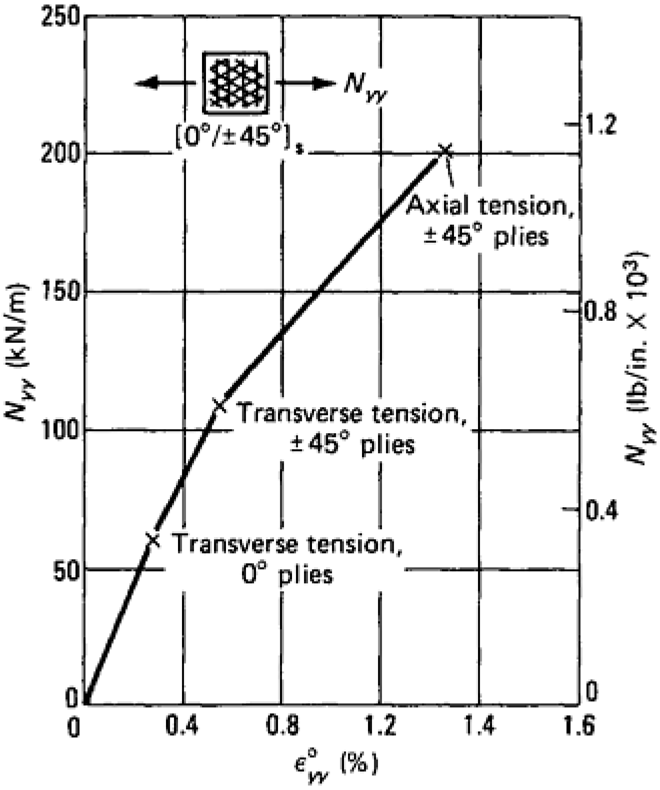

Fig. 18 Load-strain response, tensile N_{yy} loading

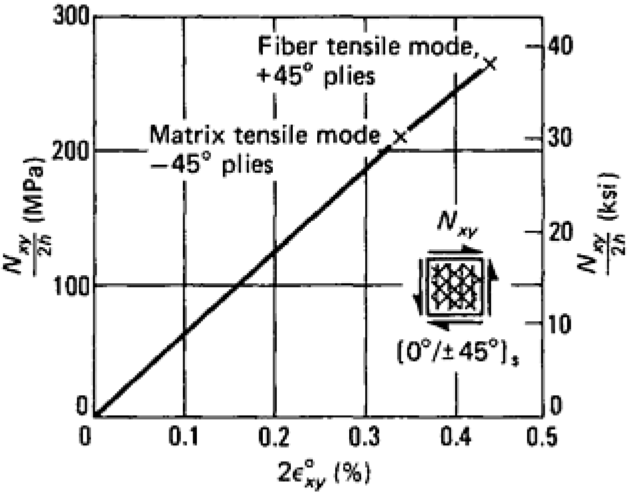

Fig. 19 Stress-strain response, N_{xy} loading

The laminate loading in Fig. 17 consists of uniaxial tension in the direction of the 0° fibers, or the laminate *x* direction. The laminate response is seen to be linear to the load where the 0° fibers fail in axial tension. Because the failure mode is fiber breakage, no additional load-carrying capability exists.

In Fig. 18, the laminate loading consists of uniaxial tension perpendicular to the 0° fiber direction, or in the laminate *y* direction. The laminate response in this example is not linear to first fiber failure. Two distinct knees exist in the load-strain response. The first slope discontinuity corresponds to a transverse tensile failure in the 0° fibers. At this point, the lamina properties for the 0° plies are modified to account for the damage. Thus, for the 0° plies, the moduli E_2 and G_{12} are set to zero, and the laminate properties are reformulated.

Subjecting this damaged laminate to additional loading then yields transverse tensile failure in both the 45° and–45° plies, resulting in the second knee in the load-strain curve. When a new laminate is again formulated with all plies having moduli E_2 and G_{12} set to zero, additional loading produces fiber compressive mode failure in the 0° plies (followed immediately by fiber tensile mode failure in the 45° and–45° plies), which corresponds to the ultimate strength under N_{yy} loading.

The final membrane-loading state considered is an applied N_{xy} (Fig. 19). The response under this shear loading produces a single matrix-mode failure before ultimate or fiber-mode failure.

Examination of the three figures reveals major differences in laminate response under different loading states, simply because the ply stress states are very different from each other. This is apparent in Table 4, in which the states of stress in each ply of the laminate are listed at first-ply failure under the three membrane loadings applied. The stresses listed in Table 4 demonstrate that at the three different first-ply failure loads, different stress components in different plies are critical. When subjected to N_{xx} loading, the fiber- direction stress in the 0° plies reaches the lamina strength value first, hence promoting failure. The other ply stresses are not critical at this load. Under N_{yy} loading, the first stress component to reach the lamina strength is the transverse stress in the 0° plies. Shear loading produces a critical stress in the–45° plies in transverse tension. Thus, the critical stresses depend on loading direction.

(a) (a) Critical stress value

The differences between first-ply failure and ultimate failure are shown in Fig. 20, in which the laminate failure surface for combined in- plane extensional stresses is shown for the laminate discussed above. The dashed curve defines the combination of applied laminate stresses for which the first-ply failure occurs in the matrix mode. The solid curve defines the combined laminate stress states, which result in failure of a ply in the fiber mode. Note that for most positive values of N_{yy}, a matrix-mode failure precedes the first fiber-mode failure. Conversely, for negative values of N_{yy}, the first-ply failure is always a fiber-mode failure. The large region between these two surfaces indicates the potentially limiting effect of low transverse and shear strengths of the individual plies and hence the limiting effect of the matrix properties.

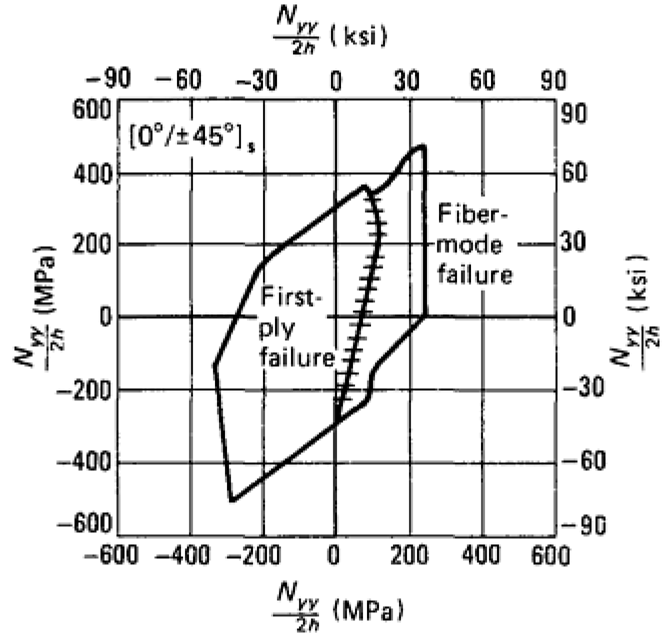

Fig. 20 Laminate failure surface for combined in-plane extensional stress states

The related failure surfaces for combined laminate membrane extensional and shear stress are presented in Fig. 21, which shows that for large membrane shear stresses, the first-ply failure is in the matrix mode. Again, the potential for performance improvement through changes in matrix properties appears to be worth considering.

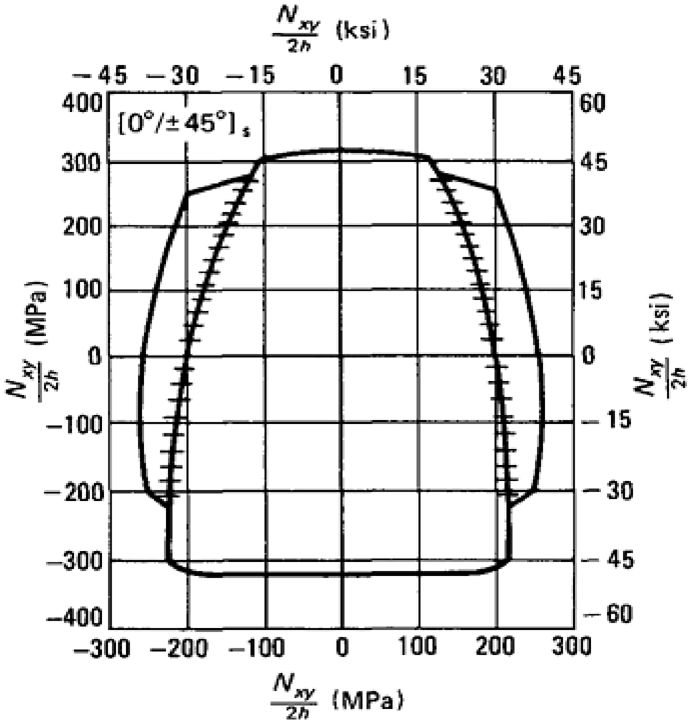

Fig. 21 Laminate failure surface for combined in-plane extensional and shear stress states

The failure surfaces of Fig. 20 and 21 illustrate the importance of knowing the difference between the loads causing first-ply failure and ultimate failure. It is first necessary to determine whether there is additional load capacity in the laminate beyond the point of first-ply failure. A necessary condition for this is stability of the laminate (that is, it must be able to carry loads) after the loss of laminae stiffnesses associated with matrix-mode failure. For example, an angle-ply laminate (±θ) experiencing matrix- mode failure when subjected to an axial load will be unable to carry that load. However, any laminate having fibers oriented in three or more directions can generally carry load after matrix- mode failure. An estimate of load-carrying capability can be obtained by using netting analysis.

In Table 5, laminate analysis predictions for first-ply failure strength and ultimate failure strength are shown, as well as netting analysis predictions for ultimate failure strength. In both the N_{yy} and N_{xy} loadings, the netting-analysis strength predictions are considerably larger than the first-ply failure laminate analysis predictions, indicating that considerable strength remains beyond first-ply failure. The netting analysis, however, predicts a lower strength than lamination theory for N_{xx} loadings, indicating that first-ply failure corresponds to ultimate failure. Because of the trends of the type indicated in Table 5, netting analysis can be a useful tool in composite strength predictions.

Table 5 Failure loads and modes, [0°/±45°]$_s$ laminate

Loading type	**Laminate analysis**						Netting analysis

Strength. A conventional definition of material strength is the maximum static stress, or combination of stresses, that can be carried by the material. For example, in a simple uniaxial tensile test, strength is the highest stress achieved before the material breaks. In a metal, other points on the material stress-strain curve have also been found to be significant in considering the maximum stress to be applied to a material; for example, the proportional-limit stress and the material 0.2% offset yield stress are valuable measures of material strength. Similarly, in composites, several characteristic stress levels should be considered in the evaluation of strength. The primary stress levels of interest are the stress at which first-ply failure occurs and the maximum static stress (stress resultant divided by laminate thickness) that the laminate can carry.

In the calculation of first-ply failure, residual thermal stresses must be considered. Residual stresses are the ply stresses induced in a laminate as a result of fabrication processes. Typical resin matrix composites are formed under a combination of elevated temperature and pressure, which promotes matrix curing. When the laminate is subsequently cooled to room temperature, significant residual processing stresses develop. How to include these stresses in the failure analysis presents a problem. The rationale for including them is obvious: the stresses exist after processing and can therefore be expected to influence the occurrence of first-ply failure. However, there is also a rationale for not including them. Because all resin matrix materials exhibit viscoelastic, or time-dependent, effects, a significant portion of the residual processing stresses can be assumed to dissipate through stress relaxation. Additionally, the processing stresses may be reduced through the introduction of transverse matrix microcracking. A limited amount of cracking may occur without significantly affecting the laminate elastic properties. This problem is complicated by the difficulty of measuring the residual stresses in a laminate and of observing first-ply failure during a laminate test.

From an analytical point of view, when laminae properties are known, it is possible to calculate a laminate stress-strain curve (including or excluding residual thermal stress effects) and determine first-ply failure,

subsequent ply failures, and maximum stress at failure. From an experimental point of view, it is possible to measure a laminate stress-strain curve and determine proportional-limit stress and maximum stress. The existence of these different characteristic stress levels in laminated composite materials must be recognized, just as both a yield stress and an ultimate stress are known to characterize metallic materials. These stress levels for composites, as for metals, must be used with different factors of safety. At present, the proper action seems to be to use analytical strength predictions (both first-ply failure and ultimate failure) in the preliminary design phase, and experimental strength values for final design.

When experimental strength data are used for laminates, the problem of combined loading conditions arises again. The difficulties of combined-load testing preclude the purely experimental approach; the uncertainties of failure mechanism cloud the choice of analytical interaction criteria. A reasonable approach appears to be represented by the following sequence: analytical calculation of ultimate strength via netting analysis, or any other straightforward method; use of the analytical result to define the shape of the interaction curve; use of experimental data for single-stress components to define amplitudes of the interaction curve; and confirmation via limited combined-stress testing for a condition of practical interest.

It is common practice in the aerospace industry to neglect the residual thermal stresses in the calculations of ply failure. Data to support this approach do not appear to be available. However, at the present time, damage tolerance requirements limit allowable strain levels in laminates to a range of 3000 to 4000 μm/m. This becomes the dominant design restriction and eliminates the need to resolve the effects of residual thermal stresses. As materials of improved impact resistance are developed, first-ply failure calculations will become more significant. It appears that thermal stresses should be included in first-ply failure calculations unless their omission were to create an improved degree of conservatism. Careful stress-strain testing of laminate coupons should be used to define design allowables.

Whichever stress values are used, design charts in the form of so-called carpet plots are of great value for the selection of the appropriate laminate. Figure 22 presents a representative plot of this type for the axial tensile strength of laminates having various proportions of plies oriented at 0°, ±45°, and 90°. Appropriate strength data suitable for preliminary design can be found for various materials in Ref 1 and 5.

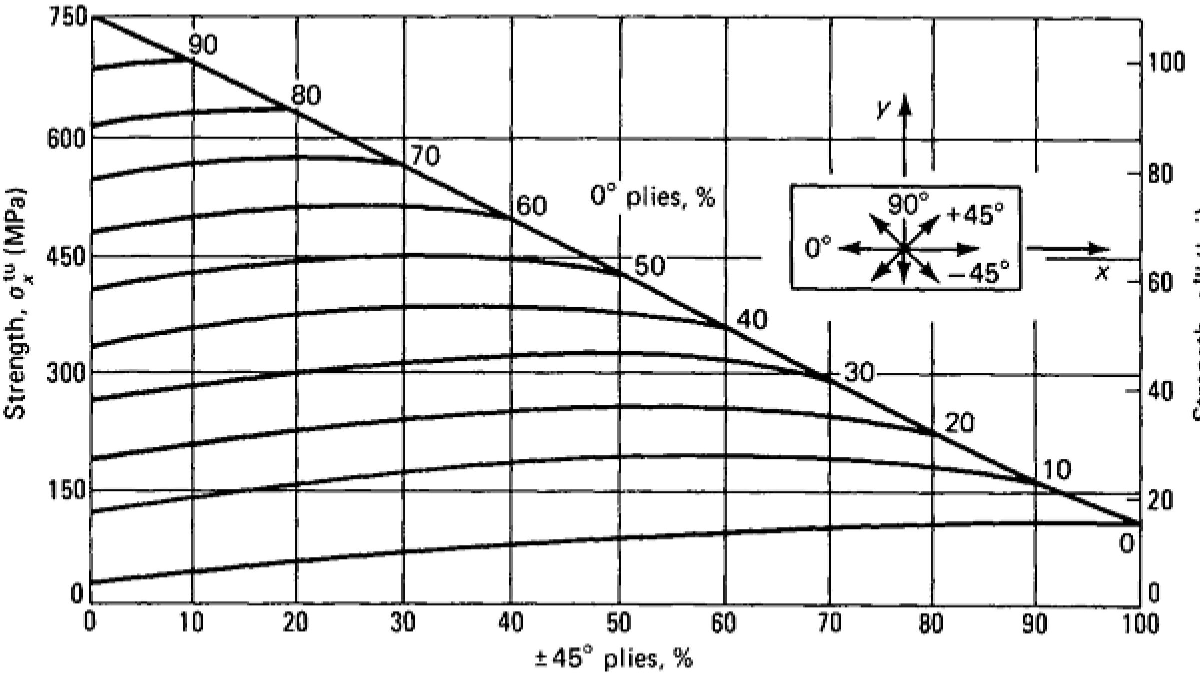

Fig. 22 Tensile strength of $[0°_i/\pm45°_j/90°_k]_s$ family of high-modulus graphite-epoxy laminates at room temperature

Fracture. The presence in a structure of a hole or other discontinuity introduces local stress concentrations that, if high, can result in initial localized failure. In metals, a common consequence of these effects is the formation of a small crack at the region of stress concentration. When there is a combination of high stress intensity and low resistance of the metal to crack propagation, the result is failure due to cracking. This failure mechanism is generally termed fracture. The mathematical technology that has been developed to treat this problem uses fracture mechanics methods and is called structural-integrity technology (Ref 1).

For composite laminates, the problem is complicated by the heterogeneity of the material, both at the microscale level and on a layer-to- layer basis. The complexity of this problem is illustrated by the laminate analysis of a plate with a hole. In a symmetric, balanced laminate having a circular hole and subjected to in-plane axial tension, the plate may be regarded as an orthotropic plate whose properties are the effective laminate moduli defined in the section “Laminate Properties” in this article. Solutions for stress concentrations in such a plate are available (Ref 6). The stresses obtained from such a solution define local values of the stress resultants, which can be treated as the stress resultants applied to the actual laminate. In general, at any point in the plate this will define a combined loading with all three stress resultants being nonzero. Following the laminate stress analysis methods, the stress state in each ply can then be found, thereby defining the variation of ply stresses throughout the plate.

Sample results obtained by the above procedure are presented in Fig. 23. The tangential stress around the periphery of the hole is plotted. The solid line represents the stress from the orthotropic plate analysis, which is equivalent to the average value of the in-plane ply stresses. At the edge of the hole, these average tangential stresses are the only nonzero components of the stress resultants; elsewhere in the plate all three stress resultants generally will be nonzero. The dotted lines are the tangential stresses in the individual plies computed from laminate theory. In general, all the stress components in each ply will be nonzero, even at the edge of the hole. This is the same effect as treated in the discussion of interlaminar stress: The boundary conditions are satisfied in laminate analysis only by the average stresses.

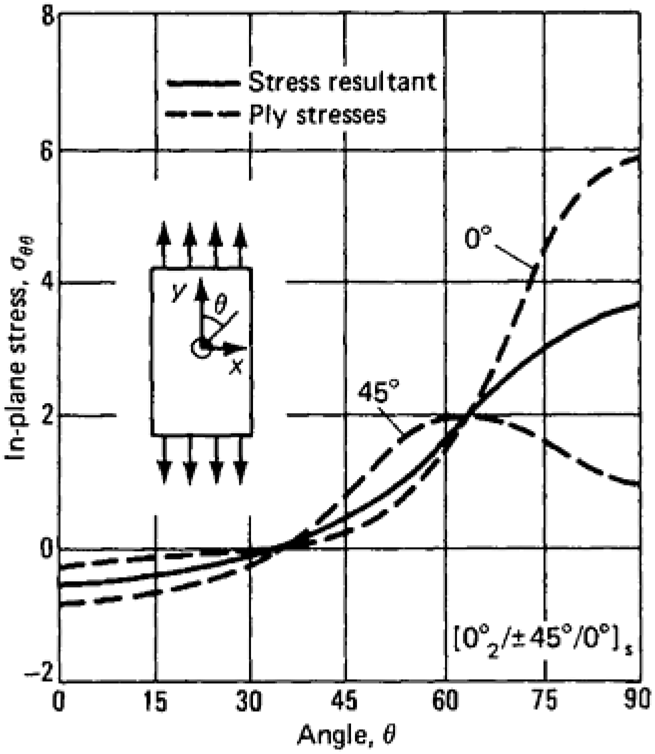

Fig. 23 Laminate theory calculations for stresses around a hole

In Fig. 23, the lamina stresses at the edge of the hole will not be correct, and interlaminar stresses will exist. These interlaminar shear stresses are shown in Fig. 24 at the various ply interfaces; the interlaminar normal stresses are shown in Fig. 25 at the midsurface interface. These interlaminar stresses are normalized with respect to the average applied stress. The magnitudes of these stresses are substantial.

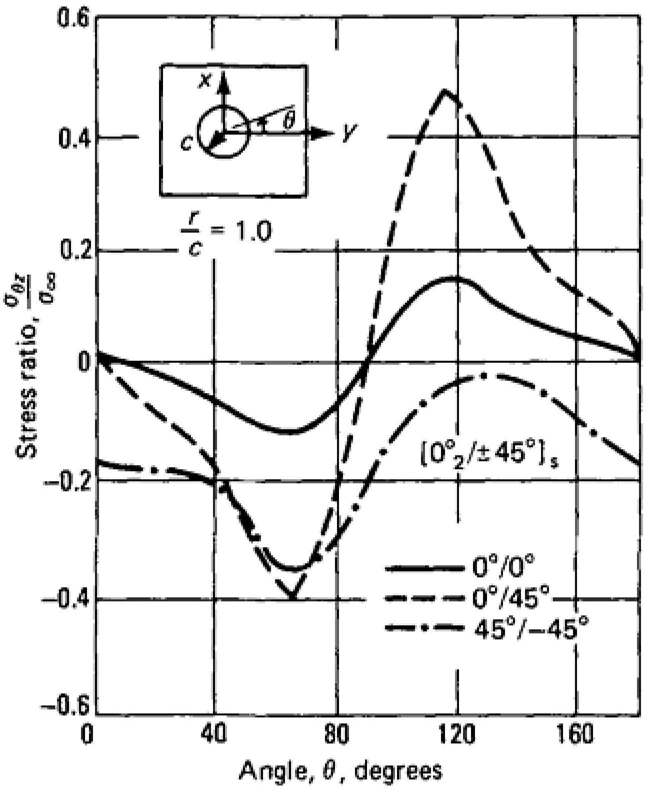

Fig. 24 Interlaminar shear stress at a hole

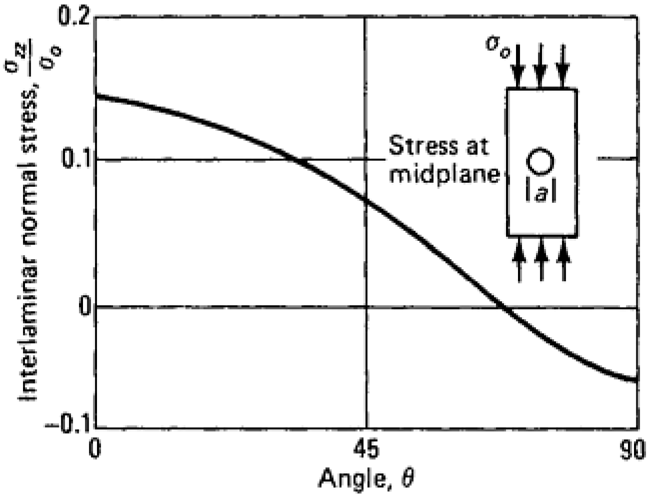

Fig. 25 Interlaminar normal stress at a hole

Associated with the interlaminar stresses is a modification of the in-plane stress state in each ply. Thus, as described for the free-edge problem, the only nonzero in-plane stress component in each ply at the edge of the hole is the tangential stress, $\sigma_{\theta\theta}$. This combination of in-plane and interlaminar stresses varies strongly with the coordinate. The variation takes place near the hole, where the average in-plane stress components are also varying. This complex state of stress can cause various failure mechanisms. Clearly, interlaminar disbonding is a possibility at various locations at or near the edge of the hole. Intraply matrix-mode failure in any ply is another possibility. At elevated stress levels, it is reasonable to expect diverse local matrix failures. This complex problem can be treated by the method described below.

Using the laminate properties methods, the effective in-plane laminate stiffnesses, E_x, E_y, and G_{xy}, may be calculated for any laminate. With these properties specified, a balanced symmetric laminate may be regarded, for purposes of structural stress analysis, as a homogeneous, orthotropic plate. Orthotropic elasticity theory may be used for evaluating stresses around a hole in such a plate (Ref 6). Examples of the resulting stress concentrations are shown in Fig. 26 for various carbon-epoxy laminates. The laminae orientation combinations influence both the magnitude and the shape of the stress variation in the vicinity of the hole. The high stresses at the edge of the hole may initiate fracture.

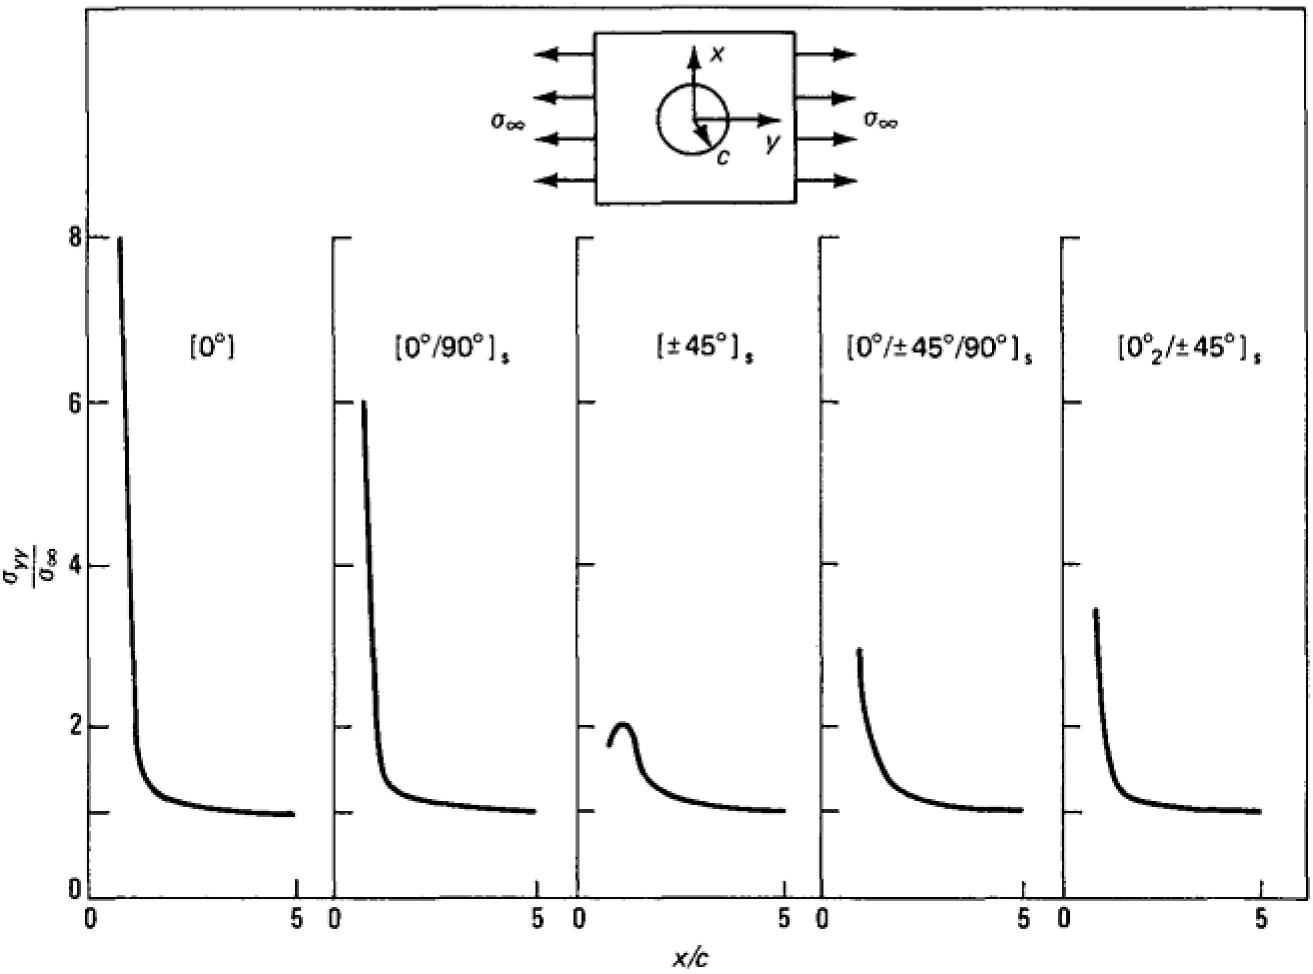

Fig. 26 Stress-concentration factors for a circular hole in a homogeneous, orthotropic, infinite plate

If the laminate fails as a brittle material, fracture will be initiated when the maximum tensile stress at the edge of the hole equals the strength of the unnotched material. In a tensile coupon with a hole, as in Fig. 26, the failure will occur at the minimum cross section and will initiate at the edge of the hole, where the stress concentration is at a maximum. The stress-concentration factor of interest is one that includes the finite- width effect, illustrated in Fig. 27 for an isotropic plate with a central, circular hole. Stress distributions are shown for various ratios of hole diameter, *a*, to plate width, *W*.

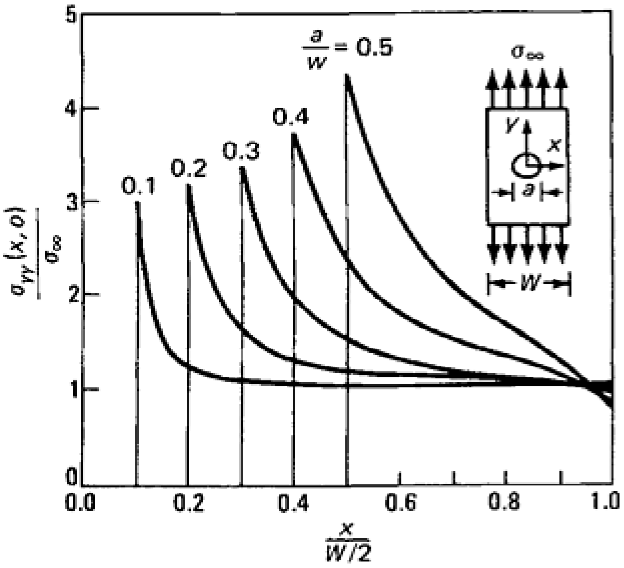

Fig. 27 Stress distribution around a hole in a finite- width plate

The basic stress-concentration factor for this problem is the ratio of the axial stress at the edge of the hole ($x=a/2$ and $y=0$) to the applied axial stress, σ_∞. For small holes in an isotropic plate, this factor is equal to 3. For large hole sizes, the average stress at the minimum section, σ_n, is higher than the applied stress, σ_∞, and is given by the relation:

$$\sigma_n = \frac{\sigma_\infty}{\left(1-\frac{a}{W}\right)} \qquad \text{(Eq 88)}$$

The net section stress-concentration factor, K_n, is the ratio of the maximum stress to this average stress. Thus:

$$K_n = \frac{\left[\sigma\left(\frac{a}{2},0\right)\right]/\sigma_\infty}{1-\frac{a}{W}} \qquad \text{(Eq 89)}$$

Laminate fracture for the elastic-brittle case will occur at stress σ_{fr}, that is:

$$\sigma_{fr} = \frac{\sigma^{tu}}{K_n} \qquad \text{(Eq 90)}$$

A material that fails in this fashion is called a notch-sensitive material. In contrast, a ductile material will yield locally, alleviating the stress- concentration effect. In the extreme, this will result in a uniform stress distribution at the net section, as shown in Fig. 28. For this case, failure will occur when the average net section stress equals the material strength, or:

$$\sigma_{fr} = \sigma^{tu}\left(1-\frac{a}{W}\right) \qquad \text{(Eq 91)}$$

A material that fails in this way is known as a notch-insensitive material. Practical laminates may be expected to fail in a fashion that is neither of these two extreme cases.

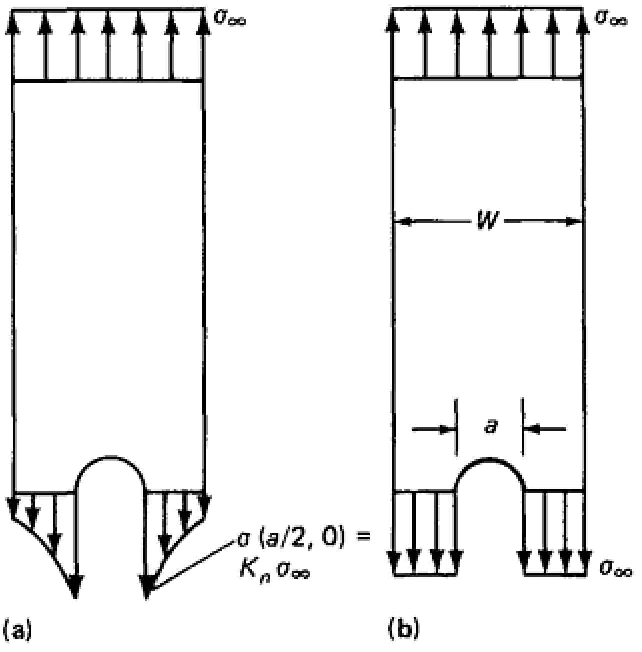

Fig. 28 Idealized limit cases for failure. (a) Notch-sensitive. (b) Notch-insensitive

Various matrix damage effects are expected to occur at the maximum-stress locations. These localized damages reduce the material stiffness and diminish and spread the stress-concentration effects. As a result, although fracture will occur because of stress concentration, it can be expected to occur because of lesser stress-concentration factors than those calculated from orthotropic elastic stress analysis of the notched laminate. Semiempirical methods for evaluating this reduction in stress concentration have been proposed.

The point stress theory (Ref 7) proposes that the elastic-stress distribution curve (Fig. 26) be used but that the stress concentration be selected at a distance, d_0, from the edge of the hole. Thus, the numerator of Eq 89 should

be evaluated at the point $x=a/2+d_0$. The characteristic length d_0 must be evaluated experimentally. The average-stress theory (Ref 7) takes a similar approach by proposing that the elastic-stress distribution be averaged over a distance, a_0, to obtain the stress concentration. Thus:

$$K_n = \frac{\int_{a/2}^{(a/2)+a_0} \sigma_y d_x}{\int_{a/2}^{W/2} \sigma_y d_x} \qquad \text{(Eq 92)}$$

Again, the characteristic dimension, a_0, must be found experimentally. The two approaches are illustrated in Fig. 29. For both methods, the resulting stress concentration is used in Eq 90 to define the fracture stress.

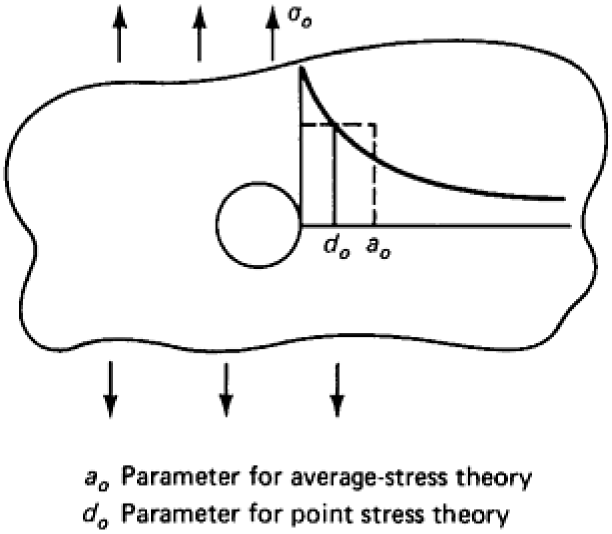

Fig. 29 Representation of characteristic dimensions for semiempirical fracture theories

Representative results are plotted in Fig. 30 to illustrate the differences associated with the different types of material behavior. The ratio of strength of the plate with a hole, σ_{fr}, to that of an unnotched laminate, σ^{tu}, is plotted as a function of hole size. For the notch-insensitive material, this course clearly shows a linear decrease in failure stress with hole size due to the reduction in net cross-sectional area. The lower curve, for a notch-sensitive material, shows an immediate drop in strength with the introduction of even a small hole due to the local stress-concentration effect. The semiempirical theories (both have similar effects) show a rapid but more modest drop due to stress concentration. Experimental data for laminates support the use of either of the semiempirical theories for fracture of a laminate with a hole.

Intra- and Interlaminar Cracking

The ply cracking and delamination discussed earlier may be analyzed using an energy method. This method basically integrates the laminate stress analysis and the concept of effective material flaws into the classical theory of fracture mechanics. The laminate stress analysis is used to determine three-dimensional state of stress in constituent plies. Elastic fracture mechanics criteria are used to describe the propagation behavior of matrix cracks. However, in order to render a rational prediction for matrix crack initiation, the concept of effective material flaws is first introduced.

In this concept, two basic types of effective flaws are postulated. First, for the unidirectional ply, there exists a known distribution of effective intralaminar flaws, lying in the ply thickness direction, as shown in Fig. 31(a). These flaws effect intralaminar cracking. Second, in each ply- to-ply interface, there exists a known distribution of effective interfacial flaws, lying parallel to the ply interface, as shown in Fig. 31(b).

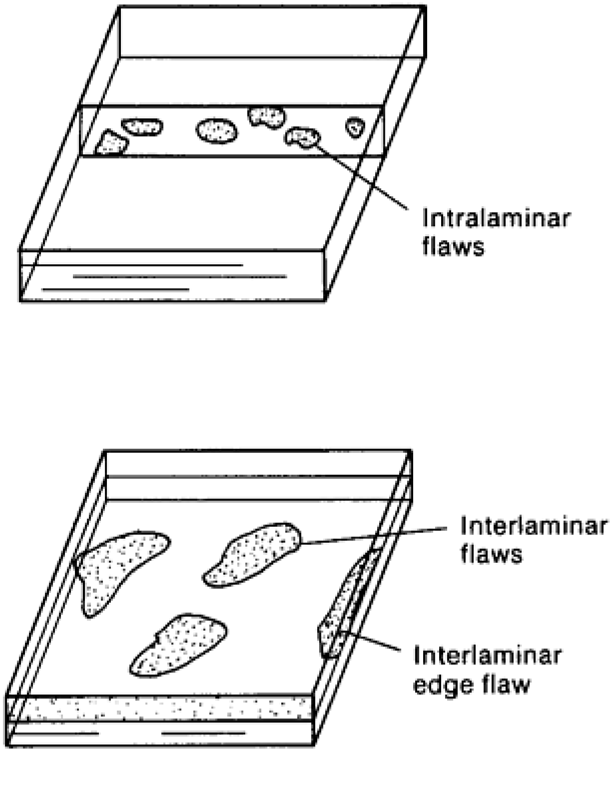

Fig. 31 View of (a) effective intralaminar flaws. (b) Effective interlaminar flaws

At this point, the effective flaws remain a hypothetical quantity, though they are considered inherent properties of the basic ply material system. It is postulated that the presence of the effective flaws does not effect any change in the elastic constitutive properties of the ply. But, at some critical laminate loading, one (or more) of the flaws can be transformed into a matrix crack that is measurable at the phenomenological scale.

The condition governing the transformation from a particular effective flaw to a detectable matrix crack is provided by a criterion of the theory of brittle fracture (Ref 8). Because the size and the location of a particular flaw are known, it is possible to perform an elastic stress analysis by treating the flaw as a crack; the crack-tip stress intensity factor $K(a_0, \sigma_0)$ or the strain energy release rate $G(a_0, \sigma_0)$ can be calculated in terms of the initial crack (flaw) size, a_0, and the applied laminate load, σ_0. The condition for a_0 to propagate and to become detectable is given, for example, by:

$$G(a,\sigma_0) = G_c \quad \text{at } a=a_0 \qquad \text{(Eq 93)}$$

where G_c is the material fracture toughness against the considered mode of matrix crack propagation. The stability of propagation is determined by the functional dependence of G on the crack size, a. Namely, if $dG/da > 0$ at $a=a_0$, the propagation is unstable; if $dG/da < 0$, the propagation is stable; that is, there is no crack growth.

Interlaminar Cracking, Free-Edge Delamination

The energy approach outlined previously has been applied to analyze the initiation and propagation of free-edge delamination (Ref 9, 10). In order to illustrate the specific procedures involved in the energy analysis, let us consider the $[\pm 25°/90°]_s$ tension coupon. When this coupon is loaded in uniaxial tension ϵ_0, significant interlaminar stresses develop near the free edges. In fact, these interlaminar stresses are large enough to cause free-edge delamination as the first failure mode in the laminate. Of course, the question is at what critical ϵ_0 and in which ply interface will the delamination initiate. Also, the question of delamination stability must be answered.

Interface Flaw. To answer these questions, begin with the assumed distribution of interfacial (effective) flaws. Identify in each ply interface and along the laminate free edge the most dominant effective flaw having a uniformly elongated shape with a width a_0 (Fig. 31b). This interfacial flaw is capable of transforming into an interfacial crack as soon as the laminate stress field reaches the critical level.

Energy Release Rate Curve. Second, the most dominant edge flaw is treated as a crack of the same size, a_0, and the crack tip strain energy release rate $G(a_0, \epsilon_0)$ is calculated.
The strain energy release rate, G, when calculated numerically, can be expressed in explicit terms of the crack size a, and the applied laminate strain, ϵ_0.

$$G(a,\varepsilon_0) = C_\varepsilon(a)\, 2t\varepsilon_0^2 \quad \text{(Eq 94)}$$

where $C_\epsilon(a)$ is a coefficient function explicitly depending on a but implicitly depending on the location of a ply interface, the ply stacking sequence of the laminate, and the ply elastic constants.
If the residual thermal stresses due to laminate curing are significant and their effects are to be included in the calculation of G, it then is necessary to define the laminate stress-free temperature, T_0. Usually, T_0 is approximately the same as the laminate curing temperature. Thus, at the ambient temperature, T, the laminate is exposed to a uniform thermal loading, $\Delta T = T - T_0$. In such a case, the strain energy release rate due to the combined loading of ϵ_0 and ΔT can be expressed as:

$$G(a,\varepsilon_0,\Delta T) = \left[\sqrt{C_\varepsilon}\ \varepsilon_0 - \sqrt{C_T}\Delta T\right]^2 (2t) \quad \text{(Eq 95)}$$

where C_T is another coefficient function expressed in terms of a. Note that a minus sign associated with the ΔT term is only a convention, because the value of ΔT is always negative.
Figure 32 shows the computed strain energy release rate coefficient functions C_ϵ for interfacial cracking in the midplane (90°/90° interface) and the–25°/90° interface. Note that the computed C_ϵ curve for delamination in the midplane contains exclusively mode I energy, as it should, while the C_ϵ curve for delamination in the–25°/ 90° interface contains both mode I and mode III energies. The ratio of mode I energy to mode III energy in the latter case is about 0.8. Similarly, Fig. 33 shows the strain energy release rate coefficients C_T for delamination in each of the same two ply interfaces.

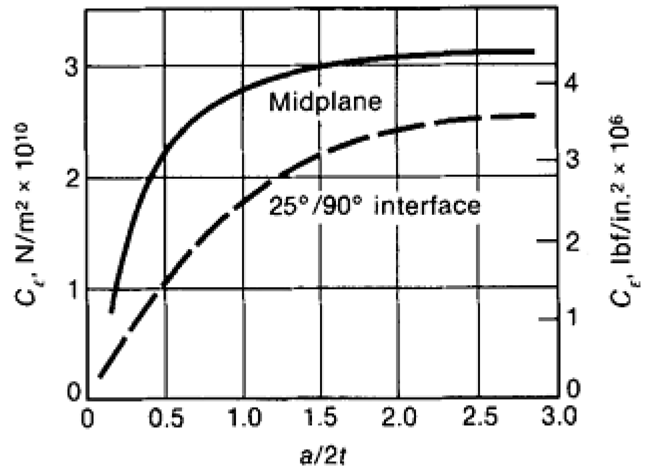

Fig. 32 Strain energy release rate coefficients, C_ϵ, for interfacial cracking in the 90°/90° and the–25°/ 90° interfaces of the $[\pm 25°/90°]_s$ laminate

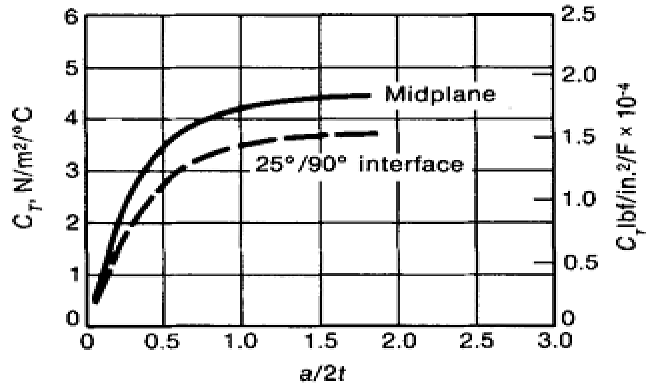

Fig. 33 Strain energy release rate coefficients, C_T, for interfacial cracking in the 90°/90° and the–25°/ 90° interfaces of the $[\pm 25°/90°]_s$ laminate

It is seen that the characteristics of all the energy curves are similar. Namely, the curve rises sharply from 0 at $a= 0$ and reaches a limiting value at $a=a_m$. The physical meaning of a_m is not exactly known. However, the free-edge effect may be interpreted as fully developed when a delamination reaches the size a_m. The size of a_m is approximately of the order of a couple of ply thicknesses for most laminate situations (Ref 10).

Determining the Exact Delaminating Interface. A comparison of magnitudes of the strain energy release rate curves for the $[\pm 25°/90°]_s$ laminate shown in Fig. 32 and 33 shows that edge delamination in the laminate midplane would release more strain energy than delamination in the–25°/90° interface. Whether the midplane (mode I) or the–25°/90° interface (mixed modes) will delaminate, however, is determined by the fracture criterion of Eq 93, for which the material fracture toughness G_c and the effective flaw size a_0 are yet to be specified.

Laboratory experience with graphite-epoxy laminates has shown that G_c measured for mode I delamination is generally lower than that measured for mixed-mode delamination. In fact, mixed-mode G_c has been found to increase with the amount of shearing mode (11, 12 13). Assuming this is the case in the present example, it is then possible to conclude that the laminate midplane will delaminate first. Hence, the C_ϵ and C_T curves for the midplane and G_c for mode I should be used in Eq 93.

Determining the Critical Laminate Strain. With the interface and mode of delamination identified, the last information needed in using Eq 93 is the size of a_0. Because a_0 is a hypothetical quantity, however, it is essentially a random variable. Yet, given the functional relationship $G(a)$ as expressed in Eq 94 or 95 and the values for ΔT and G_c, a one-to-one relationship between ϵ_0 and a can be obtained from Eq 93 (Fig. 34). If all the possible values of a_0 are represented by some probability function, $f(a_0)$, then there is a corresponding range of ϵ_0 values for which Eq 93 is satisfied. While the exact size, a_0, of the most dominant effective flaw is not known, the minimum critical ϵ_0, which is associated with all values of $a_0>a_m$, can now be determined from Fig. 34.

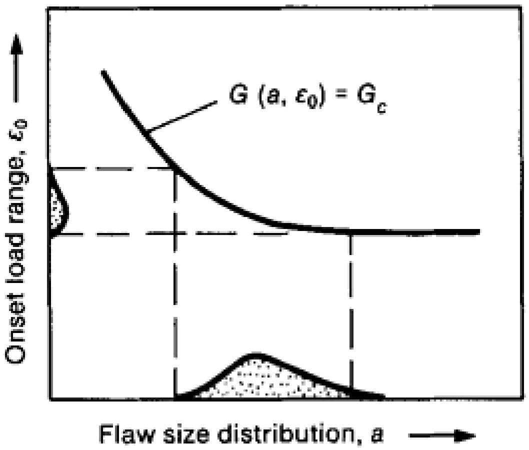

Fig. 34 Fracture relationship between the critical load range (ϵ_0) and the effective flaw size distribution $f(a)$

As mentioned before, the value of a_m is on the order of one or two ply thicknesses, while the actual initial edge delamination observable at the macroscale is on the order of the laminate thickness. Hence, delamination onset can be predicted by the minimum critical strain associated with $a_0>a_m$. Thus, from Eq 93 and in conjunction with Eq 95, the predicted minimum critical strain for initial delamination propagation is given by:

$$(\varepsilon_0)_{cr} = \frac{\left[\sqrt{(G_c/2t)} + \sqrt{C_T}\,\Delta T\right]}{\sqrt{C_\varepsilon}} \quad \text{at } a > a_m \qquad \text{(Eq 96)}$$

where the coefficients C_ϵ and C_T are taken from the calculated energy curves for the midplane.

To determine the propagation stability, the functional form of C_ϵ and C_T for all $a>a_m$ is examined. Accordingly, it is concluded that the stability behavior of free-edge delamination is neutral. In reality, however, the propagation is generally stable, with the degree of stability depending on whether other modes of matrix cracking develop subsequent to delamination initiation.

Intralaminar Cracking, Transverse Cracks

The energy analysis procedures outlined above for the free-edge delamination problem have also been applied to simulate intralaminar cracking in laminates (Ref 14). Here, the $[0°/ 90°]_s$ graphite-epoxy tensile coupon serves as an example. As discussed earlier, free-edge effect is relatively unimportant when the coupon is under uniaxial tension. Hence, an analysis of transverse cracking in the 90° layer can be developed without regard to the influence of free-edge stresses.

Initiation and Growth Characteristics. At the macroscopic scale, the formation of a transverse crack is simply a sudden separation of the 90° layer. When this happens, it often gives off acoustic emissions. At the microscopic scale, however, the exact nature of the event is unclear. It may be postulated again that the crack is caused initially by the coalescence of those material microflaws that lie in the thickness direction in the 90° layer. The effect of this coalescence is represented by the propagation of an effective flaw (Fig. 31a) in the thickness direction. The crack, however, is unable to propagate through the 0° ply and is either arrested at or blunted to propagate along the 0°/90° interface. The latter then becomes a localized delamination. In either case, the propagation is not catastrophic. This allows an increase of the applied tension, which, in turn, can cause another transverse crack to form at another location. In this manner, a series of transverse cracks can be formed along the length of the coupon as a function of the tension loading.

Figure 35 shows a plot for the number of transverse cracks (per centimeter length) versus applied tension relationships, obtained by testing a family of $[0°/ 90°_n /0°]$ coupons (n= 1, 2, 3, 4) made of the T300/934 graphite-epoxy system (Ref 15). From the plot, it can be seen that for the n= 1 coupon, transverse cracking did not occur until the load had reached the critical level, causing fiber breaking in the 0° plies. For the other three coupons, however, each yielded a cumulative crack development curve that is characteristically distinct from the others. These results clearly indicate that the occurrence of any one particular crack in a given coupon is essentially probabilistic in nature but that the developmental character of the cumulative cracks as a whole seems to follow a rather deterministic rule.

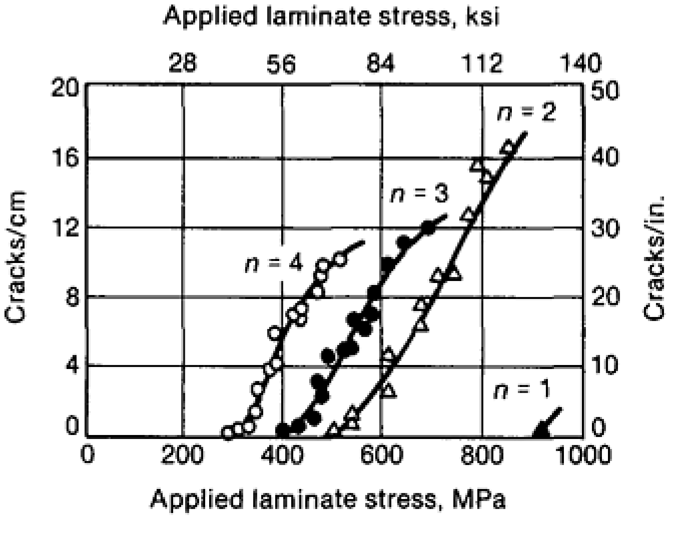

Fig. 35 Experimental crack density versus load plots for a family of T300-934 $[0°/90°_n/0°]$ laminates under uniaxial tension, 2 specimens each. n= 1, 2, 3, 4

Effective Flaws. Now, for the sake of simplicity, it may be assumed that the effective intralaminar flaws are one-dimensional, being oriented in the ply thickness direction, as shown in Fig. 36. The linear size of an individual flaw is denoted by $2a$, and its location is denoted by x. Then, for the unidirectional ply (thickness $2t$), the discrete random variables (a_i, i= 1, M) and (x_i, i= 1, M) characterize the size and the location distributions of the effective intralaminar flaws. At this point, the exact values for (a_i) and (x_i) are not known, but are assumed to be inherent ply properties. As such, these can be determined by some suitable experimental measurements to be discussed subsequently.

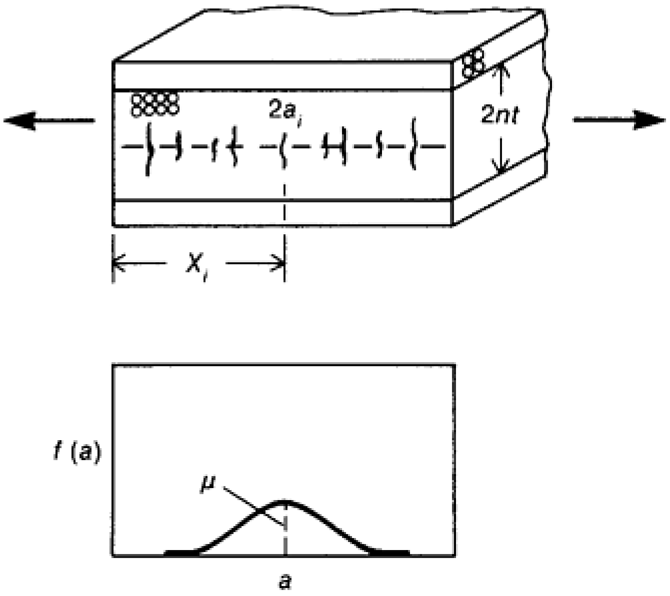

Fig. 36 Idealized effective intralaminar flaw distribution in the 90° layer

When two or more 90° plies are grouped together, such as in the [0°/90°$_n$/0°] coupons with n> 1, the effective flaw size distribution in the grouped plies will be different from that of the single ply, although their spacing distribution may be assumed to be the same. Here, a volumetric rule (Ref 16) can be used to express the flaw size distribution, ($a_{i,n}$), in n-plies in terms of the flaw sizes, (a_i), of the single ply:

$$a_{i,n}=a_i(n)^{2/\alpha} \qquad \text{(Eq 97)}$$

where i= 1, M, and α is an arbitrary constant related to the distributional characteristics of (a_i) and the particular volumetric rule used in deriving the relationship in Eq 97 (see, for example, Ref 16).

Onset of the First Crack. The [0°/90°$_n$/0°] coupon is now considered under the applied tensile strain, ϵ_0, as shown in Fig. 36. Each of the flaws is capable of propagating into a transverse crack. The propagation of any one of the flaws, say the ith flaw a_i, is governed by Eq 93. There, the strain energy release rate $G(a_i, \epsilon_0, \Delta T)$ associated with the ith flaw must first be calculated. In addition, the fracture toughness, G_c, must also be determined a priori. It is noted that for the present problem, transverse cracking is essentially in mode I. Hence, G_{Ic} should be determined first and then used in Eq 93.

The calculation of $G(a_i, \epsilon_0, \Delta T)$ can be performed by finite-element procedures. The calculated G is then expressed in the form of Eq 95. Figures 37 and 38 show, respectively, the $C_\epsilon(a)$ and $C_T(a)$ functions for n= 1, 2, 3, 4. Here, the unique character of the C_ϵ or C_T curves is worth noting. It is seen that both C_ϵ and C_T increase sharply from a= 0 to reach their respective maxima, $C_{\epsilon,\max}$ and $C_{T,\max}$; these maxima occur at about three-fourths the thickness of the 90° layer. After this point, they both decrease toward the 0°/90° interface at a=nt. This behavior is consistent with the observed fact that transverse cracking can be initially unstable (that is, in giving off acoustic emissions) but is immediately arrested at the 0°/90° interfaces.

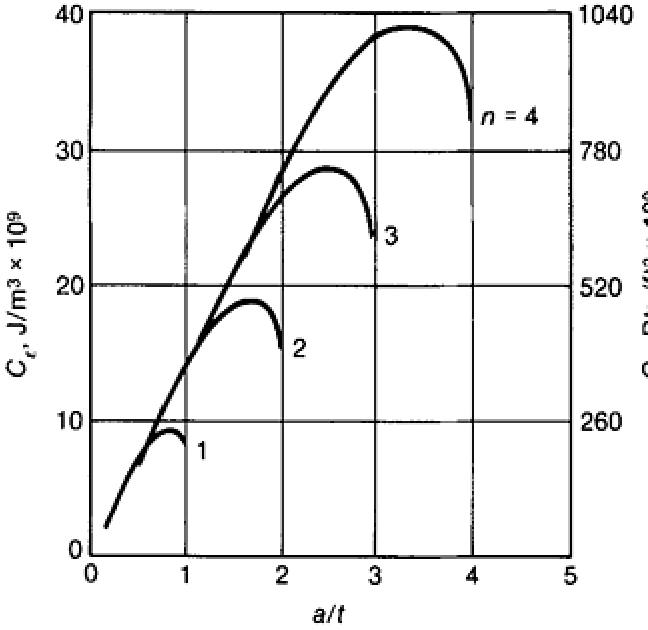

Fig. 37 Strain energy release rate coefficients, C_ϵ, for transverse cracking in [0°/90°$_n$/0°] laminates, n= 1, 2, 3, 4

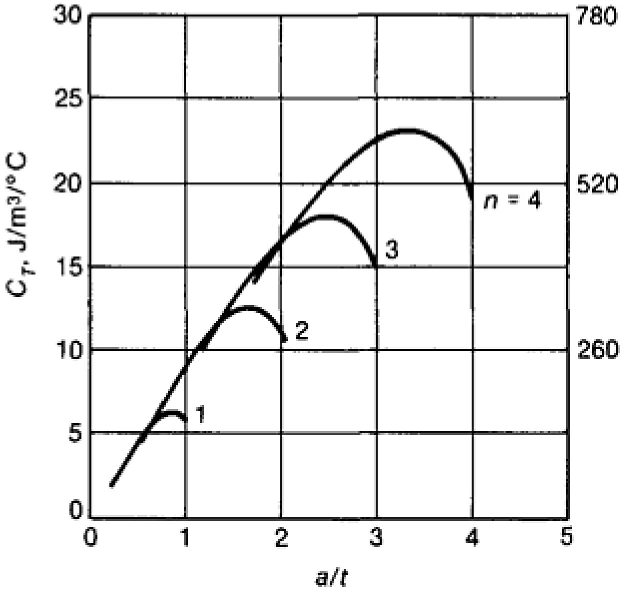

Fig. 38 Strain energy release rate coefficients, C_T, for transverse cracking in [0°/90°$_n$/0°] laminates. n= 1, 2, 3, 4

Now, for the first crack to form, let the largest of (a_i) be denoted by a_{max}. Then, the critical strain (ϵ_0) for the onset of the first crack is given by Eq 96 for a=a_{max} and G_c=$G_{T\ c}$.

Actually, because each (a_i) must be smaller than the half-thickness of the 90° layer, nt, and in all likelihood, a_{max} is only slightly less than nt, a minimum $(\epsilon_0)_{cr}$ can be found by substituting $C_{\epsilon,max}$ and $C_{T\ ,max}$ in Eq 96.

Shear Lag Effect. Assume that the transverse crack is arrested at the 0°/90° interfaces. Then, the local tensile load formerly carried by the unbroken 90° layer is now transferred to the adjacent 0° plies. If the 0°/90° interface bonding is strong, a slip of the interface (delamination) is not possible. Then, a localized interlaminar shear stress τ_{xz} is developed near the transverse crack termini, as shown in Fig. 39. This interlaminar shear stress decays exponentially a small distance away from the transverse crack, and at the same time, the in situ tensile stress σ_x in the 90° layer regains its far-field strength. This local load transfer zone, known as the shear lag zone, is proportional to the thickness of the 90° layer, 2nt. Hence, the thicker the 90° layer, the larger the shear lag zone. For the present problem, one side of the shear lag zone is about 12nt.

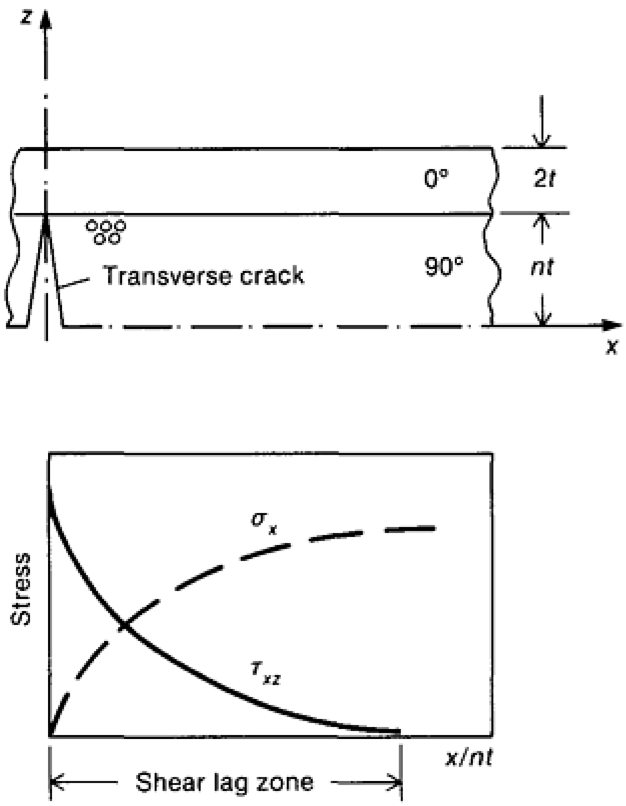

Fig. 39 Shear lag zone due to a transverse crack in the [0°/90°]$_s$ laminate

If there is an effective flaw located near a transverse crack (Fig. 40), the flaw is under the influence of the shear lag casted by the transverse crack. The degree of influence depends on their relative distance, *s*. Specifically, if the size of this flaw is 2*a*, and the associated strain energy release rate is $G(a, \epsilon_0, \Delta T, s)$, then the shear lag effect on the strain energy release rate can be expressed by the factor, $R(s)$, defined by:

$$R(s) = \frac{G(a, \varepsilon_0, \Delta T, s)}{G(a, \varepsilon_0, \Delta T)} \qquad \text{(Eq 98)}$$

where $G(a,\epsilon_0,\Delta T)$ is calculated without the influence of shear lag. It may be noted that the numerical range of $R(s)$ is between 0 and 1, as shown in Fig. 40.

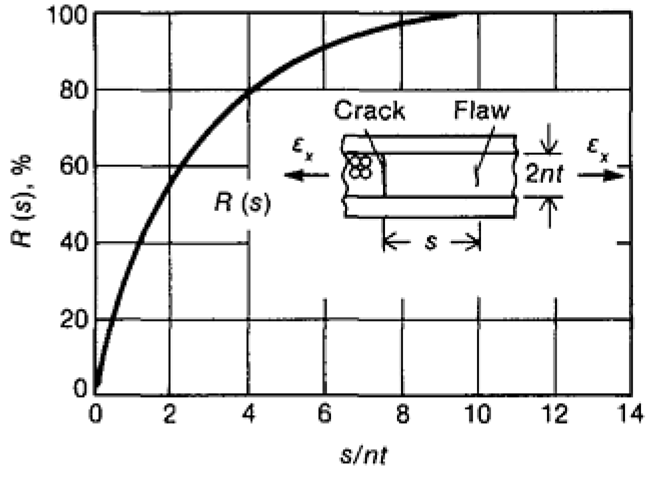

Fig. 40 Strain energy release rate retention factor, *R*(*s*)

If a flaw is situated between two consecutive cracks, then it is under the shear lag effect from both cracks. The associated strain energy release rate, G^*, is given by:

$$G^*(a,\epsilon_0,\Delta T) = R(s_l)G(a,\epsilon_0,\Delta T)R(s_r) \qquad \text{(Eq 99)}$$

where s_l and s_r are distances from the flaw to the left crack and the right crack, respectively.

Multiple Cracks. After the formation of the first crack from the largest flaw in (a_i), subsequent cracks can form from the remaining flaws at laminate strain appropriately higher than $(\epsilon_0)_{tr}$. A Monte Carlo search routine is then commenced to determine the next flaw that yields the highest strain energy release rate G^*, with the shear lag effect casted by any existing crack or cracks included. The laminate strain corresponding to the next crack, which should be higher than $(\epsilon_0)_{cr}$, is determined by using G in Eq 96.

Successive searches for the next most energetic flaws follow, and the entire load sequence of transverse cracks is simulated. In essence, this search procedure mimics the transverse cracking process as it would occur naturally.

Determining the Effective Flaw Distribution. The difficulty in the preceding simulation procedure lies in the fact that the effective flaws are hypothetical quantities and that they can only be determined indirectly at the macroscale. Appropriate experiments in which distributed intralaminar cracks occur must be devised.

In Ref 16, the effective flaw distribution in $[90°_2]$was determined by testing $[0°_2/90°]_s$ tension coupons. The shaded band in Fig. 41 was formed by test data obtained from four specimens, plotted in terms of crack density versus applied tension (average laminate stress). This band, statistically speaking, resembles a cumulative formation behavior of the transverse cracks as a function of the applied tension. The band possesses a certain position relative to the stress scale, a certain characteristic curvature, and an asymptotic value in the crack density scale.

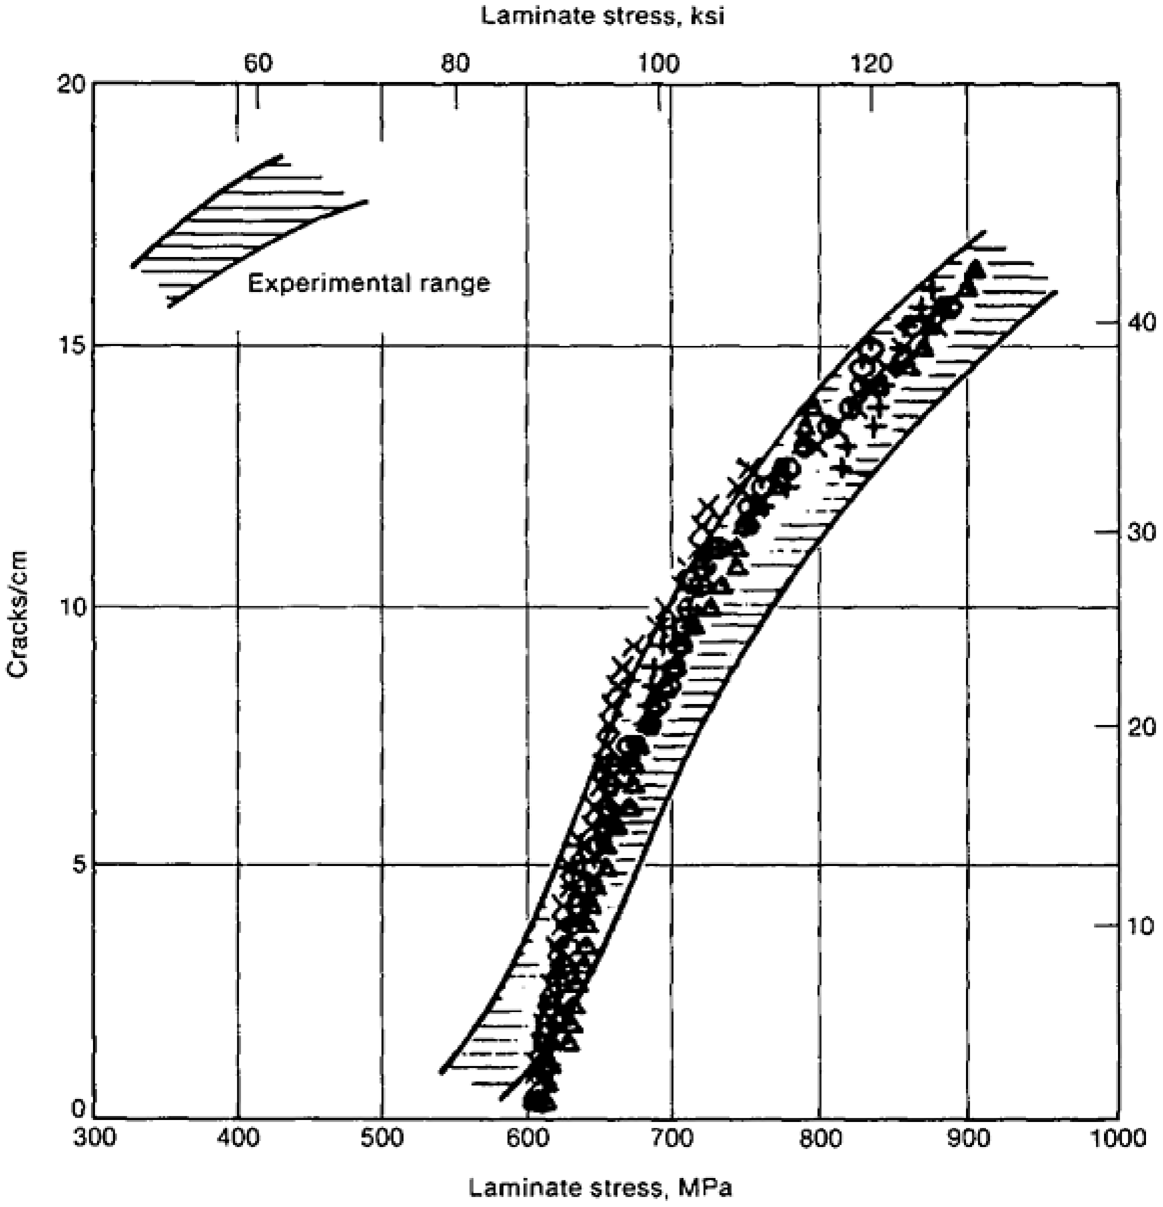

Fig. 41 Experimental (shaded) and simulated (points) transverse crack density versus laminate tension relations. Data from four $[0°_2/90°]_s$ coupons

This band is used to determine the flaw distribution in the [$90°_2$] layer. To do so, a random number generation scheme is employed. First, the number of flaws, *M*, in a unit length of the 90° layer is assumed. Second, a set of *M* random values is generated in the interval of (0,1). These *M* random values are assigned to be (x_i), which are the locations of the flaws along the unit length of the 90° layer. Third, the sizes of the *M* flaws (a_i) are described by a Weibull cumulative function:

$$F(a) = 1 - \exp\left[-\left(\frac{a}{\beta}\right)^{\alpha}\right] \qquad \text{(Eq 100)}$$

with the parameters α and β so far being unknown.

A new set of *M* random values is again generated in the interval (0,1). These values are then assigned to (F_i), corresponding to the values of $F(a)$ at $a=a_i$. Thus, for appropriately assumed values of α and β, one determines from Eq 100 the flaw size a_i for each assigned value of F_i.

With the flaw distribution (sizes and locations) now characterized, though the values of α, β, and *M* are still assumed, a simulation of the transverse cracking process can be performed as outlined previously. The correct choices of α, β, and *M* must be ones that closely simulate the experimental band shown in Fig. 41. Generally, α primarily affects the curvature of the band, β shifts the band along the stress scale, and *M* determines the asymptotic value of the band on the crack density scale (Ref 16). Figure 41 shows the crack density development relations for four simulated specimens, along with a set of appropriately chosen α, β, and *M* values.

With α, β, and *M* chosen from the preceding experiment, flaw size distribution in any number of grouped 90° plies can be found using Eq 97. For example, the band in Fig. 42 represents the experimental results from four [$0°_2/90°_2$]$_s$ coupons, while the simulated results for four samples of the same coupons are shown by scattered dots. Figure 43 shows a similar comparison for four [$0°_2/90°_4$] coupons. In both cases, the basic flaw distribution found from the [$0°_2/90°_2$]$_s$ coupons was used in conjunction with Eq 97 in the simulation.

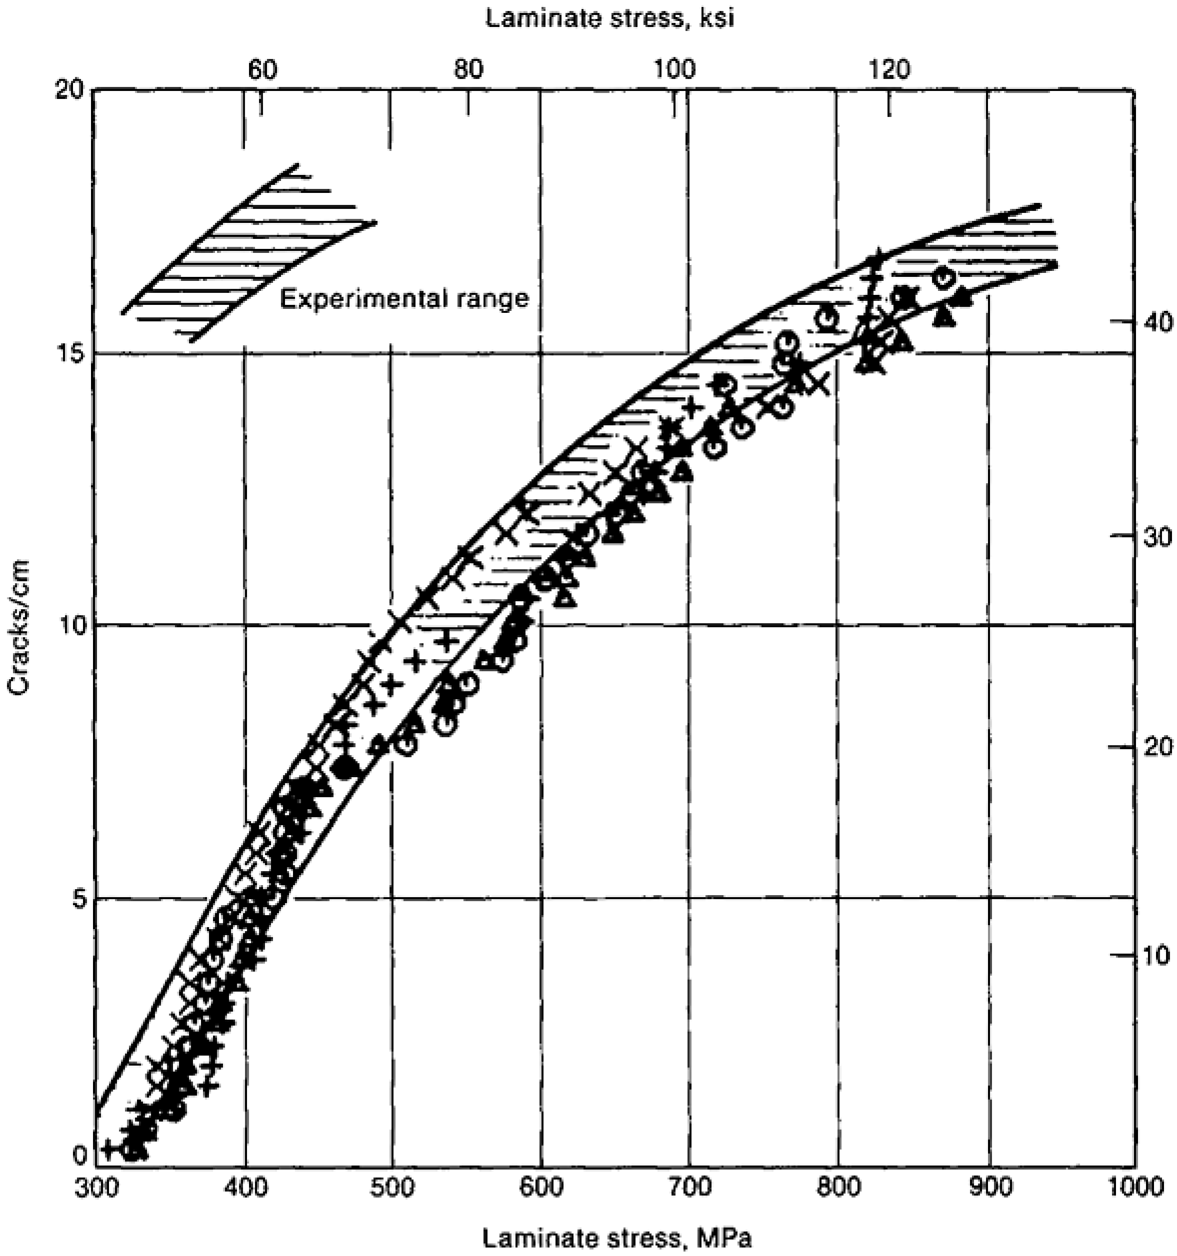

Fig. 42 Experimental (shaded) and simulated (points) transverse crack density versus laminate tension relations. Data from four $[0°_2/90°_2]_s$ coupons

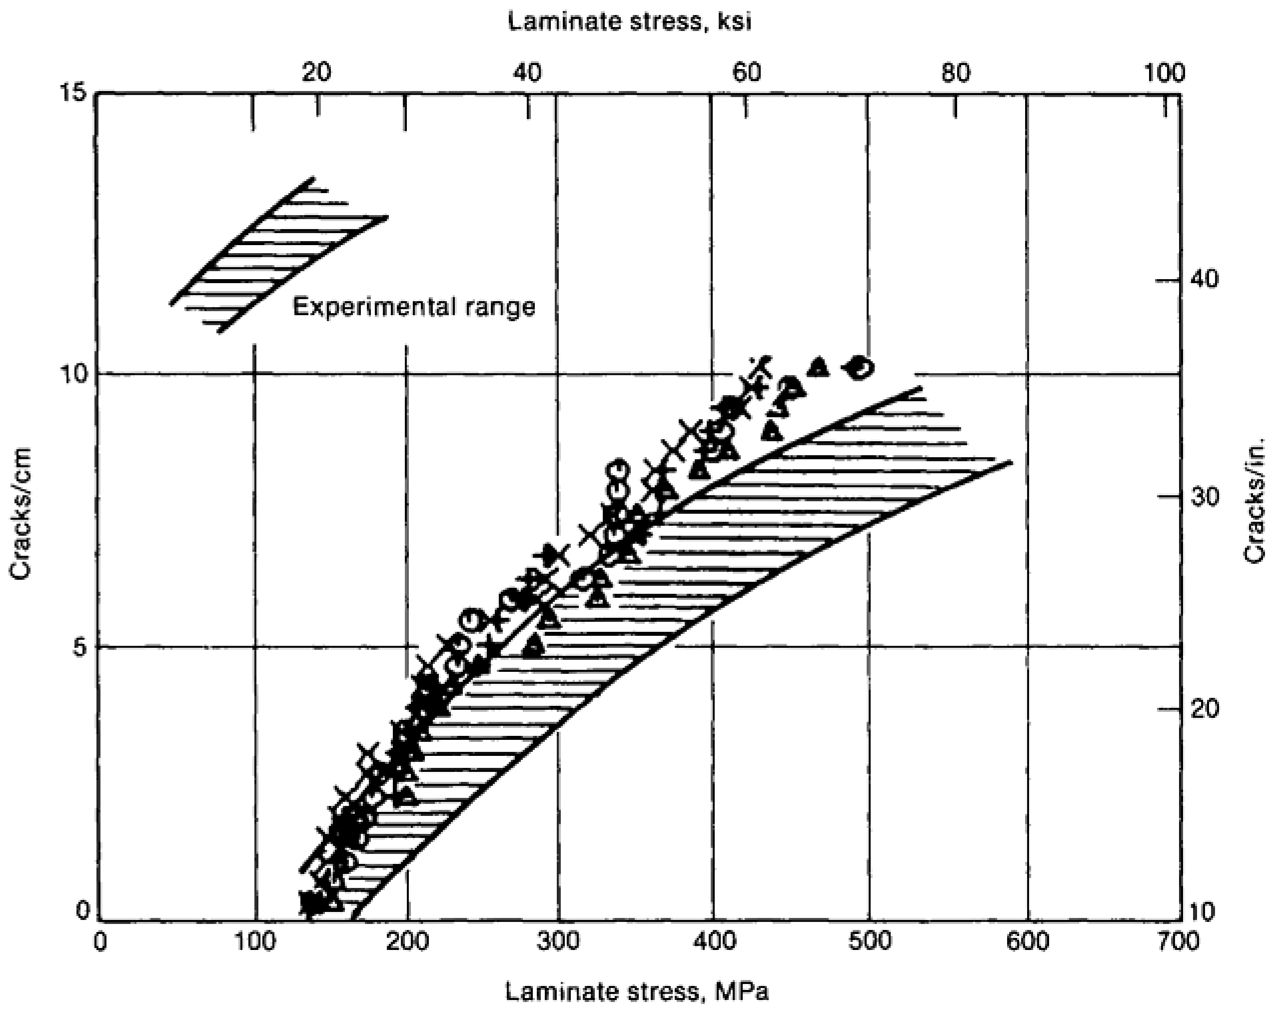

Fig. 43 Experimental (shaded) and simulated (points) transverse crack density versus laminate tension relations. Data from four $[0°_2/90°_4]_s$ coupons

Of course, the uniqueness of the determined flaw distribution in the basic ply cannot be proved. Specifically, the values of α, β, and *M* determined experimentally could assume different sets of values for the same set of experiments. This difficulty, it is felt, will remain as long as an exact analysis of the cracking mechanisms at the fiber-matrix scale is unavailable.

Characterizing Strength from a Structural Design Perspective

L.J. Hart-Smith, J.H. Gosse, and S. Christensen, The Boeing Company

Introduction

THIS ARTICLE presents a comprehendable and comprehensive physics-based approach for characterizing the strength of fiber-reinforced polymer composites. It begins with background information on the goals and attributes of this method The article then addresses the characterization of fiber failures in laminates, because these are at the highest strengths that can be attained and, therefore, are usually the design objective. An exception would be if the design goal is to maximize energy absorption, rather than static strength. The discussion proceeds to situations in which the matrix fails first, either by intent, by design error, or because of impact damage. The state of the modeling propagation and arrest of matrix damage follows.
Comparisons of this physics-based approach are then made to empirically based failure theories.

Characterizing Strength from a Structural Design Perspective

L.J. Hart-Smith, J.H. Gosse, and S. Christensen, The Boeing Company

Background on Characterization

The mechanical properties of fiber-polymer composites can be characterized at a number of levels—at the constituent level, at the lamina level, and at the laminate level. The appropriate level at which to characterize a specific property varies with that property. Some cannot be characterized at any level higher than for the isolated constituent. Others cannot possibly be measured until the fibers have been embedded in the resin. The approach adopted here is to measure the properties at the most relevant level and, equally, to characterize them in the model at the highest level that does not lose the minimum level of physical definition that is needed. There is a conscious rejection of the common hypothesis that fiber-polymer composites need not be modeled with any greater precision than for a homogenized lamina that does not even differentiate between layers with fibers in one or two directions. However, equally, there is an acknowledgement that it is not possible to predict laminate strengths on the basis of the properties of dry fibers and bulk resin alone. What is presented here is the *least* complicated model that is simultaneously sufficiently comprehensive to cover the standard needs for the design of fibrous composite structures.
The basic analysis is performed at the customary unidirectional lamina level, for a number of reasons:

- A most-practical limitation is the need for compatibility with standard finite-element analysis codes, such as ANSYS, ABACUS, NASTRAN, and COSMOS. Even so, it is vital to incorporate strain magnification factors to differentiate, when necessary, between strains in the fibers, the matrix, and the laminae.
- It is also necessary to include all contributions to residual thermal stress, those that exist within isolated unidirectional laminae as well as those that are caused by laminating together plies of different fiber orientations. The former set are customarily referred to as *intralaminar* thermal stresses and the latter as *interlaminar* thermal stresses. The basic analysis is performed in terms of strains, rather than stresses, because the properties governing the strength of both the fibers and the matrix turn out to be simpler to express, and comprehend, that way.

- The unidirectional lamina is the lowest possible level at which certain phenomena can be characterized without misrepresenting the physics governing the behavior of structural laminates. Modeling a woven fabric layer as a single ply, for example, precludes all possibility of assessing matrix failures in that layer. In addition, modeling at the lamina strain level makes it possible to superimpose different possible failure mechanisms to identify the sequence in which they would occur. This capability is particularly important in the context of damage propagation.

It is most important to emphasize that all analyses presented here are physics based. None rely on curve fits to make up for incomplete understanding of the phenomena. It is likely that there are still more features of the behavior of fiber- polymer composites that have not been accounted for, because there may be further as-yet-unidentified properties awaiting discovery. In the event that such enlightenment does occur, in the future, there will be no need to revise any of the analyses that are governed by the properties that already are included. This is often not the case with even the best of empirical analyses.

The analyses are presented for unidirectional tape laminae, but apply equally to woven fabric layers when they have been properly decomposed into two equivalent orthogonal tape layers in the manner described in Ref 1. Backing out the equivalent "ply" properties ensures that the appropriate level of crimping in the fibers is accounted for. Since matrix-dominated transverse properties cannot be measured for bidirectional laminates, the transverse properties of unidirectional laminae are used. (Fiber crimping has no effect on these.)

Tools for the analyst who does not need to know everything about composites are also addressed, because there are some well-established and reliable approximate methods that cover a great number of design requirements. These include the maximum-strain model (Ref 2) for glass-fiber-reinforced plastics and the truncated maximum-strain model (Ref 3) for polymers reinforced by carbon fibers. At the constituent level, however, the representation of the individual fibers is the same. The difference shows up at the lamina level, because of the vastly different transverse stiffnesses of the two fibers, in comparison with the stiffness of the matrix. Further differences arise from the different fiber strains-to-failure in comparison with that of the matrix. These theories can be used quite safely by anyone who understands what they cannot do. They have only limited capacity in regard to matrix failures. One must either design laminates that are fiber-dominated for all loads the structure will experience, thereby avoiding matrix failures by precluding their occurrence until after the limit load has been reached, or one must use a more comprehensive theory that properly represents matrix failures if there is no simple design solution available. It should be noted that these particular empirical failure models are 100% mechanistic, so their capabilities and limitations are easily established. What must be avoided are those theories, usually referred to as interactive, in which the theories cannot possibly be related to physical phenomena, and for which, therefore, no bounds of applicability have ever been established.

Because the models presented here are more closely tied to more fundamental physical properties than is customary, the analysis methods are actually simpler than usual, because there is no need to compensate for effects that are present in the test coupons and structure, but not included in the analysis. In addition, the reliance on a mechanistic basis permits complete characterizations with fewer reference properties than have been needed in the past.

There have been a great number of composite failure models published elsewhere. Several are described in Ref 4. The authors are aware of these prior works, some of which are discussed here. However, most of them advocate different approaches, based on models for homogeneous anisotropic solids, that cannot characterize the behavior of the heterogeneous fiber-polymer composite laminates as fully as the methods discussed here.

There is a statistical variability to all of the materials properties discussed here. It is assumed that proper interpretation of the data is applied, using mean values for elastic constants and A- or B-allowables for strengths, depending on the application. However, it is necessary to add a warning that most of the variability perceived in the past has nothing to do with the properties in question, but is the result of inappropriate design of many of the standard test coupons, which is compounded by the difficulties in testing any brittle materials. Bonded tapered tabs where loads are introduced have been a chronic source of premature failure, peeling off the outermost plies of the coupon. The inherent variability in fiber and polymer properties is no greater than for typical metal alloys. Most of the time, only the highest test result in each set comes close to being valid, particularly when there is great scatter. Fortunately, the pedigree of the reference properties can be separated from the theories in which they are used.

The characterization of fiber failures in laminates is presented first. Then situations in which the matrix fails first either by intent, by design error, or because of impact damage follow. It is shown that the longitudinal

compressive strength of embedded fibers can be limited by the ability of the matrix to support them. It is also affected by stacking sequence and by blocking of parallel plies. The new models have shown progress in also covering the propagation and arrest of matrix damage, followed by its possible spreading further at still higher loads or by catastrophic failure of the matrix, the fibers, or both. However, it is considered premature to claim that the tools have been developed to such a robust level for analysis of events subsequent to the initial structurally significant damage. In any event, the ability to tolerate further load application is very dependent on the application. It is far more likely to be permissible for structures subjected to only single monotonic loads than for structures like those in aircraft. In aircraft, many different loads can be applied in random order, and the strengths would become path-dependent, or worse, if the onset of significant structural damage were not defined as design ultimate strength in each case.

The Strength of Embedded Fibers under Arbitrary Biaxial Loads

There are three basic failure mechanisms by which fibers can fail, but only one of these, *shear*, can cover all possible states of combined stress (Ref 5). The other two, *brittle fracture* and *compressive instability*, are limited to specific domains on the strain plane and become local truncations superimposed on the primary shear failure envelope, which is shown in Fig. 1 for isotropic glass fibers and in Fig. 2 for orthotropic carbon fibers.

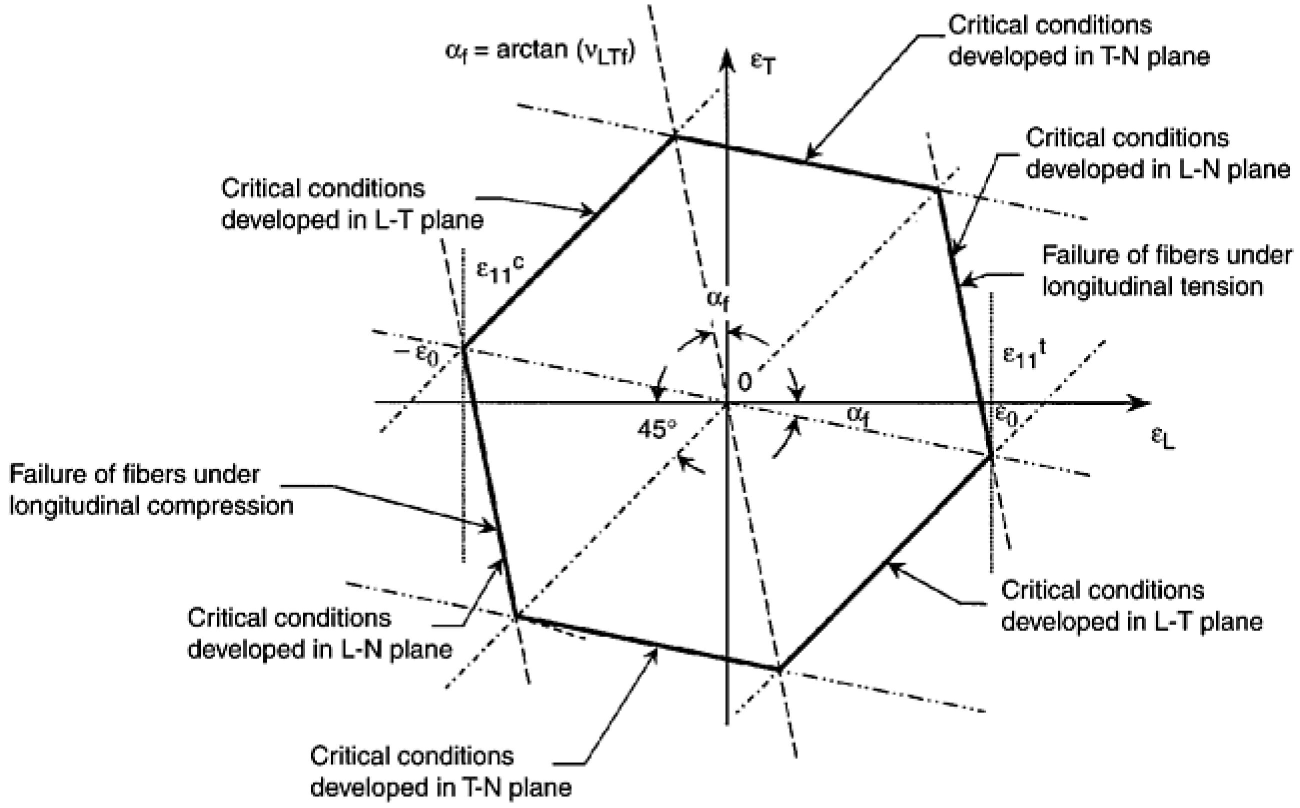

Fig. 1 The strength of glass fibers embedded in polymer matrices, in terms of fiber strains

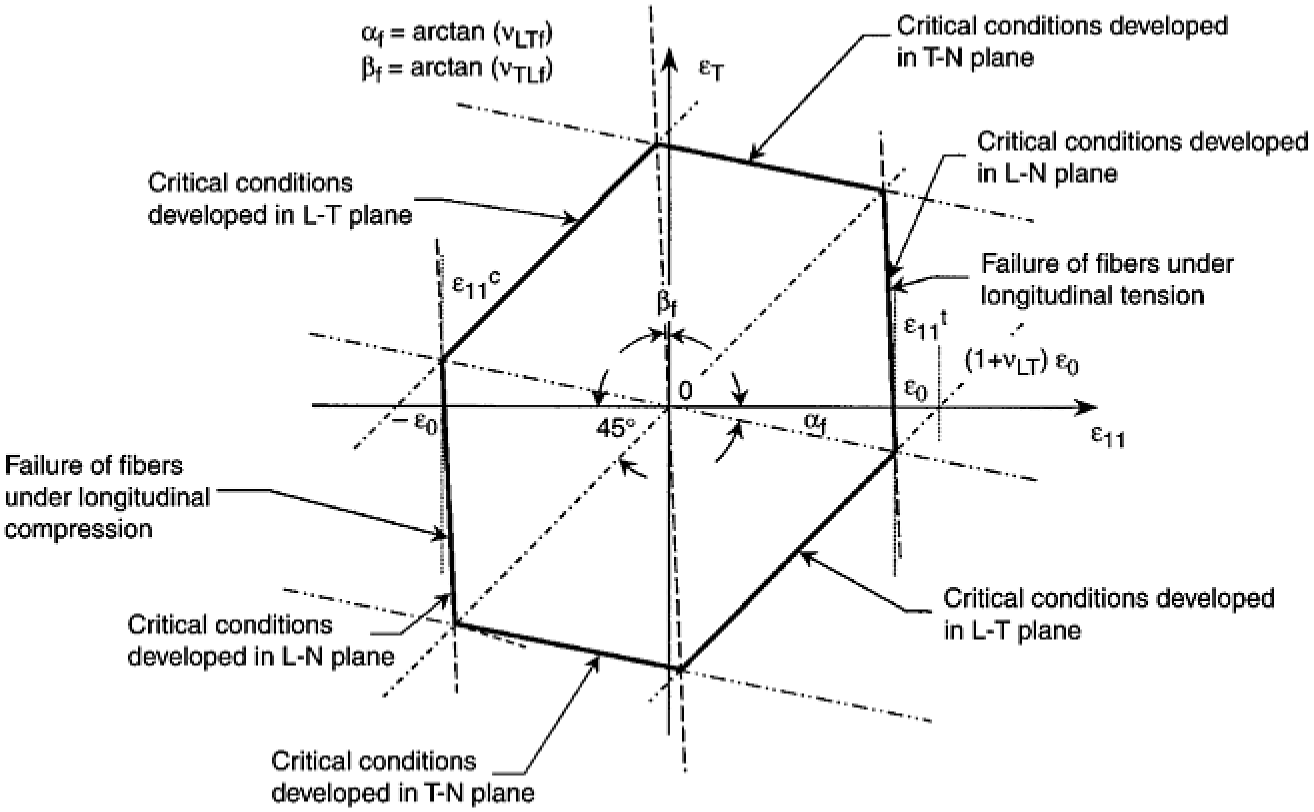

Fig. 2 The strength of carbon fibers embedded in polymer matrices, in terms of fiber strains

Maximum-Strain Failure Diagrams. For the reader unfamiliar with strain failure diagrams, important elements of it are detailed. A shear strain envelope for fibers is shown in Fig. 1. The longitudinal fiber strains, ϵ_L, are plotted horizontally, following the usual convention that positive strains are extensions and negative ones are compressive. ϵ_0 is the longitudinal strain at failure. Strains in the transverse direction, ϵ_T, are plotted vertically.

The area within the irregular hexagon represents conditions of strain less than the failure criterion. The failure limits are represented by the hexagon itself. As noted in Fig. 1, the sides each represent a different set of critical conditions. N is the normal, perpendicular direction to the L-T plane, where L and T refer to the longitudinal and transverse in-plane direction relative to the fibers. The angle α_f is related to ν_{LTf} (the major Poisson's ratio of strain in the T-direction to the strain in the L-direction, caused by stress in the L-direction). In Fig. 2, the angle β_f is related to the minor Poisson's ratio, ν_{TLf} (the ratio of the strain in the L-direction to strain in the T-direction, due to stress in the T- direction).

Figure 1 shows the shear failure envelope for isotropic glass fibers, and Fig. 2 presents orthotropic carbon fibers. Only the major Poisson's ratio is involved for glass fibers, while two are needed for the carbon fibers.

Biaxial Strains. Figure 2 identifies the various planes, with respect to the fiber axes, that become critical with changes in the combination of biaxial strains. The same conditions pertain for glass fibers. It is significant that the uniaxial tensile and compressive fiber strengths *must be equal* according to this failure mechanism, thus $\epsilon_{11}^{t} = \epsilon_{11}^{c}$. This is why a fiber shear failure mechanism was proposed in Ref 6, because this equality had been observed for the carbon fibers of the day. However, there also needs to be provision for other failure mechanisms, because the equality is not true for high-strain carbon fibers, unless they are specially stabilized, and was probably never true for glass fibers. The shear failure mechanism is necessarily sensitive to transverse stresses acting on the fibers whenever the sign of those stresses is opposite to that acting along the length of the fiber.

Uniaxial Stress. Other failure mechanisms are sensitive to only the longitudinal stress in the fiber. One example is brittle fracture of glass fibers resulting from surface imperfections, such as those caused by attack by moisture. Another is failure of carbon fibers, initiating where defects were created in the original precursor from which the fibers were drawn. Both of these phenomena can be added to Fig. 1 and 2 in the form of constant stress cutoffs parallel to the nearly vertical lines therein. The measured longitudinal tensile strength of the fibers will reflect the lower of these two possibilities. It will not be possible to differentiate between the two without microscopic analysis. The reason why the older high- strength carbon fibers, like T-300, appear to be governed by shear failures is presumably that, in that case, the brittle fracture cutoff lies beyond the shear failure limit. These additional tensile cutoffs are combined with the basic shear failure envelope in Fig. 3.

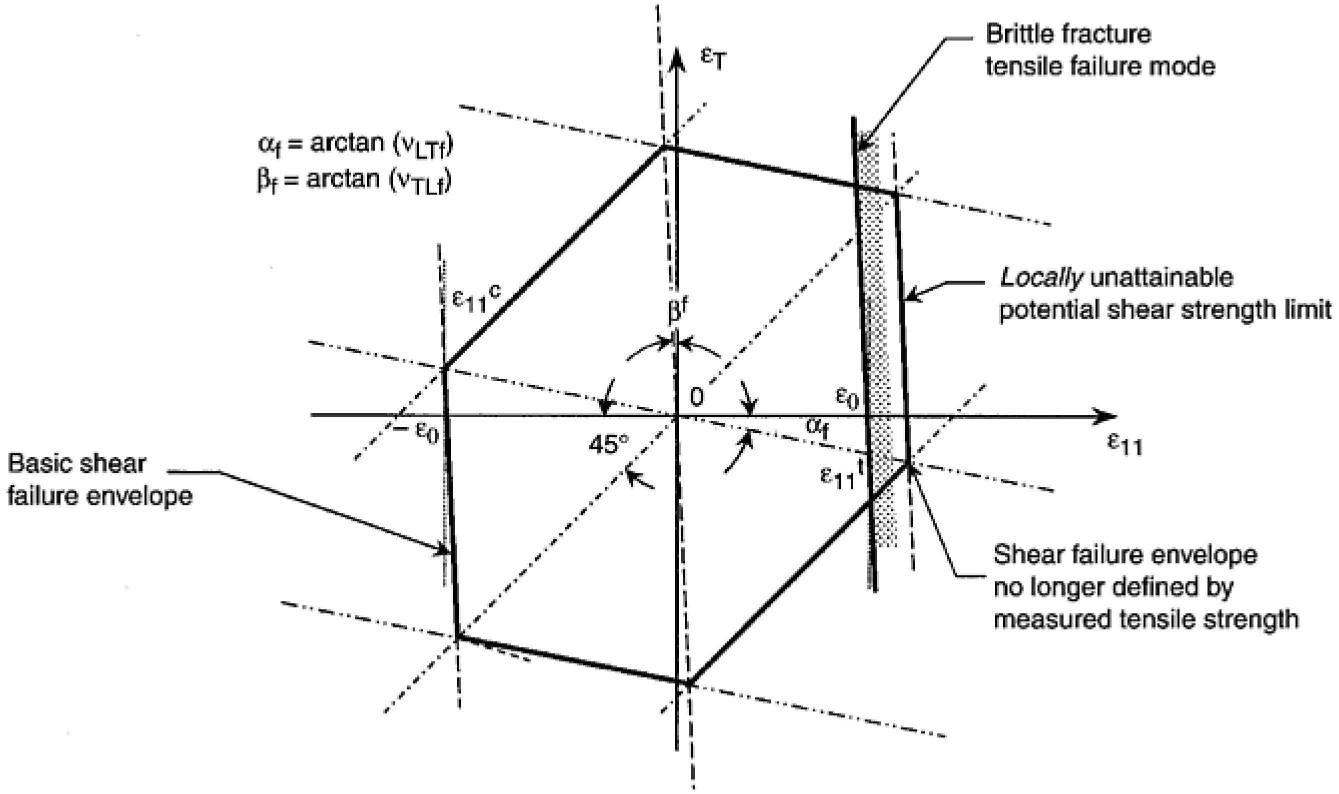

Fig. 3 Additional tensile strength limits for fibers embedded in polymer matrices. The shaded area is affected by the brittle fracture mechanisms.

Conservative Shear Strength Limits. The structural analyst may have little interest in knowing which failure mechanism governs tensile fiber strengths, particularly in the case of glass fibers. The engineers stressing

carbon-fiber-reinforced laminates may have a little interest, because of the difficulty of locating what to them appears to be a 45° sloping cutoff in the second and fourth quadrants of their customary maximum-strain failure model. There are very few reliable data points with which to locate what is perceived as the shear failure envelope if the fibers fail by brittle fracture first. It has become customary in such cases to relocate the 45° sloping cutoffs to pass through the measured unidirectional tension strength, as shown in Fig. 4. Doing so is clearly conservative. However, new German test techniques (Ref 7) offer hope that reliable direct measurements of fiber shear failure may become possible. In their technique, a single layer of 45° fibers is wound around a carrier tube that is sufficiently strong and buckle- resistant that the strain at failure of embedded fibers subjected to nominally equal and opposite strains can be established. (Note that it is a little more complicated than this, of course. The transverse strain will be equal to the longitudinal strain only at the lamina level. There will be somewhat less transverse strain developed in the fibers themselves—very much less in the case of glass fibers. There may also be residual longitudinal compression applied to the fibers, particularly in the case of carbon fibers, because of thermal dissimilarities between the fibers and the underlying carrier tube. Nevertheless, all of these effects can be compensated for by standard micromechanical analyses. This German technique is actually a major breakthrough, relying only on identifying the most suitable material for the carrier tube, to ensure that it does not fail first. It can obviously be extended to all biaxial states of strain, permitting systematic verifications of any proposed fiber failure envelope.)

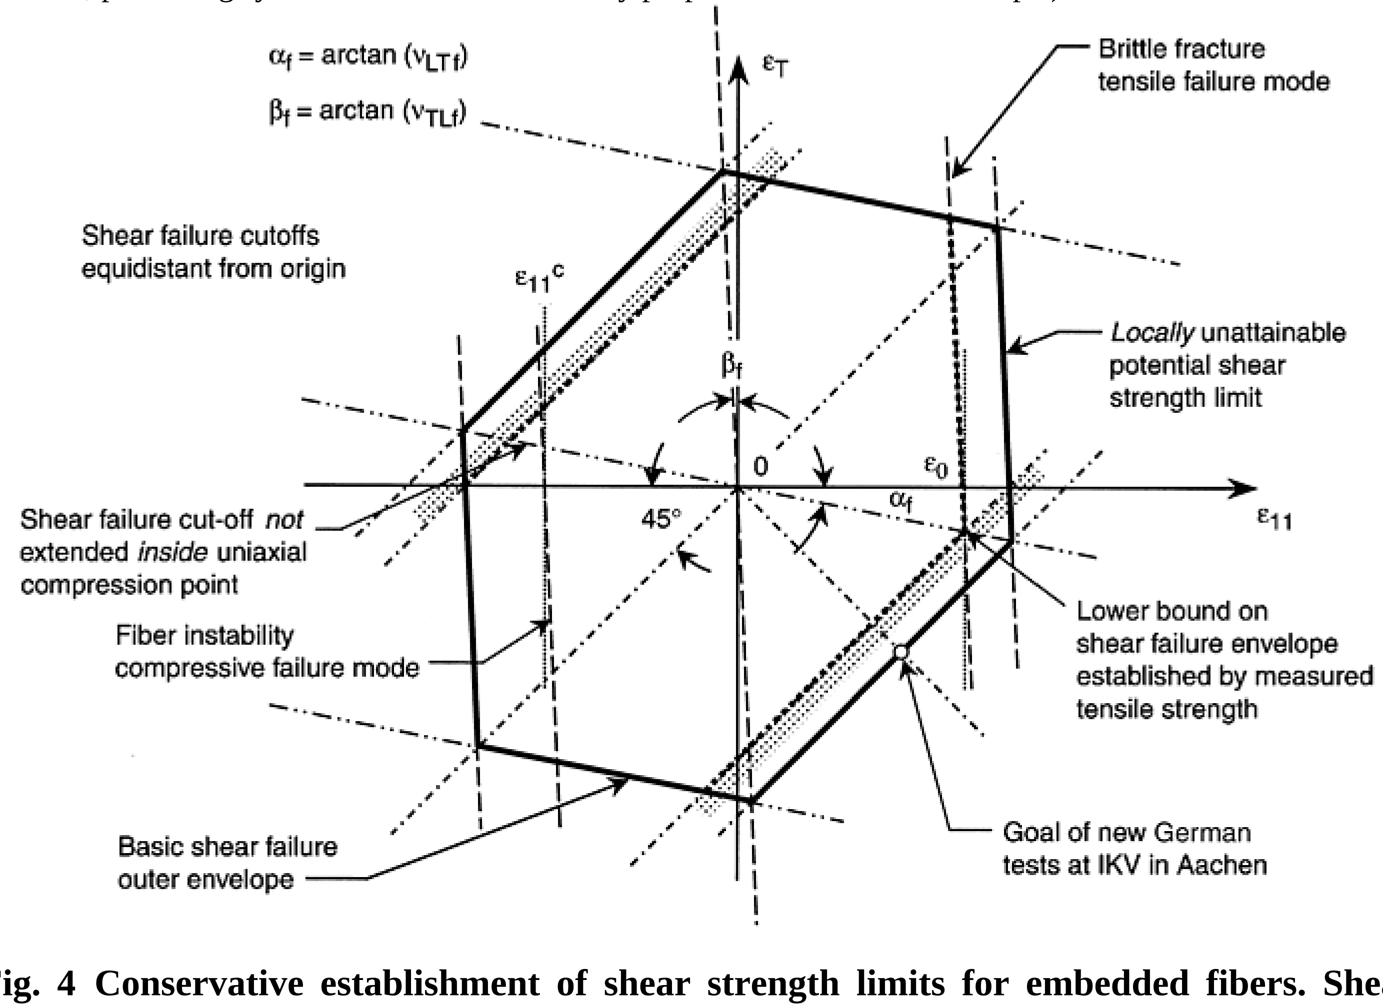

Fig. 4 Conservative establishment of shear strength limits for embedded fibers. Shear failures in the second and fourth quadrants have been relocated, as indicated by the gray bands.

Compressive Strength. The customary measured longitudinal compressive strengths (or strains-to-failure) of high-strain carbon fibers are clearly far less than those shown in Fig. 2. Only completely stabilized individual fibers have been shown to have such strengths and failure modes, as reported in Ref 8. Most of the time, the matrix in typical laminae or laminates is unable to stabilize the fibers sufficiently well to attain the shear failure strength. Various forms of instability can precede reaching the compression strength limits shown in Fig. 1 and 2. This process is actually quantified later in this article in the context of matrix failures. It will suffice here to say that this limit has been conventionally represented as an experimentally located constant strain line on the lamina strain plane, which is shown subsequently to be closely equivalent to a constant stress limit at the fiber

level, parallel to the closest-to-vertical lines shown in Fig. 1 and 2 and closer to the origin. This has been a reliable empirical technique for structural design, provided that the designs are *restricted* to the laminates in which there are fibers in a sufficient number of directions, and in which extreme limits on blocking of parallel unidirectional plies discourages the incidence of serious failures in the matrix. The in situ compression strength of fibers is actually far more complicated at this level of physical reality, as is discussed later. It should be noted that the data analysts for MIL-HDBK-17 (Ref 9) are confirming that there does not seem to be a unique lamina compressive strength, the way there is for the equivalent tensile strength.

It should also be noted that the two 45° sloping lines in Fig. 1 and 2, and their derivatives, remain equidistant from the origin, even when the in situ longitudinal tensile and compressive strengths differ. In the absence of specific test data to precisely locate these portions of the fiber failure envelope, the correct (conservative) procedure is to locate both of them by the higher of the longitudinal tensile and compressive strengths.

The Strength of Embedded Fibers Characterized at the Lamina Level

The strain in the matrix parallel to the fibers must obviously be the same as in the fibers, except at free edges. However, this is not true in the transverse direction. Therefore, allowance must be made for the differences between transverse strain in the fiber, the matrix, and the lamina. Analyses for accomplishing these distinctions have been around for decades, but recognition of the need to employ them seems to have been appreciated only by some researchers and analysts focusing on mechanistic failure models. Reference 5 contains some simple approximate solutions for this problem, based on continuity of stress through the diameters of the aligned fibers. Because the factors so derived are in the form of ratios, the calculations are isolated from the added complication that there is variation in stress through the thickness of each lamina. The steps involved in these calculations are illustrated in Fig. 5, starting from the exactly 45° slope for the fibers and determining the corresponding slope for the lamina. The strain amplification factors, $R\epsilon$, depend slightly on the fiber array, K, and appreciably on the fiber volume fraction, V_f, so it is important to be consistent in the values used.

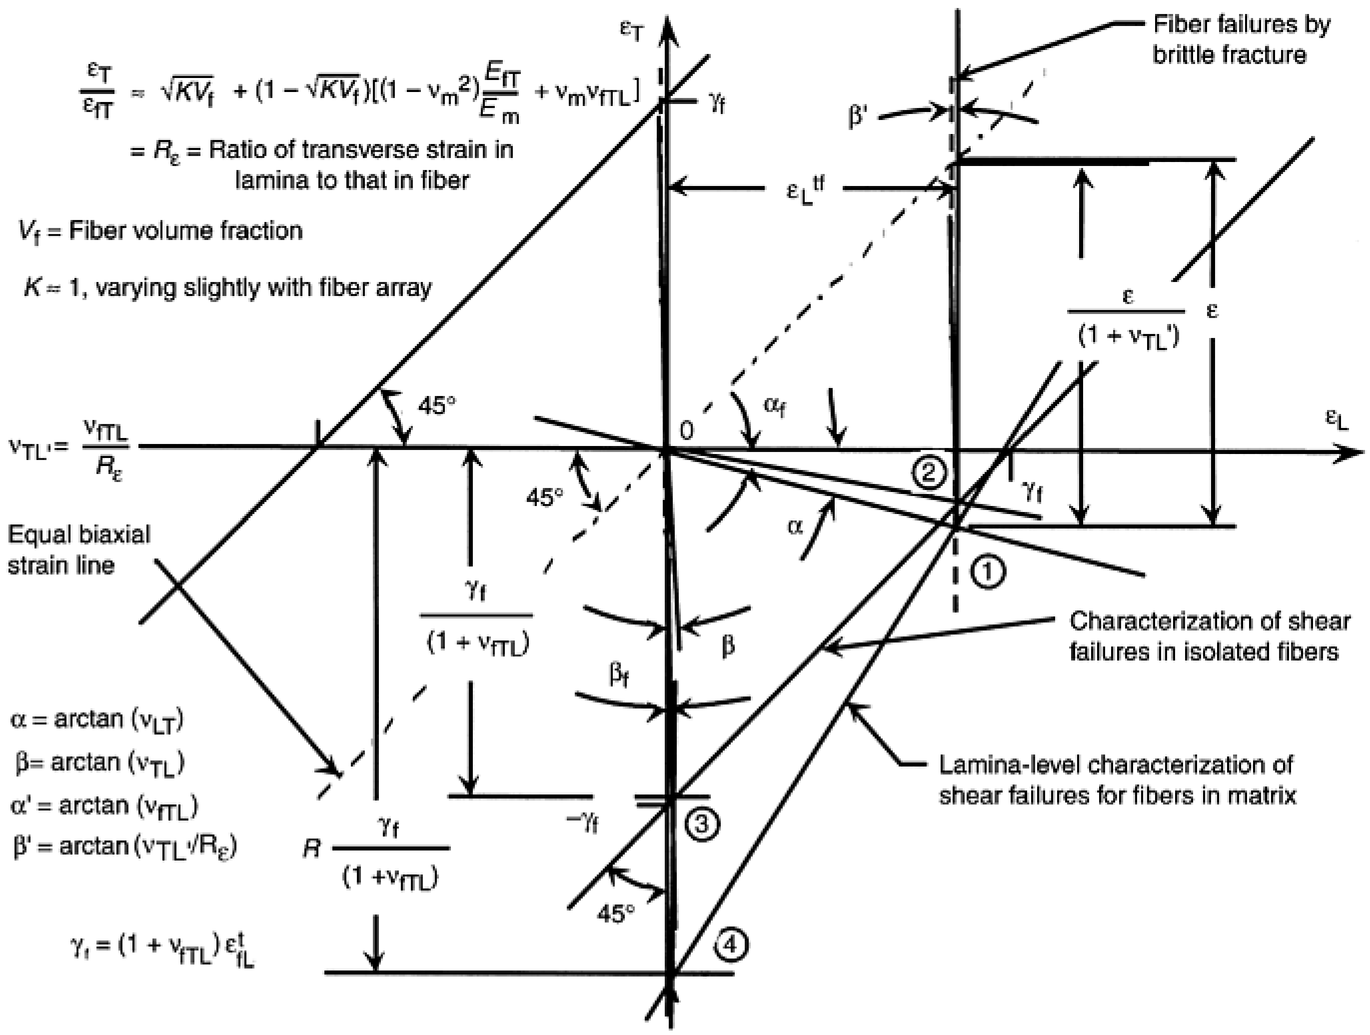

Fig. 5 Strain amplification factors between fiber- and lamina-level models for fibers embedded in polymer matrices. Circled numbers 1 through 4 indicate the sequence by which the points were located. γ_f is the fiber shear strain, E_{fT} istransverse modulus of elasticity of the fiber, and E_m is the modulus of elasticity of the matrix. Subscripts f, m, L, and T refer to fiber, matrix, longitudinal, and transverse, respectively.

At the pure transverse tension case, in the absence of longitudinal stress, a typical amplification factor, *R*, between the transverse strain in the lamina and that in glass fibers is a little over 5, while that for carbon fibers is only about 1.5. Figure 5 displays this latter case. Because the Poisson's ratio for the lamina is about 50% higher than for the carbon fiber, the slope of the lamina-level failure envelope in the second and fourth quadrants is little affected by the distinction between transverse strains in the fiber and the lamina. For glass fibers, on the other hand, the slope is increased to almost 90°. Both of these seemingly contradictory slopes are based on the *same* fiber failure mechanism, shear between axes at ±45° to the longitudinal axis of the fibers, as explained in Ref 5. Note that the same kind of transverse strain amplification factors apply to all other states of biaxial stress, too. All of the nearly vertical lines become even more so, because $\beta \ll \beta_f$. This difference arises because of the expansion of transverse strains needed to fail the fibers, when expressed at the lamina rather than fiber level. The failure envelope for the glass-fiber lamina is expanded so much in the transverse direction that it is obvious that longitudinal fiber failures in any orthogonal (90°) plies would precede transverse failures in the fibers in the reference (0°) lamina, even if the matrix were strong enough to apply such stresses (which it is not).

Having explained the origin of the various facets of the embedded fiber failure envelope, by starting at the constituent level, it is appropriate to relate them to the more traditional establishment of these same facets at the lamina strain level. This is because the actual measurements on which the model is based are made at that level. Only the thermoelastic constants of the constituents are needed at that lower level for the strain amplification and residual thermal stress calculations. Historically, only two measurements have been made for fiber failures,

one in longitudinal tension and the other in longitudinal compression. There is now hope that a third may be added, to locate the fiber shear cutoffs whenever they cannot be defined precisely by the higher of the longitudinal tension and compression states. The lamina-level measurements and the underlying constituent failure mechanisms are related in Fig. 6 for a typical carbon-fiber polymer lamina. The corresponding diagram for a glass-fiber-reinforced polymer lamina would be far taller, as in Fig. 7, and the 45° sloping lines in the glass-fiber reference plane would be almost vertical at the lamina level.

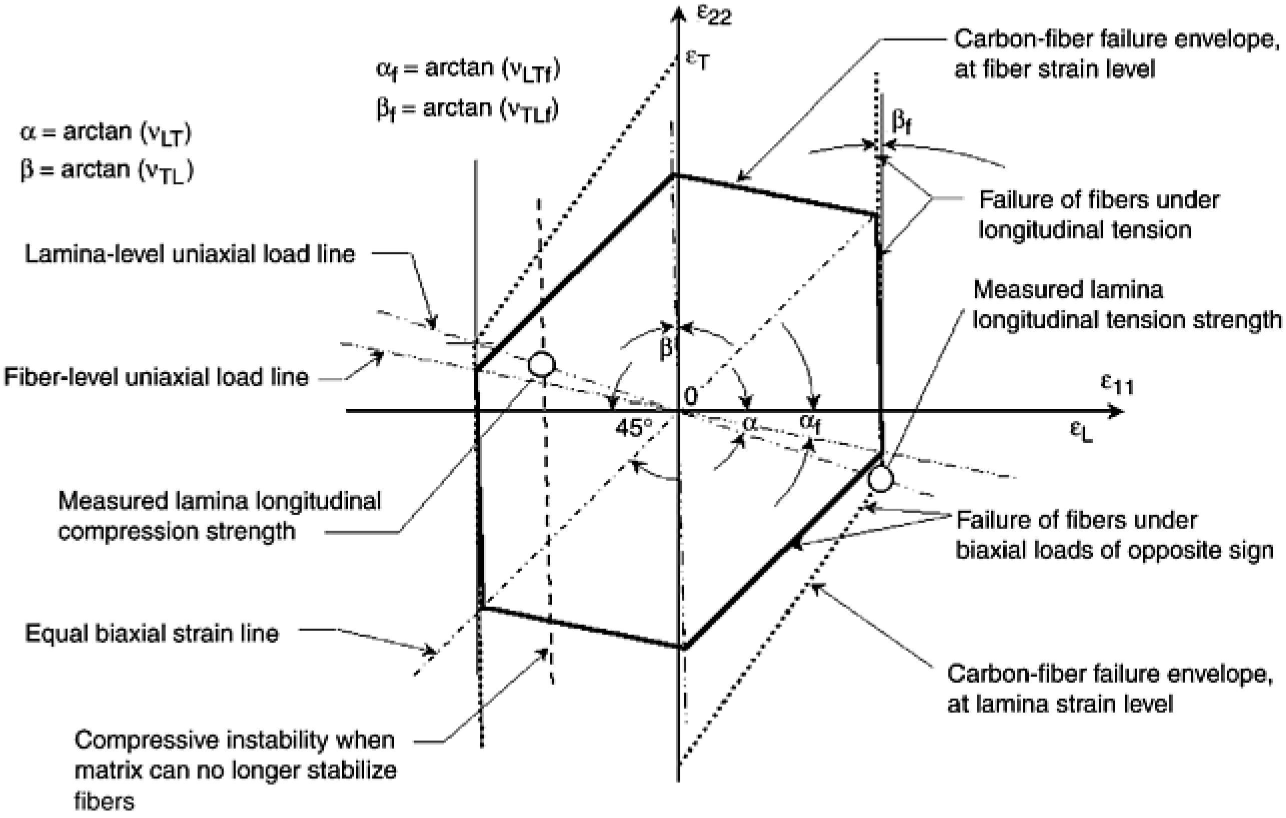

Fig. 6 Fiber failure envelopes at the constituent and lamina strain levels for carbon fibers in a polymer. Circles indicate lamina test data points.

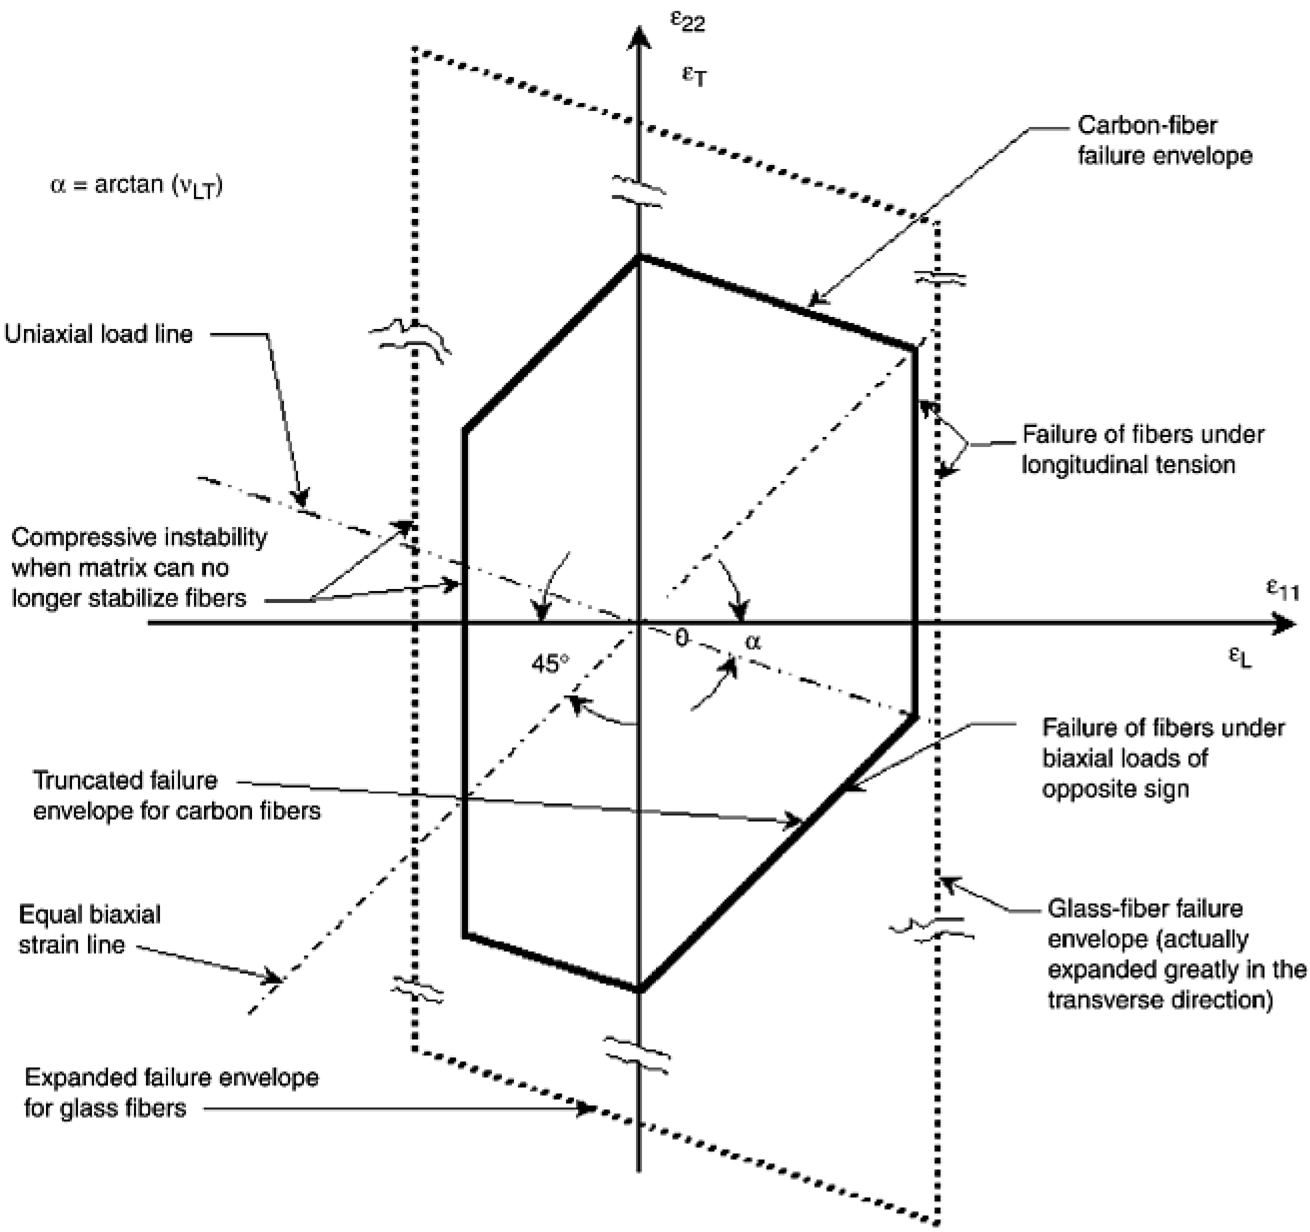

Fig. 7 Fiber failure envelopes at the lamina strain level for carbon and glass fibers. Glass-fiber envelope is not to scale, being actually much taller.

Actually, the *entire* outer failure envelope is defined by the shear failure mechanism within the fibers, but many people associate *only* the second and fourth quadrants with that mechanism, because they are thinking at the macro-, rather than micro-, level. Failure to add this cutoff, in those quadrants, to the commonly used maximum-strain failure criterion would have no effect on strengths predicted in the first and third quadrants, for any fibrous reinforcements, but would over-estimate the in-plane shear strengths for ±45° laminates, or sublaminates, for carbon fibers.

The nearly vertical lines in Fig. 6 in the first and third quadrants are so close to vertical that it is a reasonable approximation to simplify analyses by making them true “constant strain” lines at the lamina level, even though they originated as constant stress lines at the fiber level, as explained previously. This has been done in Fig. 7, which also shows how the lamina-level envelope for glass-fiber failures is expanded tremendously in the transverse (vertical) direction in comparison with the corresponding carbon-fiber envelope.

It is important to note how few fiber-dominated strength measurements are actually needed to employ this failure model—*three at the maximum*, with only two being used customarily, as shown in Fig. 7. The *entire* shear failure envelope is defined by a single strength measurement. The unidirectional tension and compression strengths are relatively easy to obtain, when they are different. This is provided that one pays attention to the many difficulties that have been encountered in the past and focuses only on the simpler test coupons that have been well validated in the process of explaining the premature failures with other coupons. The shear reference

strength has been difficult to establish experimentally in the past, again because of the use of inappropriate test coupons. See the article "Lamina and Laminate Mechanical Testing" in this Volume. (Significantly, the present model is consistent with the best of these measurements, using the Douglas bonded tapered rail-shear test coupon described in Ref 10.) Most of the time, the measured strengths would undercut the measured uniaxial tension strength, which is impossible. It is shown in the subsequent section on matrix failures that even the embedded fiber compression strength can be dispensed with, in most cases. The highest possible compression strength cannot exceed the limit set by the shear failure mechanism, which is usually defined by the tension strength measurement, except for boron filaments, which are stronger in compression than in tension. Despite the great number of test coupons that are incapable of measuring these embedded fiber reference strengths, those that are reliable are extremely simple to perform, as described in Ref 1.

Characterizing Strength from a Structural Design Perspective

L.J. Hart-Smith, J.H. Gosse, and S. Christensen, The Boeing Company

Strength Properties for Polymer Matrices Confined Between Fibers

Just as there are only three possible mechanisms of failure for glass and carbon fibers embedded in polymer matrices, there are only two possible mechanisms—and therefore only two physical properties—describing the *initiation* of failure in the constrained polymer. These are *dilation* and *distortion* (Ref 11). These two characteristics alone are universally applicable, because they are *intrinsic materials properties*. The *orientation* of the fracture surface is defined by the largest principal strain, but the strain itself is not an intrinsic property. Additional properties are needed to describe the propagation of damage, and they are introduced later.

Dilation. The parameter characterizing dilatational (volume increase) failure is the first strain invariant, J_1. This is simply the sum of the three principal strains, although, actually, it has the same value with respect to any triorthogonal coordinates. This invariant is defined as:

$$J_1 = \varepsilon_1 + \varepsilon_2 + \varepsilon_3 \quad \text{(Eq 1)}$$

If the local volume of the matrix is increased sufficiently, failure will occur by cracking on a plane perpendicular to the highest principal strain. Because most fiber-polymer composites are cured at elevated temperatures, it is necessary to account for microlevel strains equivalent to the thermally induced residual thermal stresses in the matrix, because of the constraints from the fibers. The strains in Eq 1 are with respect to the stress-free state of the matrix.

If a sufficiently good transverse tension test is available for a unidirectional (90°) lamina, a superficial lower bound estimate for J_1 can easily be established from the simple formula:

$$J_1 \approx \varepsilon_T(1 - 2\nu_{TL}) \quad \text{(Eq 2)}$$

in which L and T refer to the customary longitudinal (0°) and transverse (90°) directions of the fiber. The residual thermal stresses will increase this value. Because ν_{TL} is extremely small for unidirectional composite laminae, J_1 will be roughly on the order of the transverse strain-to- failure. However, there is more to the process of establishing the value of J_1 than this. It is well known that most attempts to measure ϵ_T can result in premature failures. The most consistently good results have been obtained by surrounding the block of 90° layers by surfacing plies of soft ±45° glass or carbon fabric. (It is recommended that the number of nested 90° plies be between 10 and 20.) It is then necessary to use the finite- element method or standard lamination theory to analytically compensate for the fact that the surfacing plies have different thermoelastic properties from the core of 90° plies, but the improvement in test results, often by as much as a factor of two, justifies this added work. In any event, it is also necessary to employ a micromechanical model (Fig. 8) to account for the strain amplifications between matrix and lamina, arising from their different mechanical and thermal properties of the fiber and polymer, so that the true state of strain is defined. There are five mechanical amplification factors that are multiplied by the five nodal mechanical tensor strain components, three for shear and two for the components normal to the fiber direction. The J_1 invariant is then always evaluated by Eq 1. At the observed load drop, corresponding to the initiation of transverse cracks within the 90° plies, the coupon should be analyzed at the interior of the laminate and not at the laminate free edge. The justification for this procedure can be found in Ref 11. The critical location is also traditionally found to be located at the interstices between the fibers, as is evident in Fig. 8. At that location, ***all*** strain components are typically positive, because of the customary residual thermal stresses. The radial strain in the matrix immediately adjacent to the fibers is typically negative, because of the same residual thermal stresses* This has the effect of reducing J_1 there and making the interstices between the fibers more critical most of the time. It should also be noted that the highest contribution to J_1 often comes from the residual thermal stress parallel to the stiff fibers, an increment of strain that is overlooked in most analyses. The macrolevel strain in the matrix parallel to the fibers is obviously extremely limited. However, J_1 must be evaluated with respect to a stress-free condition for the matrix. For this reason, a second micromechanical model, such as that in Fig. 8, is prepared for thermal stresses alone. The six nodal thermal strain components are superimposed on the six micromechanical strain components. With both the nodal mechanical and thermal strain tensors properly modified for micromechanical effects, they can now be added together for all selected nodes. Nodal calculation of any quantity can now proceed.

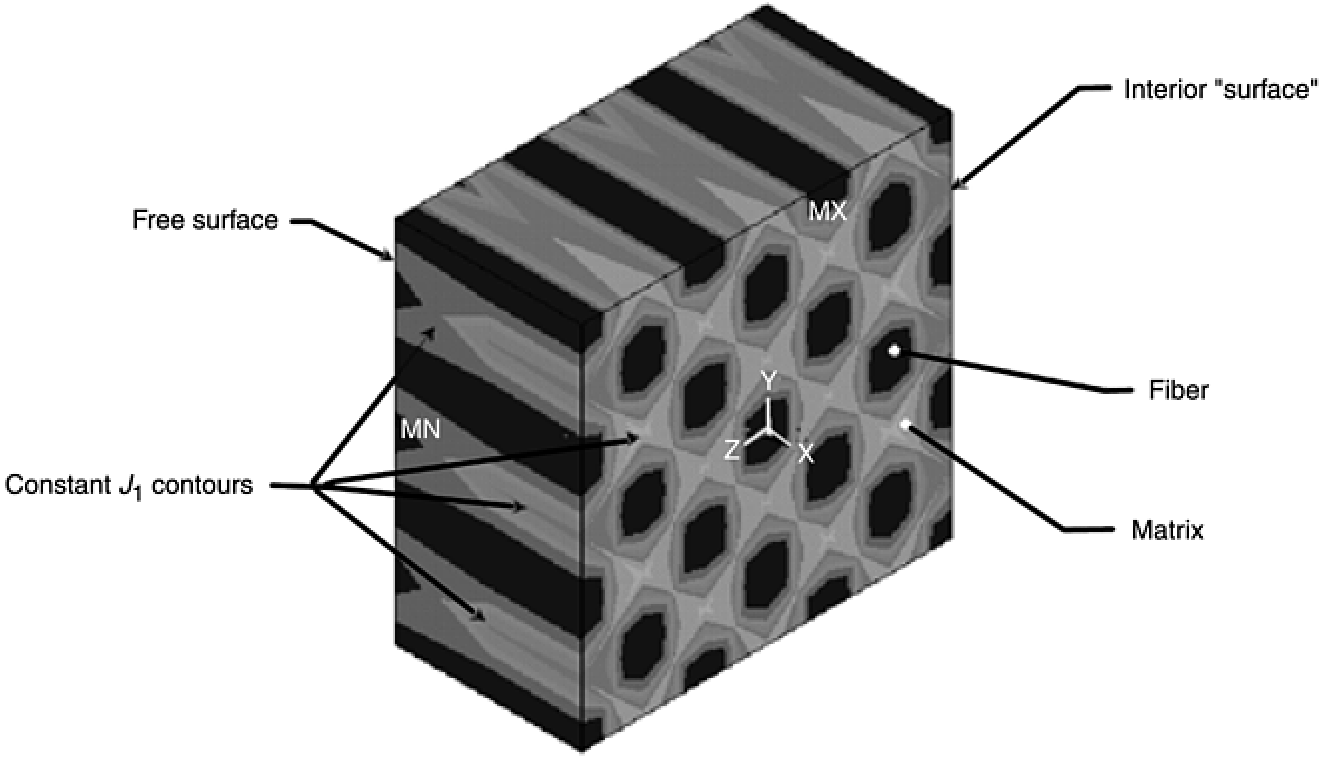

Fig. 8 Micromechanical model to relate lamina-level strains to constituent-level strains in unidirectional lamina. Shading represents contours of constant J_1, which is the sum of the three principal strains. Typically, radial strains in the matrix immediately adjacent to the

fibers are negative, so J_1 is lower here and higher between the fibers. MX indicates where the strain in variant J_1 reaches its maximum value; MN identifies the minimum.

It is sometimes necessary to differentiate between conditions at stress-free edges of laminates and in the middle of each lamina, where planes perpendicular to the fibers remain plane. Fig. 8 shows that there is a difference between the J_1 values at these two locations, so it is important to use the appropriate values. Figure 8 shows only one end of the model; the front face is actually a section cut through its middle. This process to establish the micromechanical amplification factors and thermal strains for superposition is done only once, at the time of incoming receiving inspections, and J_1 is treated just like any other effective universal property, such as the longitudinal tensile strain to failure, ϵ_0, or fiber failures in the lamina. The evaluation process for J_1 is influenced by the fiber volume fraction and by the temperature at which the tests are performed, but is valid for all fiber patterns. The approximation given in Eq 2 fails to account for some of the needed effects and is *not* a universal property. (As noted earlier, there are correct levels at which the properties should be established.)

It is very important that all the micromechanical models be prepared using standard, universally available computer codes, so that they can be reproduced by *any* user of these theories. Under these conditions, the preparation and use of these models is not at all difficult. Nevertheless, the number of fibers in the cross section and the length of the model must be such as to ensure that the model is long enough to exceed the load transfer distances between fibers and matrix. (This may be set at ten fiber diameters, if no specific data are available.)

Distortion. The other effective strength property of constrained polymers is a function of the second deviator of strain, or equivalent strain (also referred to as the von Mises shear strain). The equivalent strain is also an invariant, being defined as:

$$\varepsilon_{eqv} = \sqrt{[(\varepsilon_1' - \varepsilon_2')^2 + (\varepsilon_2' - \varepsilon_3')^2 + (\varepsilon_3' - \varepsilon_1')^2]/2} \qquad \text{(Eq 3)}$$

in which the ϵ_1's are the *local* principal strains in the matrix, also including strains equivalent to the residual thermal stresses. Because all of the differences between strains in Eq 3 are shear strains, this invariant characterizes *distortion* of the polymer in the *absence* of any change in volume. A superficial estimate of the order of magnitude of the equivalent strain can be established from a pure in-plane shear load with respect to the L and T (1 and 2) axes. A shear strain of γ_{LT} is equivalent to equal-and-opposite longitudinal strains of $\gamma_{LT}/2$, so Eq 3 would predict that:

$$\varepsilon_{eqv} \approx \sqrt{\frac{3}{4}}\gamma_{LT} = 0.87\gamma_{LT} \qquad \text{(Eq 4)}$$

However, this test is very difficult to perform reliably. A more accurate test from which to deduce the critical equivalent strain is by transverse compression, by an amount ϵ_{22}^c. In this case, the critical equivalent strain is approximated by the relation:

$$\begin{aligned}\varepsilon_{eqv} &\approx \varepsilon_{22}^c\sqrt{[(1+\nu_{21})^2 + (1+\nu_{23})^2 + (\nu_{23} - \nu_{21})^2]/2} \\ &\approx \sqrt{\frac{13}{9}}\varepsilon_{22}^c\end{aligned} \qquad \text{(Eq 5)}$$

if we assume that $\nu_{21} \approx 0$ and $\nu_{23} \approx \frac{1}{3}$.

Equations 3 and 5 imply a relationship between γ_{LT} and ϵ_{22}^c on the order of:

$$\varepsilon_{22}^c \approx \gamma_{LT}/1.39 \qquad \text{(Eq 6)}$$

We should *not*, therefore, expect these to be independent properties in the way they have been perceived in the past. They are *both* governed by the *same* failure mechanism.

As with the property J_1, the precise value of ϵ_{eqv} is a material property that needs to be established only once, using a micromechanical model to properly account for the differences between the lamina-level strains and those in the constituents. At the macrolevel, the residual thermal stresses cannot create distortions in the 1-2 and 1-3 planes, with respect to fibers in the 1-direction, away from free edges. However, between the fibers, such shear strains *can* exist in the 2-3 plane, because of the radial compressive stresses and hoop tension stresses around the fibers.

Figure 9 is a three-dimensional plot of these two matrix failure criteria, with the distortional condition portrayed by an infinitely long, circular cylinder and the dilatational condition shown as a flat plate cutoff, perpendicular

to the axis of this cylinder, precluding the attainment of the distortional failures in the presence of quite small dilation (volume increase). A most important implication of this criterion is that the two modes of matrix failure do not interact. This is easy to understand, because distortion can occur in the absence of dilation, and vice versa. However, there are many different sets of strains that can equate to satisfying the critical distortion criterion. This criterion indicates that failure is not possible under equal triaxial compression.

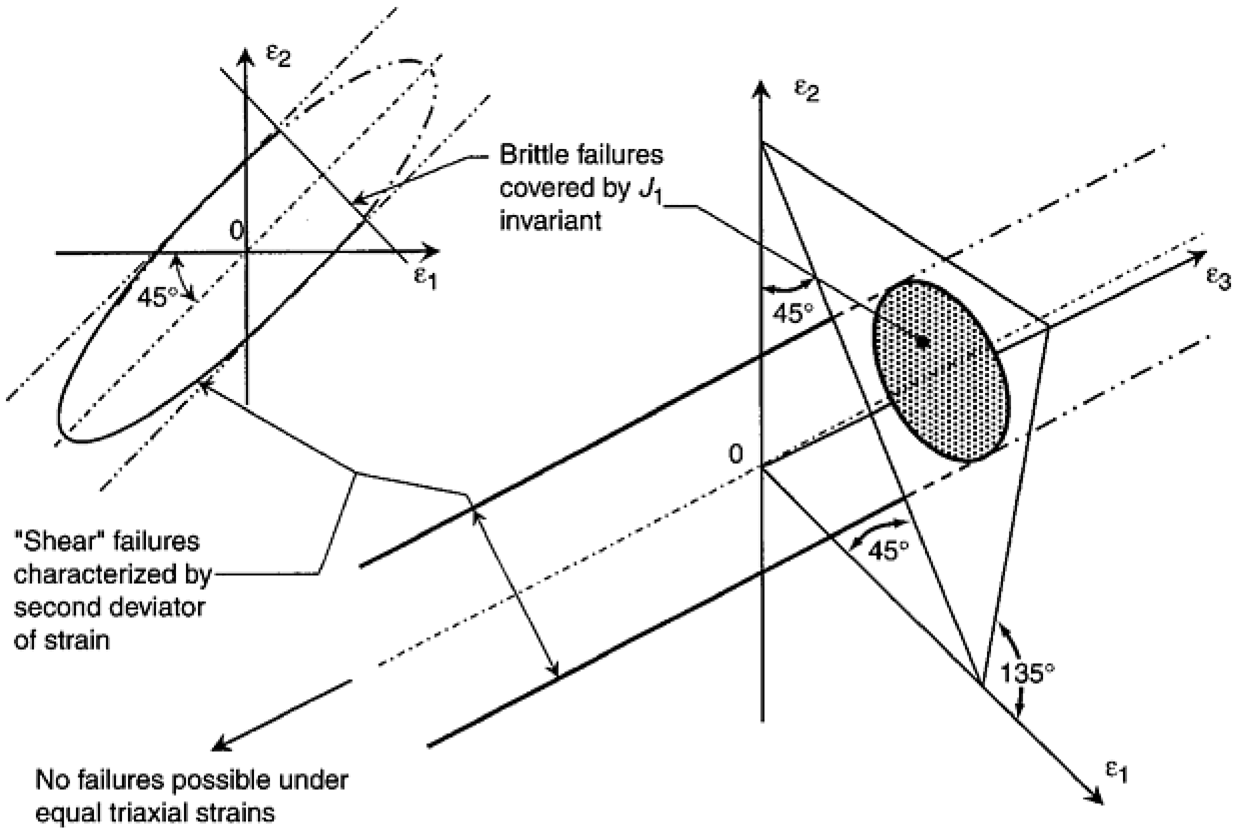

Fig. 9 Two-mechanism characterization of matrix failures in composite laminates. Distortion is shown at the long, circular cylinder and dilation as the flat plate cutoff perpendicular to the cylinder.

A zero transverse stress ($\sigma_3 = 0$) section cut through the failure envelope in Fig. 9 is clearly consistent with the truncated ellipse failure model for constrained polymers reported by Sternstein et al. (Ref 12) and others (see inset in Fig. 9). However, it should be noted that zero transverse stress at the lamina level does not translate directly to the absence of this stress at the constituent level, because of the customary induced thermal stresses. The application of this matrix failure model has shown that the–45° sloping line for critical J_1 values in Fig. 9, at the constituent level, can look very different when expressed in terms of lamina strains, being almost rectangular for a 0°/90° laminate because of the high residual thermal stresses.

An interesting observation surfaced during a discussion on this theory with colleagues at the Defence Evaluation and Research Agency in England, concerning the randomness of fiber arrays. Given that studies by these authors and others have confirmed only a weak influence of the nature of regular fiber arrays (hexagonal, square, diamond, etc.), but a significant influence of fiber volume fraction, it would seem that the micromechanical models used for these analyses could have the number of fibers in the element adjusted to simulate the varying fiber spacing in real laminates.

The two properties J_1 and ϵ_{eqv} cover the initiation (rather than the progression) of matrix failure under all states of combined stress, including interlaminar and intralaminar residual thermal stresses induced by the thermal dissimilarity between the fiber and polymer materials. Both can be deduced reliably by quite simple tests, transverse tension and transverse compression of unidirectional laminae. These would need to be repeated for a range of temperatures, because all polymer properties are known to be sensitive to this as well as other environments. However, the presence of the fibers embedded in the polymer matrix can cause the initial matrix damage to be arrested. (Cracks parallel to the fibers in unidirectional laminae will spread catastrophically from initiation.) Additional effective ply strength properties are needed to characterize the progression of such damage. It should be obvious that matrix cracks are more likely to be arrested by laminates with fibers in

multiple directions and in laminates in which the plies in the different directions are thoroughly interspersed rather than blocked or nested together.

Footnote

* *The authors have not yet examined the situation for room- temperature-curing laminating resins and therefore cannot predict *where* the highest strains will develop in the matrix in that case. Nevertheless, the procedure outlined above will lead to the correct property. It should also be noted that the value of J_1 will also change when the laminate is saturated with absorbed moisture, but more from the change in polymer properties than from any relief of thermal stresses due to "swelling." In any event, even if the swelling was able to completely nullify the residual thermal stresses, it would do so at *only one temperature*. Increments of intralaminar (and interlaminar) residual thermal stress would be reintroduced *every* time the operating temperature was changed. No justification has ever been provided for omitting consideration of *intra*laminar residual thermal stresses in the manner adopted by so many other authors, who have formulated their models at the macrolevel and thereby overlooked microlevel effects that influence the macrolevel behavior. Any chemical contraction of the resin should be a fixed quantity, independent of temperature, and should therefore be accounted for automatically in the estimate for J_1, because these effects would be present in the test specimen.

Effects of Combined Loading on Matrix Failure Envelope

Considerable progress has been made in applying the matrix failure model described previously to the classical interaction between in- plane shear and transverse tension and compression stresses acting on a unidirectional lamina, and no need has been found for any further properties or for any changes in J_1 and ϵ_{eqv}, which are the only properties involved in the initiation of matrix failures. Figure 10 shows German test data for biaxial loads of a unidirectional glass lamina in which the predictions have been fitted to only two points, the transverse strains to failure in tension and compression. The measured in-plane shear strain was not involved.

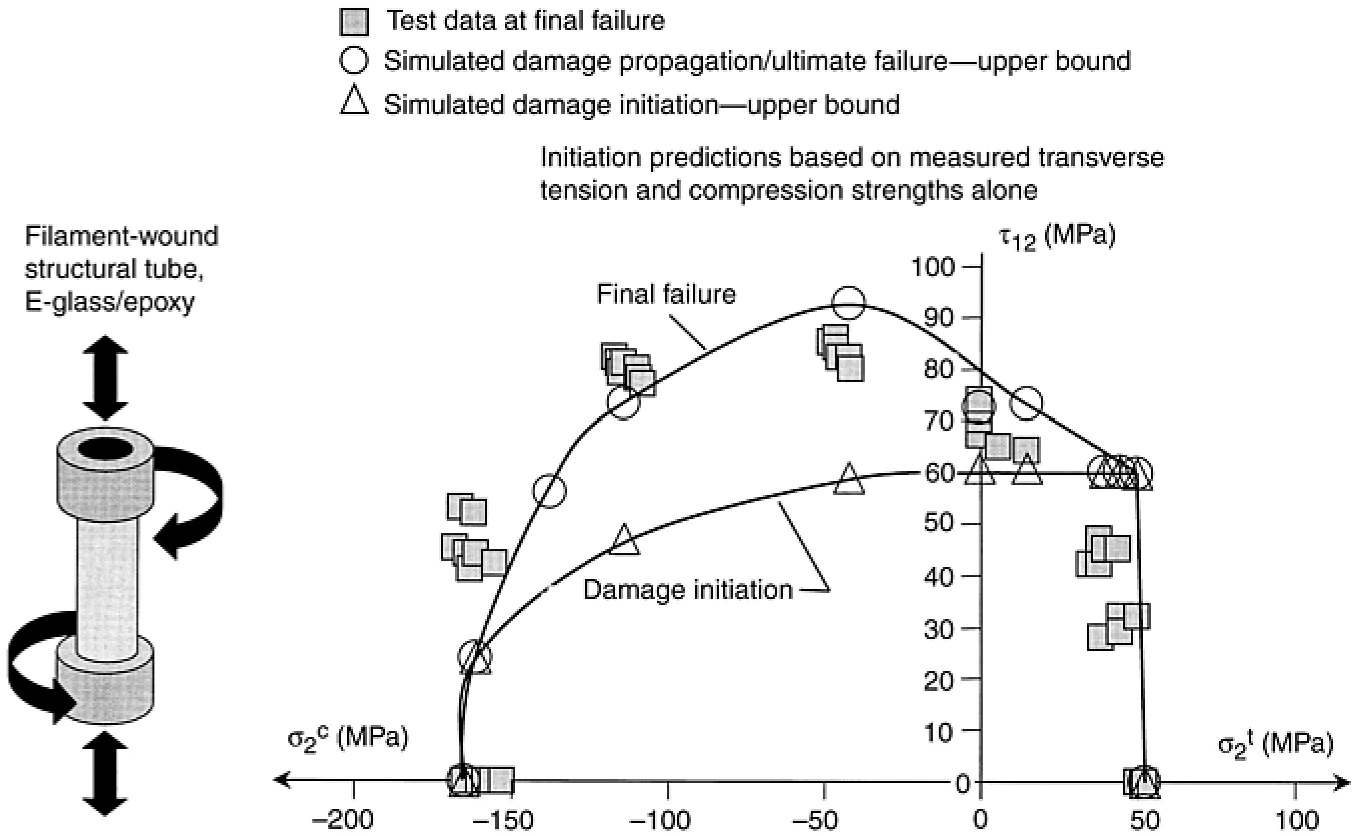

Fig. 10 Damage initiation, propagation, and ultimate failure of biaxially loaded E-glass/epoxy composite tubes. σ_2^t and σ_2^c are axial tension and compression. τ_{12} is in-plane shear stress.

These results indicate that there is no opportunity for subsequent progressive damage if the initial failure is by dilation. However, it is clear that substantial subsequent damage can be tolerated before catastrophic failure occurs. The assessment shown for damage progression has been fitted to only *one* test point. The *same* value of the J_2 invariant is used for all of the other predictions. The damage-progression model was still under development when this article was prepared, so further details must await subsequent publications.

Characterizing Strength from a Structural Design Perspective

---

Characterization of Progressive Matrix Damage

Although the ability to reliably assess the onset of damage initiation within the polymeric matrix phase is important, the ultimate goal in failure analysis is usually to determine the ultimate failure loads of composite structures. (In some structures subjected to multiple loads in random order, the *onset* of damage may need to be *defined* as design ultimate strength.) Understanding damage initiation allows for the simulation of damage progression and ultimate failure.

Actual damage can involve transverse ply cracks, delaminations, fiber-matrix debonding, and fiber fracture. At present, it is important to track this damage explicitly. Recent efforts by the authors to simulate the presence of matrix damage (no fiber failure) through abstract means have been successful, but the methods are new and not yet developed to the level where they can be used in production environments.

Although the damage initiation mechanisms are not synergistic, it can be assumed that damage progression will involve both dilatational and distortional deformations. Equations 1 and 3 can be used to express J_2 (the second invariant of strain) as a function of both J_1 and γ, where J_2 is the sum of the products of the principal strains:

$$J_2 = \varepsilon_1'\varepsilon_2' + \varepsilon_1'\varepsilon_3' + \varepsilon_2'\varepsilon_3' = \frac{(J_1^2 - \gamma^2)}{3} \quad \text{(Eq 7)}$$

The result is a critical arrest property, ($J_2{}^a$), that can be used to map matrix damage once matrix damage has been initiated without fiber failure. The arrest property, $J_2{}^a$, can be determined by analyzing an angle-ply laminate in tension with no grip-to-grip fiber support. At the onset of damage initiation (the onset of nonlinearity in the load-displacement curve), a one-inch wide laminate will instantly suffer damage across the width of the laminate. $J_2{}^a$ is then numerically extracted from the center of the laminate at the damage initiation load. The damage arrest property is an effective intrinsic material property of the lamina. $J_2{}^a$ is only valid when fiber failure does not occur, and it only identifies what elements should have their matrix-dependent moduli, E_2, E_3, G_{12}, G_{13}, and G_{23}, reduced. The final local analysis will have each ply represented by a single element (more if convergence through the laminate thickness has not been achieved). Expressing failure mechanisms as mathematical functions allows for each element to be checked against all currently understood failure mechanisms. Each mathematical function results in a number between 0, for complete degradation, to 1, for no degradation. The failure mechanism that results in the lowest fraction is used to reduce the matrix-dependent moduli for the element under assessment. Currently, five failure mechanisms have been documented mathematically and are given in Eq 8 to 12, where *rf* refers to reduction factor.

Reduction factor a is given as:

$$rfa = \frac{\varepsilon_{eqv}}{\gamma} \quad \text{(Eq 8)}$$

It has been shown that the critical value of $J_2{}^a$ is always a negative value. Inspection of Eq 7 indicates that for $J_2{}^a$ to be negative, damage progression must be distortionally dominant. Therefore, the first failure mechanism, Eq 8, is simply the ratio of the critical value of γ, the equivalent strain, ϵ_{eqv}, divided by the element average value of γ for a given state of deformation. This failure mechanism would dominate in a laminate subject to in-plane tension.

Reduction Factor b. If a laminate is subject to out-of-plane deformation, transverse cracks may occur that could lead to delaminations. This failure mechanism is expressed mathematically as:

$$rfb = \frac{\gamma_{ip}}{\gamma} \quad \text{(Eq 9)}$$

Here, γ_{ip} is the element value of γ where only the in-plane tensor strain components are included. γ is the element value of γ where the entire strain tensor is included. As out-of-plane behavior is reduced, Eq 9 approaches unity, and Eq 8 will govern moduli degradation.

Reduction Factors c and d. If the ply volume decreases and becomes negative, and the maximum principal strain is positive, then at some point, damage will initiate within the ply, but damage progression will be very different than when the ply volume is increasing. In this case, damage progression will be retarded. Another regime lies in between volume expansion and contraction. These two additional failure mechanisms are expressed mathematically in Eq 10 and 11:

$$rfc = \frac{(1 + rff)}{2} \quad \text{(Eq 10)}$$

if J_1 + J < $_{\text{lcrit}}$ 0 *and* where *rff* = min (*rfa, rfb*).

$$rfd = \frac{(rfc + rff)}{2} \quad \text{(Eq 11)}$$

if $J_1 < 0$ and $J_1 + J_{1crit} > 0$ and where again *rff* is defined as previously.

Reduction Factor e. Finally, if a deformed ply has longitudinally compressed fibers, then the ply modulus in the fiber direction is temporarily reduced by the smallest of Eq 8 to 11. This measure is temporary and only occurs for the current state of deformation. Damaged laminates suffering fiber compression may not fail catastrophically. As a result, strains may redistribute as a function of the reduced lateral support supplied by the damaged matrix. If the next state of deformation does not involve longitudinal fiber compression, and the fiber has not failed, then the modulus in the fiber direction is restored to its original value. This final failure mechanism is mathematically expressed as:

$$rfe = \min(rfa, rfb, rfc, rfd) \quad \text{(Eq 12)}$$

In all cases, if fiber failure has occurred, then all ply moduli are reduced to 0.001% of their original values. For a converged model, every ply within every element is assessed as previously stated, resulting in a simulation of matrix damage propagation that is tied to the current state of deformation. The resulting property-reduction methodology is therefore nonarbitrary and reflects a realistic simulation of damage and its effects on critical structural behavior.

Characterizing Strength from a Structural Design Perspective

L.J. Hart-Smith, J.H. Gosse, and S. Christensen, The Boeing Company

Empirical Failure Envelopes for Multidirectional Laminates

The preceding physics-based failure envelopes are easily related to two reliable, widely used empirical failure envelopes. These are the maximum-strain model used so successfully by Puck and his disciples in Germany for glass- fiber-reinforced laminates (Ref 13) and the truncated maximum-strain failure model for carbon-fiber-reinforced laminates developed independently at several aircraft factories in the United States (Ref 3). Despite a common heritage at the constituent level, these materials are surprisingly different at the lamina level, because of the relative strains-to-failure. Glass fibers have such high strains-to-failure that it is common for structurally significant matrix failures to precede fiber failures by large margins. On the other hand, carbon fibers have such low strains-to-failure that it is quite easy to design laminates in which structurally significant matrix failures do not occur until long after limit loads have been attained or, in some cases, not until after the fibers have failed. Matrix damage from impacts is a separate issue and can clearly precede failures under the in-plane load to which structures are designed. In both cases, microcracks of no structural significance occur in the matrix, preceding any cracks that are important; in most cases, even virgin laminates are riddled with insignificant microcracks caused by residual thermal stresses.

Maximum-Strain Model. The consequence of these relative strains-to-failure is that Puck's roughly ellipsoidal failure envelope for glass-fiber-reinforced polymers is predominantly defined by matrix failures, under transverse loads and shear, truncated at the ends by fiber failure cutoffs, as shown in the simplified model characterized in Fig. 11. The reader is referred to the published works of Puck and his students for further details on this kind of analysis.

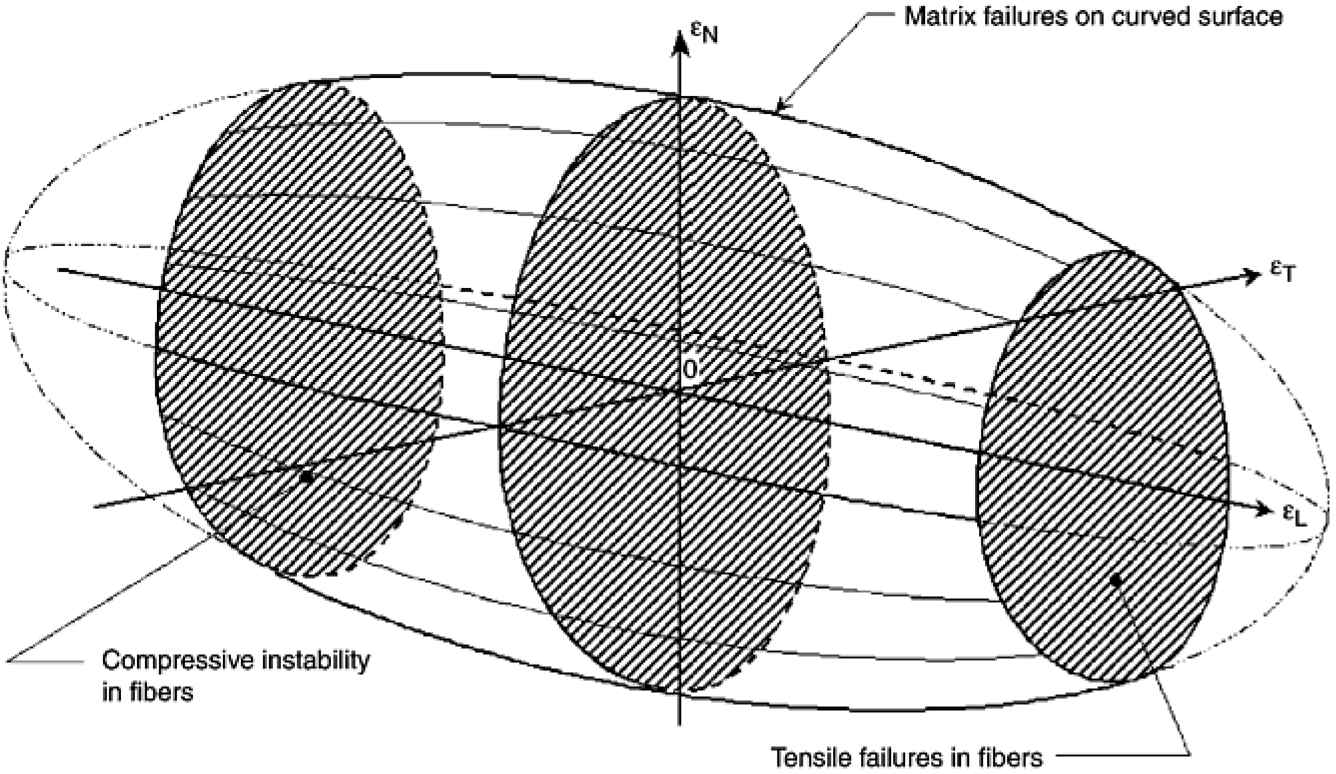

Fig. 11 Lamina-level failure model for glass-fiber-reinforced laminates

In contrast with his better-known contemporaries, Puck, in the 1960s, pointed all those who chose to follow him in the *right* direction, that the use of only mechanistic failure models was the path to follow. His progress was eventually limited by a decision to formulate his criteria at the homogenized lamina level, with no micromechanical considerations.

Because of his dissatisfaction with the models used in America, as far as the ability to predict real matrix failures was concerned, Hart-Smith had developed empirical models (for matrix failures), which he used until his collaboration with Gosse. These met with mixed success, but had always been recognized as incomplete. One failure mechanism, matrix failure under in-plane shear, could be coped with by use of secant moduli appropriate to the strains actually developed, as explained in Fig. 12.

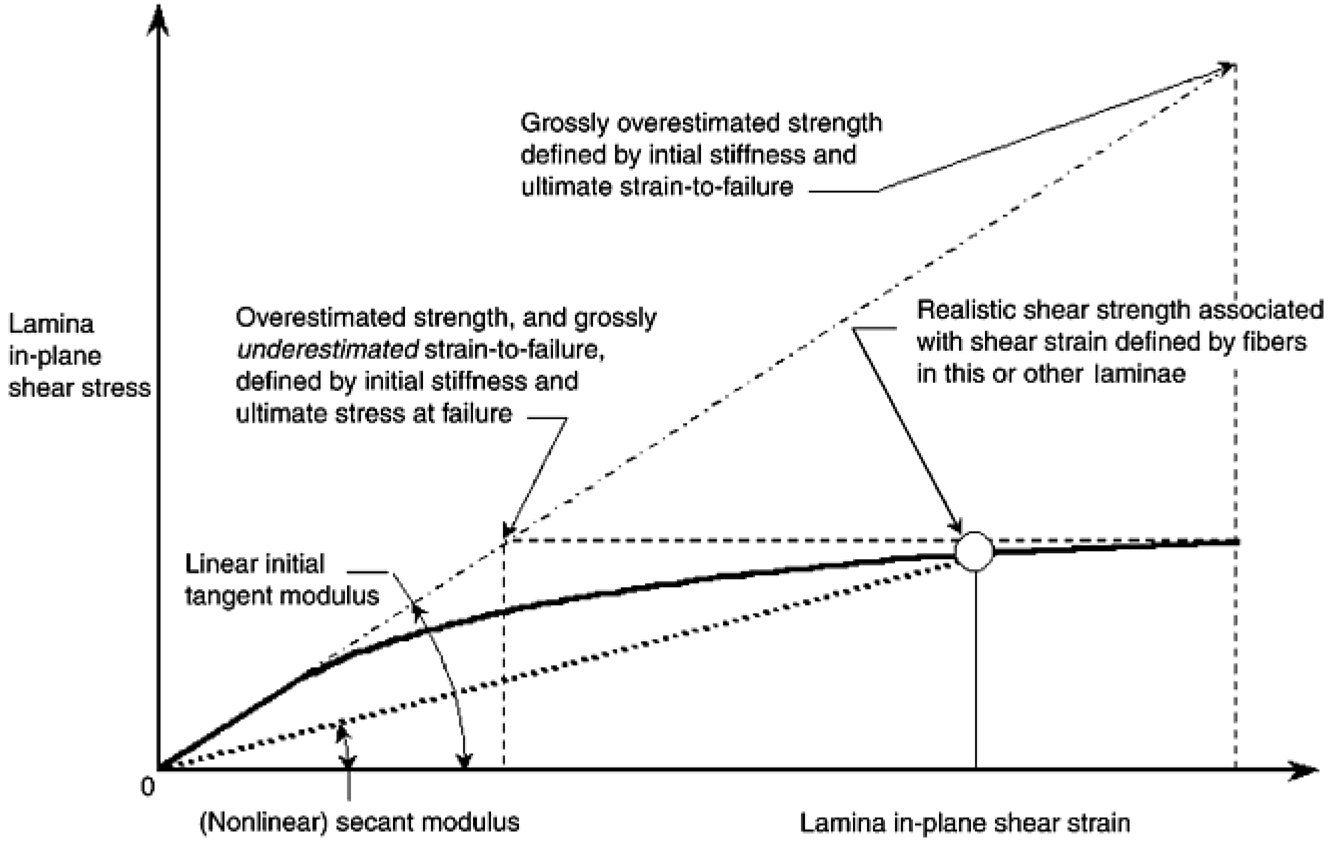

Fig. 12 Approximate modeling of in-plane shear deformation of matrix, at lamina level, in terms of secant moduli

The predictions from such a model are reasonably consistent with test data on laminates, but were always at odds with cracking failures in the matrix by transverse tension within each ply. It has long been clear that two unrelated mechanisms were involved, as indicated in Fig. 9. Hart-Smith's model for such cracking was a straight-line cutoff on the unidirectional lamina strain plane, but there was no basis for locating it. Recent calculations by Gosse have indicated that even the slope, parallel to the locus for a pure axial load in the fibers, was in need of improvement.

It is planned that Gosse's matrix failure criteria in Fig. 9 will, at some future date, be depicted in full for both unidirectional laminae and 0°/90° laminates. Preliminary calculations to this end have confirmed the existence of a straight- line (planar) cutoff for failures governed by the J_1 invariant, dominated by tensile σ_{22} stresses. Not surprisingly, they have also identified a curved surface for those matrix failures governed by the equivalent shear strain, γ_{crit}. Indeed, there is every expectation that the general form of Puck's failure model in Fig. 11 will be confirmed, except for the presence of a flat cutoff, rather than Puck's distorted ellipse, to cover the second failure mechanism. These exploratory calculations have necessitated a reappraisal of all prior matrix failure models. The planned new calculations at the lamina and laminate level will be coupled by failure criteria at the constituent level. There will be no way of progressing from lamina behavior to laminate behavior, as *has* been possible for fiber failures. The authors are therefore deferring any further recommendations about the use of approximate analyses for matrix failures until they have developed a more complete understanding. What can be anticipated, however, is that *complete* matrix failure initiation envelopes at the lamina and laminate levels will be defined by only two reference properties, just as they have been (and continue to be) for fiber failure envelopes.

Truncated Maximum-Strain Model. The truncated maximum strain failure envelope for a unidirectional carbon/epoxy lamina is shown in Fig. 13. It is customarily presented for orthogonal 0° and 90° plies to provide transverse strain limits that would otherwise be much further from the origin, as indicated in Fig. 6. The failure envelope is almost completely defined by fiber failures in the longitudinal-transverse plane, with vertical walls also defined by fiber failures, and an approximately horizontal roof defined by a constant matrix shear strain at failure. Exactly the same envelope is employed for both embedded and isolated laminae, even though there is a difference in regard to transverse tension loads, as noted previously. There is no separation between the onset of failure and catastrophic final destruction when there are no transverse fibers in adjacent plies to arrest the

spread of any initial damage. Even so, for structures that can be subjected to varying combinations of biaxial loads in random order, it is necessary to *define* the onset of structurally significant matrix damage as design ultimate strength. Otherwise, it would be necessary to face the intractable problem of path- dependent strengths.

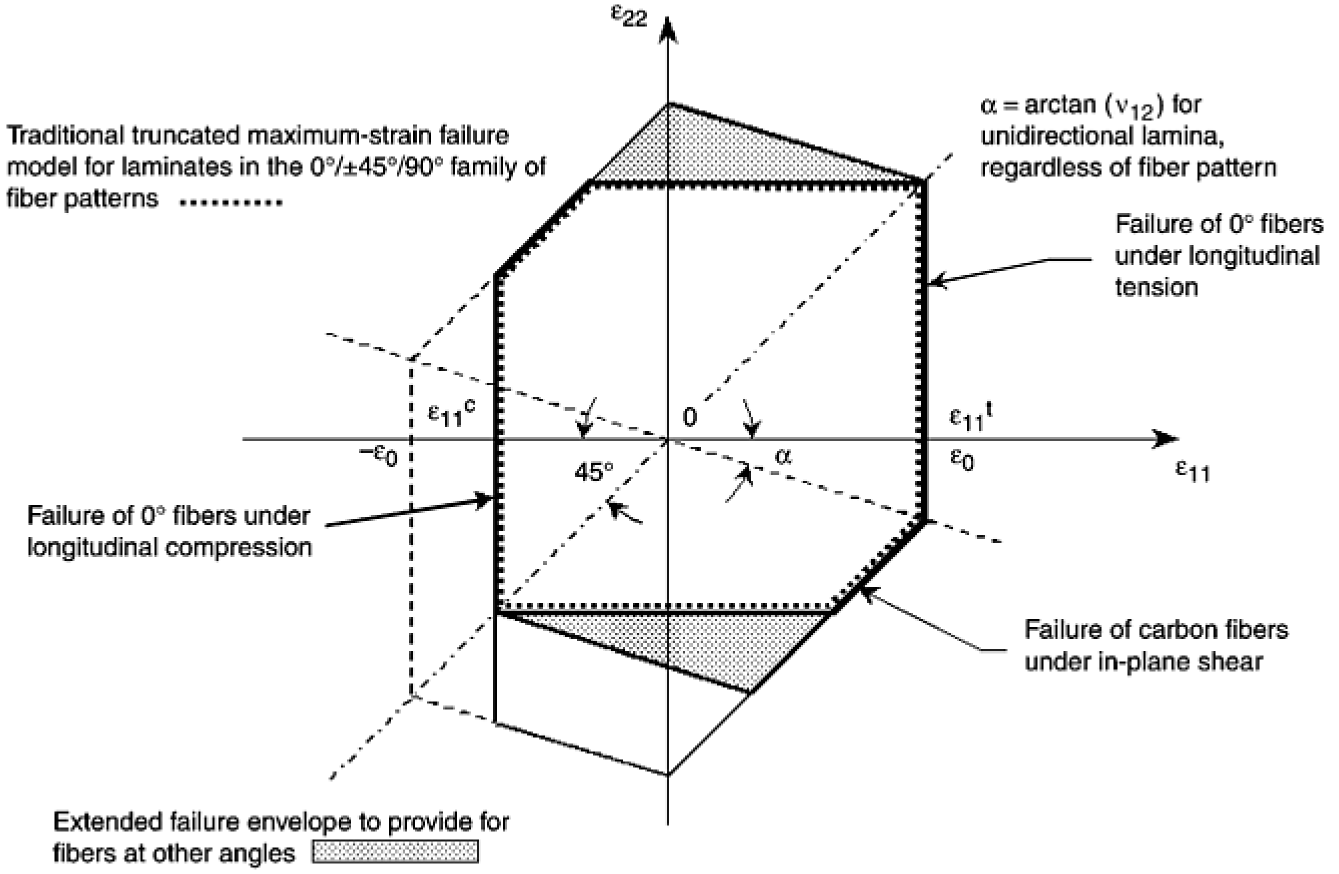

Fig. 13 Truncated maximum-strain failure envelope for carbon-fiber-reinforced polymers at the lamina and laminate strain levels

The longitudinal tension and compression strengths are defined by the simple relation:

$$\varepsilon_L^c \leq \varepsilon_{11} \leq \varepsilon_L^t \qquad \text{(Eq 13)}$$

The 45° sloping cutoffs are defined by:

$$|\varepsilon_{11} - \varepsilon_{22}| = (1 + \nu_{LT})\varepsilon_0 \qquad \text{(Eq 14)}$$

in which the longitudinal strain, ϵ_0, is the numerically greater of the tensile and compressive longitudinal strains-to-failure, ϵ_L^t and ϵ_L^c, and ν_{LT} is the primary Poisson's ratio for the unidirectional lamina. Transverse strain limits are effectively defined by the failure under longitudinal tension or compression of other plies in the laminate, at different orientations. For laminates not containing plies in a sufficient number of directions to be fiber-dominated, it has become standard in the aircraft industry to apply transverse strain limits as if such fibers had been present, to limit the design matrix strains. These limits have customarily been defined to be the same as for the fiber longitudinal strains at failure, but it was learned during the preparation of Ref 15 that this was appropriate only for laminates in the 0°, ±45°, 90° family. In laminates with fibers in other directions, it was found that the arbitrary transverse cutoffs should be defined by:

$$|\varepsilon_{22}| = (1 + \nu_{LT})\varepsilon_0 - \nu_{LT}\varepsilon_{11} \qquad \text{(Eq 15)}$$

The matrix in-plane shear limits are set by horizontal plateaus parallel to the fiber reference plane:

$$|\gamma_{12}| \leq \gamma_{LT} \qquad \text{(Eq 16)}$$

For laminates and laminae with fibers in only the 0° and 90° directions, there are no further matrix shear failure cutoffs in the approximate analyses. However, standard transformation equations should be used to convert the 0° and/ or 90° shear failure plateau into the corresponding nonhorizontal planes for plies with fibers in other directions. For example, the corner truncations shown in the second and fourth quadrants of Fig. 13 would be

supplemented by parallel cutoffs, further from the origin, for matrix shear failure cutoffs between fibers in the ±45° directions.

The same set of equations can be applied for glass-fiber-reinforced laminates by omitting Eq 10, as indicated in Fig. 7.

The failure envelope in Fig. 13 is totally noninteractive. However, this relies upon laminates in which the layers of fibers are triangulated so that they behave as structures rather than mechanisms, and in which parallel plies are not blocked together. If they were, failure could be caused by interlaminar stresses not addressed in the present analysis of potential matrix failures. Good design practice for multidirectional laminates calls for restrictions to no more than 0.25 mm (0.010 in.) of parallel fibers adjacent to a 90° change in fiber directions and no more than 0.50 mm (0.020 in.) of parallel fibers adjacent to a 45° change in fiber direction. The preferred fiber patterns shown in Fig. 14 place limits on the deviation from the quasi-isotropic pattern. These are particularly important for laminates with loaded bolt holes. Coarser limits on percentage of fibers in each direction are shown for minimum-gage, lightly loaded panels, because there are insufficient plies, in total, to create overloaded interfaces. Nevertheless, it is common practice to include nearly quasi-isotropic reinforced edges, for bolt holes, surrounding minimum-gage facesheets (particularly when they are split into two even thinner layers on each side of sandwich cores.)

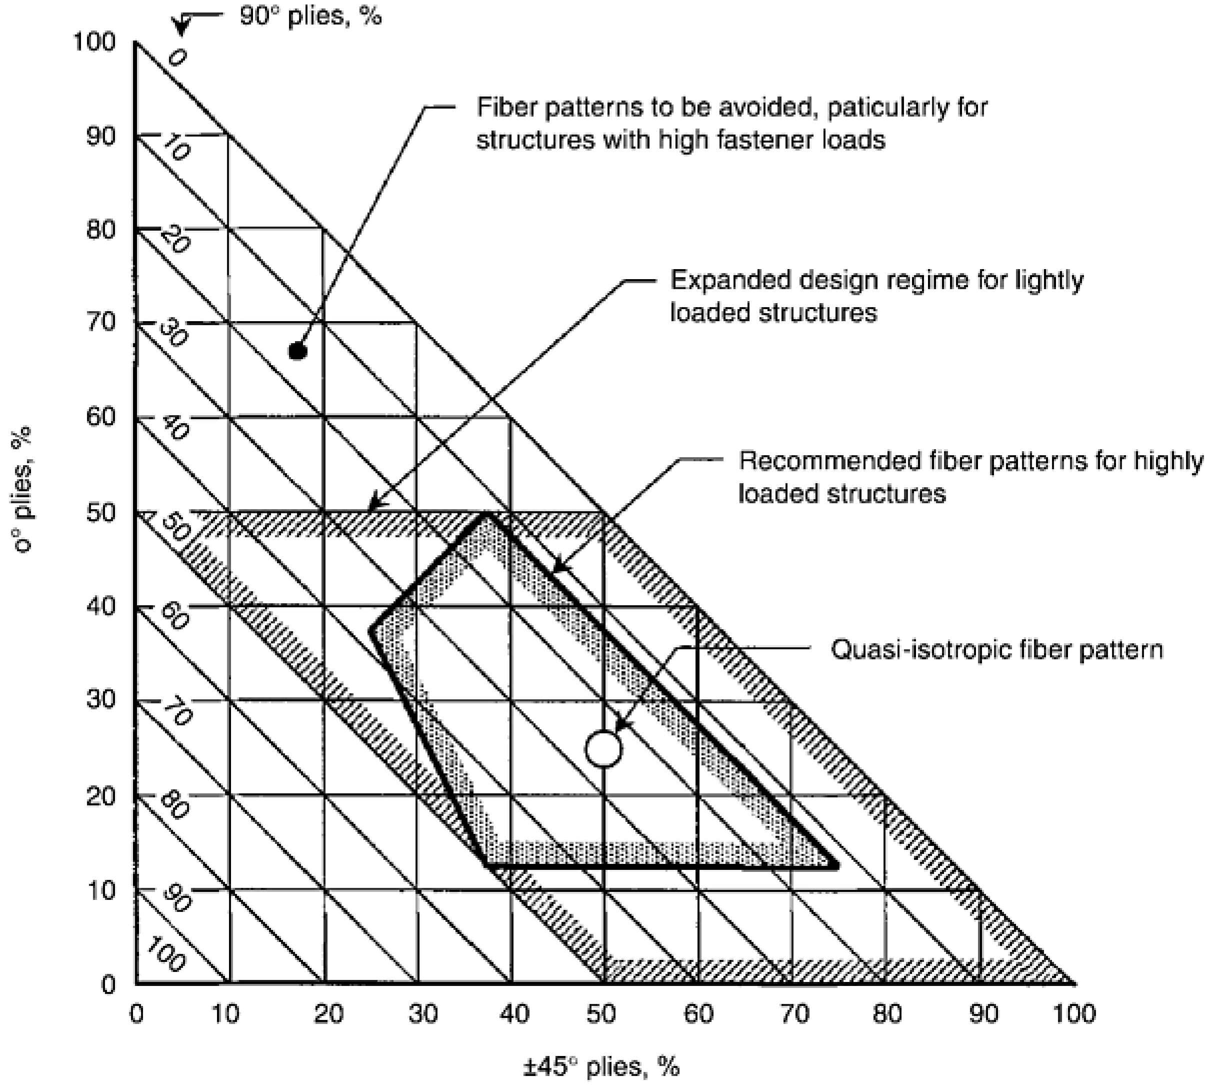

Fig. 14 Preferred fiber patterns for carbon-fiber-reinforced polymers

The truncated maximum-strain failure model was developed because, without it, the projected in-plane shear strengths for ±45° carbon/epoxy laminates, according to the original (untruncated) maximum-strain model described in Ref 2, would be far too high in light of even the best test data.

Provided that they were used in such a way as not to violate physical reality, the approximate matrix properties in Eq 2, 4, and 5 could be employed without consideration of micromechanical effects as a *lower bound* set of properties for simplified analyses of some problems. The inclusion of intralaminar residual thermal stresses and

an accounting of the greater strains in the matrix than in the lamina in the proper evaluation of these two properties would only increase their value. The authors recommend this approach only with caution, but it must be said that even this would be far more accurate than many established analysis procedures for predicting the strength of composite laminates.

Conclusions

The simple-to-comprehend physics-based failure criteria presented here for the embedded constituents of fiber-polymer composites provide the first *comprehensive* procedure for predicting the strength of composite laminates. Other than for calculating elastic stiffnesses for laminae and laminates, there is no such thing as a homogeneous composite material, only a composite of materials. It is vital to characterize the failure of the constituents separately and in a manner that includes all of the relevant macro- and microlevel stresses and strains. It has been found that strain-based models are the most appropriate formulations, for both fibers and polymer matrices. It is significant that each of the materials properties on which these analyses are based is independent of all others. All of these properties can be measured directly, although it is necessary to analytically compensate for the effects of residual thermal stresses, which cannot be measured, on the basis of measured properties for the fiber and matrix constituents. Even the simple lamina-level approximate analyses recorded here are fully mechanistic. Not one of the analyses relies on empirical curve fits through unexplained test data. It is no longer necessary to know the answer before it can be predicted.

Fracture Mechanics of Composite Delamination

T. Kevin O'Brien, U.S. Army Research Laboratory

Introduction

DELAMINATION, a separation of the fiber- reinforced layers that are stacked together to form laminates, is one of the most commonly observed failure modes in composite materials. The most common sources of delamination are the material and structural discontinuities that give rise to interlaminar stresses (Fig. 1). Delaminations occur at stress-free edges due to a mismatch in properties of the individual layers, at ply drops (both internal and external) where thickness must be reduced, and at regions subjected to out-of-plane loading, such as bending of curved beams. There are three fundamental failure modes, as shown in Fig. 2:

- *Mode I*: opening mode
- *Mode II*: in-plane shearing mode
- *Mode III*: tearing or scissoring shearing mode

Locally, delaminations typically form due to some combination of these fracture modes.

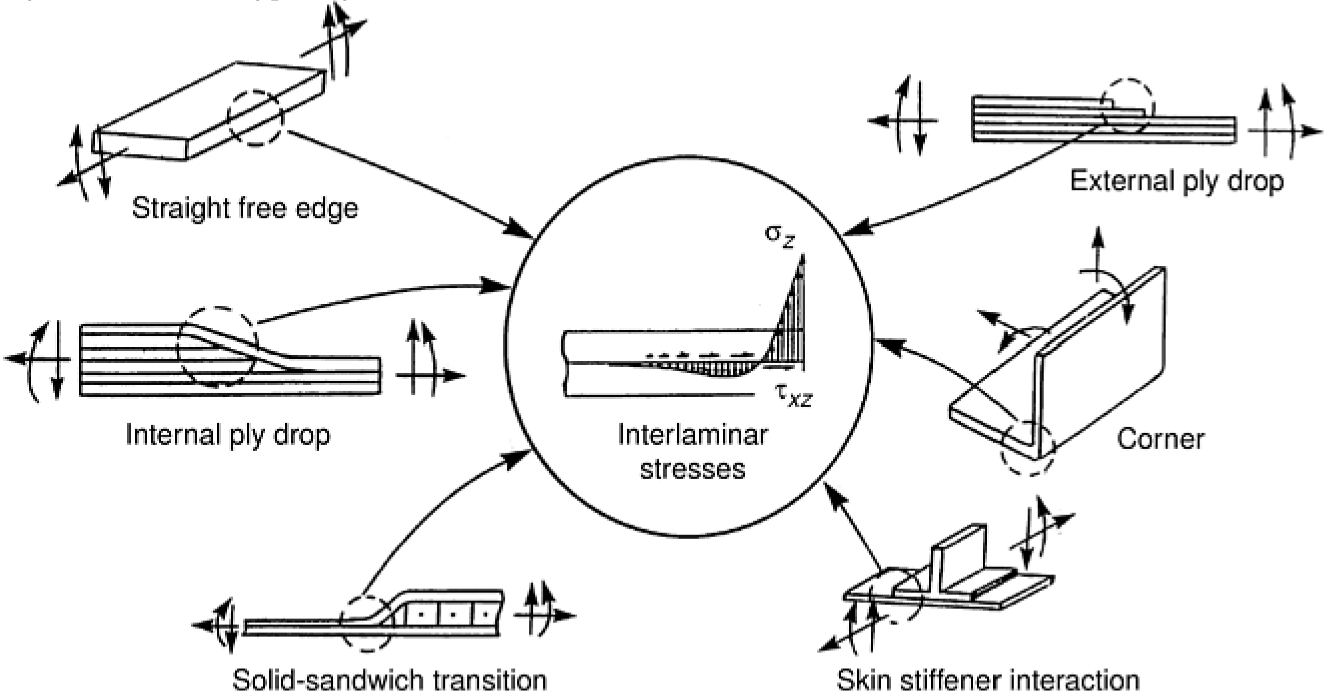

Fig. 1 Delamination sources at geometric and material discontinuities

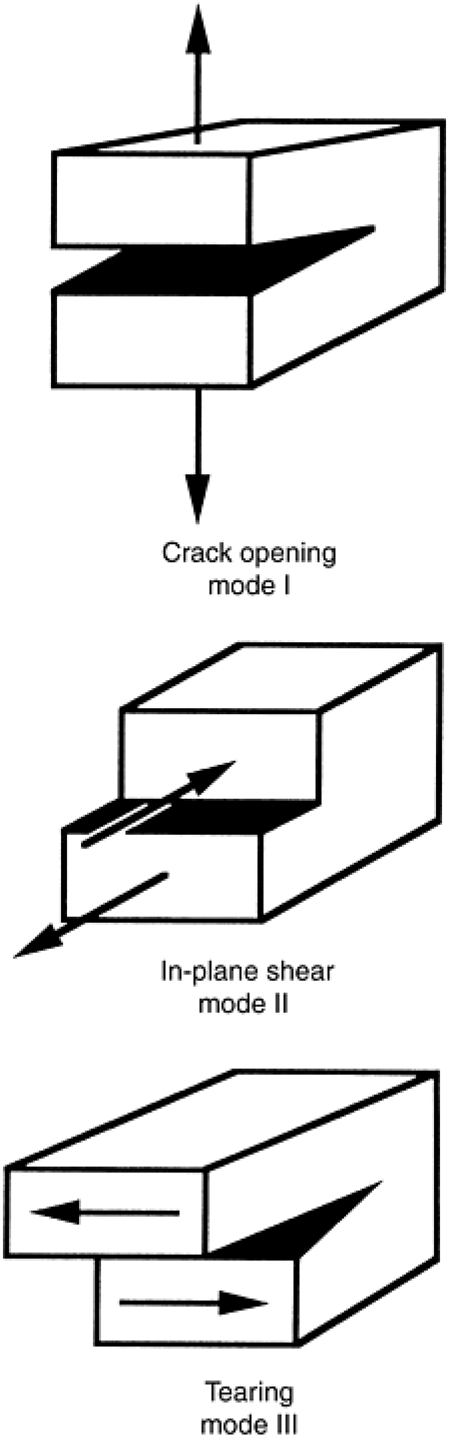

Fig. 2 Three basic modes of delamination fracture

The interlaminar fracture toughness (IFT) is a measure of the ability of a material to resist delamination. For the most general cases, the strain energy release rate values for each mode (G_I, G_{II}, G_{III}) are calculated for the configuration and loading of interest. These values must be compared to the critical value, which has been determined from material characterization tests. The critical IFT value is determined from the same combination of fundamental modes to predict delamination onset and growth.

Delamination Characterization

Typical mixed-mode I and II delamination failure criterion is shown in Fig. 3. The IFT is determined as a critical value of the strain energy release rate, G_c, plotted as a function of the mixed-mode ratio, G_{II}/G, where $G=G_I+G_{II}+G_{III}$. The pure mode I opening case is stated as $G_{II}/G= 0$, and the pure mode II case is represented by $G_{II}/G= 1$. These properties are determined using test methods that are being evaluated and standardized by ASTM and other national standards organizations, as well as the International Standards Organization (ISO) (Ref 1). The pure mode I data are generated using a double-cantilever beam (DCB) test (2, 3 4). The pure mode II data generally are generated using an end-notched flexure (ENF) test (Ref 5, 6). The mixed-mode I and II data are generated using a mixed-mode bending (MMB) test (7, 8 9). As shown in Fig. 3, the apparent toughness generally increases monotonically between the pure opening mode I case and the pure shear mode II case. Furthermore, due to the complex micromechanisms involved, the scatter of test data is very large for the mode II case (Ref 10). The test specimens are shown in Fig. 4. For cases where a mode III fracture toughness is required, the edge-cracked torsion (ECT) test is preferred (Ref 11, 12).

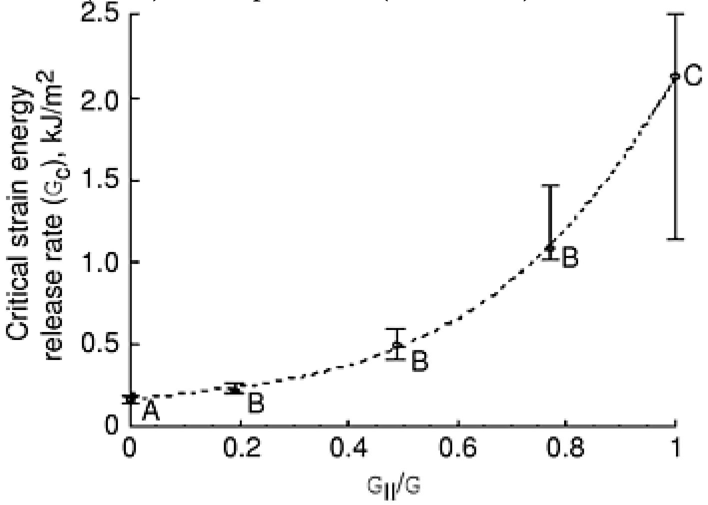

Fig. 3 Critical strain energy release rate, G_c, as a function of the mixed-mode ratio for graphite/epoxy IM7/E7T1-2. A, pure mode I; B, mixed mode I and mode II; C, pure mode II

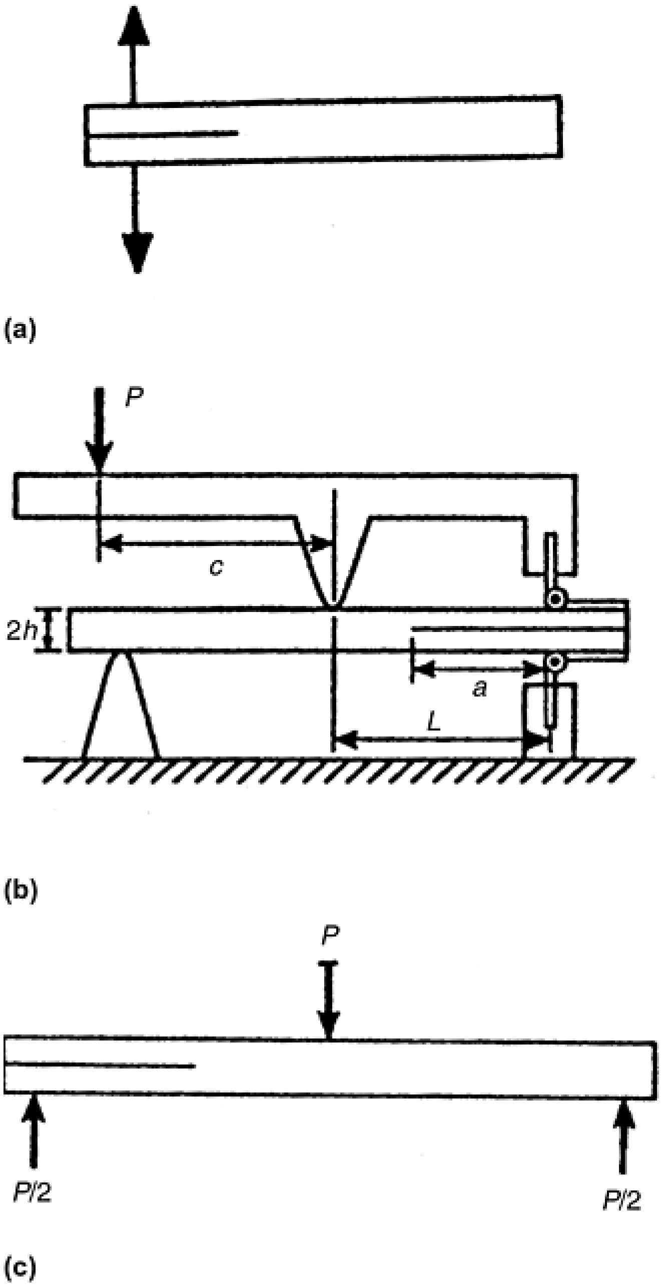

Fig. 4 Test specimens for determining G_c. (a) Mode I, double-cantilever beam (DCB). (b) Mixed mode I and mode II, mixed-mode bending (MMB). (c) Pure mode II, end notch flexure (ENF)

Because delaminations often form and grow under cyclic loads, a fatigue characterization is also desired. The classical Paris law for fatigue crack growth (which describes crack growth per load cycle as a function of the range in the stress- intensity factor) has often been generated (13, 14 15); however, the exponents in these power laws are quite high compared to similar characterizations for metals. Hence, a no-growth threshold approach is often proposed instead (16, 17 18, 19). Furthermore, for mode I fatigue, fiber bridging typically develops in the unidirectional DCB specimens (Ref 1, 17). This fiber bridging can cause a growing crack to arrest artificially early, yielding a nonconservative threshold value (Fig. 5a). Therefore, as shown in Fig. 5(b), an alternate *G* versus *N* onset curve is typically generated to achieve a threshold characterization for delamination onset (17, 18 19, 20).

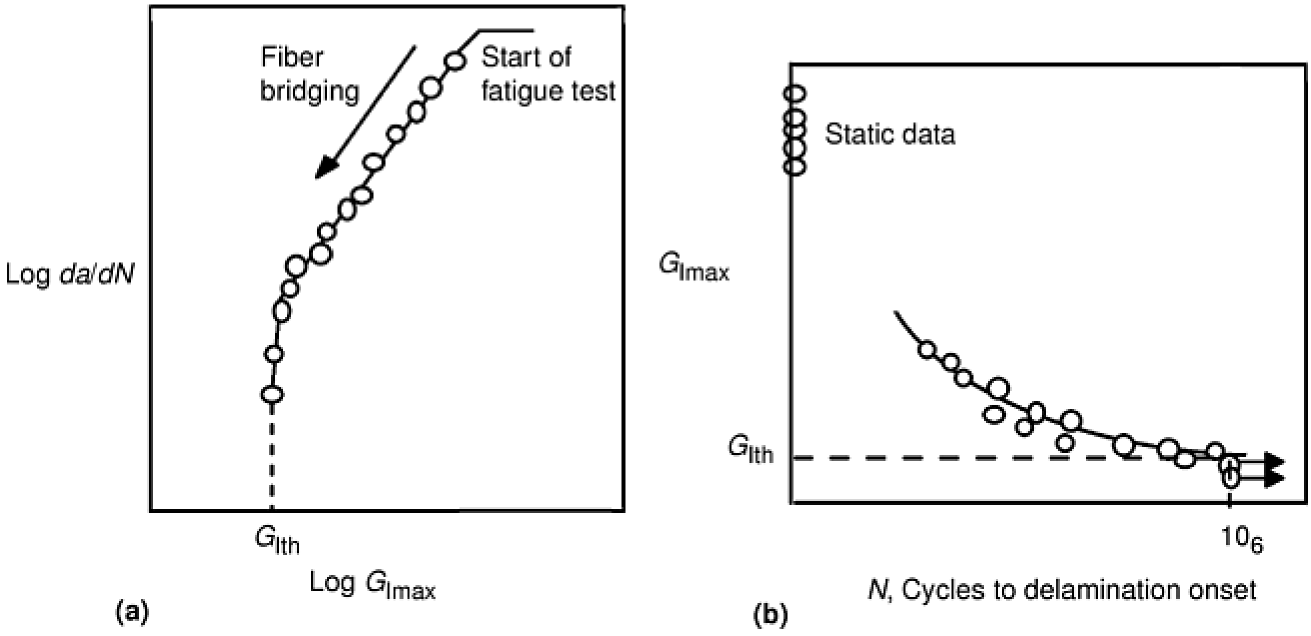

Fig. 5 Experimental techniques to obtain a strain energy release threshold, *G*, for delamination onset. (a) By delamination arrest. (b) By delamination onset

Fracture Mechanics of Composite Delamination

T. Kevin O’Brien, U.S. Army Research Laboratory

Delamination Analysis

As noted earlier, the strain energy release rate, *G*, associated with onset and growth, must be determined to predict delamination. Typically, a plot of the *G* components due to the three fundamental fracture modes (G_I, G_{II}, G_{III}) and the total $G=G_I+G_{II}+G_{III}$ are calculated as a function of delamination length, *a*, using the virtual crack closure technique (VCCT) in a finite element analysis (FEA) (Ref 21, 22). The VCCT technique, depicted in Fig. 6, utilizes the product of nodal forces and the difference in nodal displacements, to calculate the *G* components for each fracture mode. Alternate methods have also been proposed for calculating *G* (23, 24 25). For predicting delamination onset in two-dimensional problems, the peak value of the *G* versus *a*

distribution is compared to the mixed-mode fracture criterion of Fig. 3. The VCCT technique has also been extended to three-dimensional problems (Ref 26), including those involving delamination growth due to sublaminate instability in compression loaded laminates (Ref 27) and the three-dimensional effect in skin-stiffener pull-off delamination failure (Ref 28).

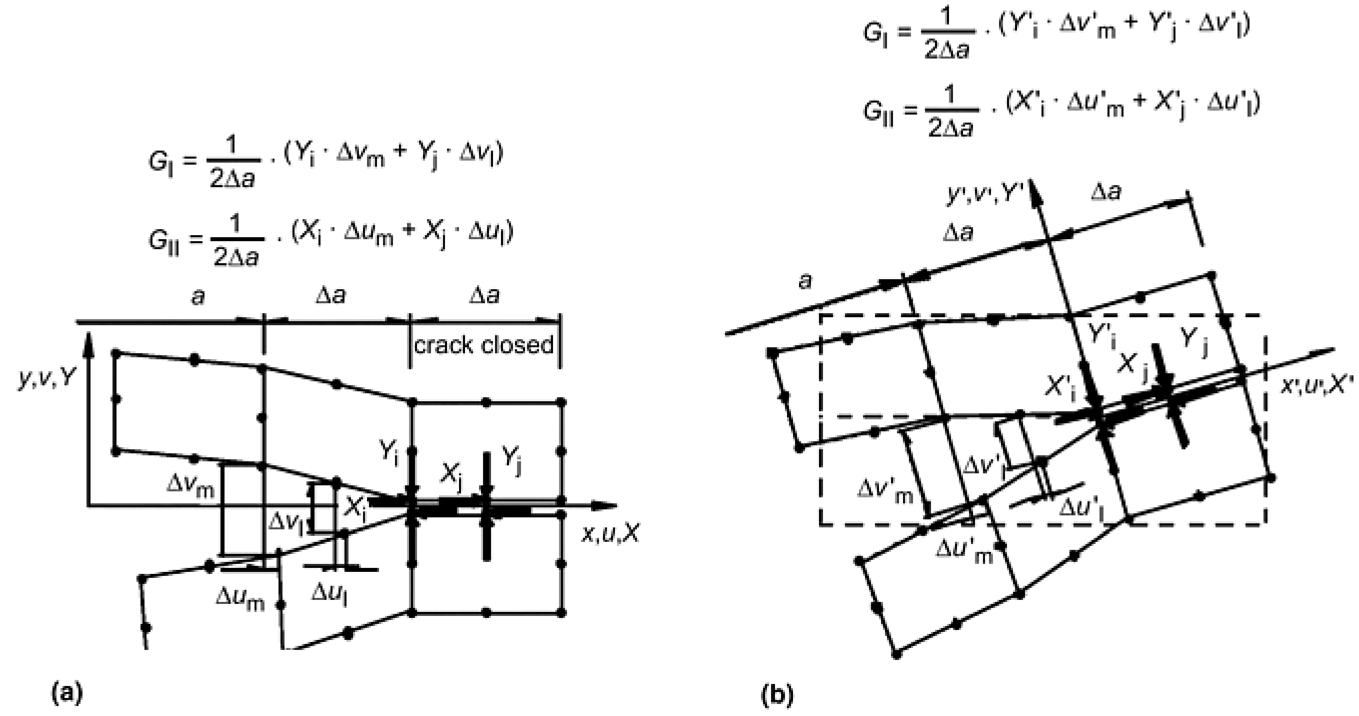

Fig. 6 Finite elements used for the virtual crack closure technique (VCCT). Eight-noded quadrilateral elements are used in (a) linear and (b) nonlinear analysis.

Delamination Prediction

Flexbeam Fatigue Life Prediction. Helicopter composite rotor hubs contain tapered flexbeams with large numbers of ply terminations, or *ply drops*, to taper the beam thickness. These ply drops may act as delamination initiation sites in the flexbeam under high combined tension and cyclic bending loads. Reference 29 describes how one-sixth sized flexbeams were tested (Fig. 7) and analyzed to determine the fatigue life, identified as onset of delamination. The ply drops of the flexbeams are detailed in Fig. 8. Fatigue delamination onset test data are plotted in Fig. 9. This characterization of the material is compared to the G distributions determined by FEA using VCCT, for the conditions shown in Fig. 10. The analysis results in the prediction of the onset of unstable delaminations from ply drops to characterize the fatigue life given in Fig. 11.

Skin/Stiffener Pull-Off Strength and Life. Figure 12 shows the prediction of pull-off loads that cause separation of the flange of a hat stiffener from the skin of a composite part. The pull- off loads associated with

delamination onset were predicted by comparing *G* values calculated from FEA using VCCT to the mixed-mode delamination failure criteria in Fig. 3 and 4 (Ref 30).

Subsequent studies led to the development of the simple specimen for studying skin-stiffener debonding (Fig. 13), which consists of a skin bonded to a tapered flange laminate (Ref 31, 32). Most recently, a generalized fatigue methodology based on the approach used in Ref 29 was developed and used to predict the delamination onset life for skin-stiffener debonding under cyclic loading (Fig. 14) (Ref 33).

Hygrothermal Behavior

Daniel R. Ruffner, The Boeing Company

Introduction

HYGROTHERMAL BEHAVIOR of cured composite materials relates to the combined and commonly synergistic effects of moisture absorption and temperature on various physical, chemical and mechanical properties. While effects for polymer-matrix composites can be substantial, thermosetting matrices are typically much more affected than thermoplastic matrices. Although hygrothermal effects should be irrelevant for metal-

and ceramic-matrix composites, their responses as newer materials and as classes are still somewhat uncertain. This article concentrates on polymer-matrix composites and is limited to the effects of moisture absorption after an established cure of the material has been completed. Effects of moisture absorption on uncured prepreg or adhesive materials on the material properties after cure can also be present but are not covered in this article. The galvanic electrochemical mechanisms experienced by some carbon/bismaleimide composites also are not covered.

Hygrothermal Behavior

Daniel R. Ruffner, The Boeing Company

General Considerations in Assessing Hygrothermal Behavior

Moisture absorption for composite materials is primarily a diffusion process dependent on environmental conditions. As a result, time is an important factor in reproducing these effects. Since moisture absorption to saturation under typical field environmental conditions can take years, the ability to reproduce these effects in the lab in the more reasonable time frame of days or weeks is critical. Validating that the accelerated aging technique used has not changed the expected field degradation mechanisms and failure modes and their effects on the performance of the material then becomes a concern.

Since hygrothermal testing is accelerated aging designed to reproduce years of exposure in service, an understanding of the conditions of service is important. The same material may be adequate for worldwide environmental conditions in excess of 20 years but fail rapidly in an industrial application with steam exposure. For many aerospace applications a service life of 20 years has been used, but with life extension and aging aircraft programs already in effect, this lifespan should be carefully reconsidered. Since the use of composite materials has expanded, potential service lives have grown from just a few years for some sporting goods to 30 to 50 years anticipated for marine and civil applications such as bridge refurbishment.

While moisture exposure typically induces the greatest degradation for most composite materials, the effects on the material of other fluids and solvents must also be assessed, at least to a degree where it is clear that moisture is in fact the most critical factor. In aerospace, the exposure to solvents, fuels, and hydraulic and deicing fluids is (at least) screened for (typically), in addition to performing the hygrothermal studies described here.

Since this is fundamentally an accelerated aging process, there is a real concern about aging performed under conditions so extreme as to change the material state at the end of conditioning from that which would be expected in service. The intent is that after accelerated conditioning for a period of weeks, the state of the coupon or structure closely approximates the condition that would be expected after years of service. If this is not accomplished, the results may be useless, or, worse, misleading. The inferences from the results on what the long-term durability of the material will be must be clearly understood as a form of extrapolation, with the associated uncertainty. Even though each material combination must be treated individually, similar results on closely related materials that have undergone successful testing and field service are frequently used to validate results to some degree.

Several different goals are associated with work in hygrothermal behavior. One is to ensure that the worst-case environmental conditions are being represented when attempting to characterize or qualify a composite material for a specific application. Even if the only moisture conditions to be represented in testing are the two extremes, completely dry and completely saturated, creating data for both conditions for every property is burdensome and almost always unnecessary. The task is to ensure that hygrothermal effects are well represented for the material properties and conditions that will control the success of the application.

Some work is dedicated to greater understanding of the diffusion phenomena as experienced by composite materials, the factors associated, and the effects such as failure modes. Much of this work is of general benefit, even if the application is just characterization of specific materials for specific applications. If the moisture absorption weight gain data from the characterization is analyzed and seen to be normal Fickian diffusion (that is, diffusion that has the same magnitude in all directions), it can provide additional assurance about the stability of the material. While the discovery of non-Fickian diffusion does not necessarily present a problem, it

can indicate phenomena such as the collection of moisture at the fiber/matrix interface or in voids. For some applications this may still be acceptable, but for other critical applications this could mean that the long-term durability of the composite material in its intended environment has not been ensured.

Absorbing moisture induces some degree of volumetric expansion, which can induce warping and other structure-performance effects similar to thermal expansion issues, in addition to the fundamental effects on the base properties of the material. While this is not commonly the most critical loading condition, it can be an issue and should be considered, as appropriate for the application.

A great deal of the uncertainty associated with hygrothermal effects is the range of differences present based on the combination of materials that make up the composite. Since the exact formulation of most commercially available composite materials is not public knowledge, making comparisons based on composition may not even be possible. Processing can also affect the hygrothermal response; for example, cure cycle differences result in changes in cure state and quality such as void volume. New processes should also be assessed, at least establishing the worst case condition for the current process for a given material. As a result of this sensitivity, some assessment of hygrothermal behavior must be made for every variant of a composite material. This sensitivity partially explains the wide range of literature values for seemingly identical materials.

As more substantial and critical composite structures have been fielded, the thickness of some is now greater than could conceivably be saturated with moisture, even under continuous worst case environmental exposure for the intended life of the structure. If modeling using the appropriate material parameters can establish this condition, then insisting on saturation for coupon and structural testing may be excessively conservative.

The worst case environmental condition is generally taken as 26 °C (79 °F) with 85% relative humidity and, as such, is used for many aerospace composite applications. The condition of the composite material after exposure to 20 years at 26 °C (79 °F) and 85% relative humidity is what is being attempted to be reproduced in the lab in one to two orders of magnitude less time. If exposure to conditions such as engine temperatures or other industrial environments is anticipated, then they may be more critical than the ambient environmental exposure.

Most composite structure is eventually assembled into larger structures, requiring either mechanical fasteners or adhesive bonding. The effects of moisture on mechanically fastened joints can be assessed in the same manner as other mechanical property tests. Adhesives used are subject to most of the same hygrothermal issues as discussed for composite materials, although glass transition temperature requirements may be less stringent.

Hygrothermal Behavior

Daniel R. Ruffner, The Boeing Company

Resins or Matrices

Since the majority of the moisture is typically absorbed by the resin, the type of resin used as a matrix can obviously have a substantial effect on the response of the composite. Epoxies are the most common thermosetting-matrix materials for aerospace, but moisture absorption and effects on properties can vary by an order of magnitude. Other thermosetting matrices include polyimides, polyester, and vinyl esters. High-performance thermoplastic matrices such as polyether etherketone (PEEK) are typically used for continuous fiber composites and have low moisture absorption properties, while others such as nylon used for discontinuous fiber composites exhibit fairly high moisture absorption.

Various materials are used to modify the base resin to improve properties such as toughness. These can be materials such as rubber, thermoplastic, or polyurethane and can substantially change the hygrothermal behavior with the same basic matrix and fiber. A variety of curing agents and catalysts are used, modifying the chemistry of the final matrix and its response.

Daniel R. Ruffner, The Boeing Company

Reinforcements

The type of reinforcement can substantially change the hygrothermal behavior. Carbon fibers are generally considered to be unaffected by most moisture conditions, and the interface between the fiber and resin is usually relatively stable. While the glass fiber itself is largely unaffected by moisture, surface effects can be substantial. Adhesion of the resin to the glass fiber is critical, and is affected by the sizes, finishes, and binders applied. The surface of the fiber can also be attacked. Aramid fibers are unusual in that they can absorb a higher weight percentage of moisture than the matrix and, as such, should be scrutinized as much as the resin. Hybrid forms, using, for example, carbon and glass reinforcements, should be evaluated individually and at least checked in the hybrid form.

The form of the reinforcement can have some influence on hygrothermal behavior. If the fiber/ resin interface is compromised and moisture collects, then continuous fibers allow an easier path for progression than discontinuous fibers. In the same manner, unidirectional material may react slightly differently than fabric or braided forms, although some of this difference may be due to the different finishes applied. In the same manner, the stacking sequence can have some influence of the damage progression. Random mats or preforms that have a substantial quantity of binder applied can absorb more moisture.

The surface treatments, coupling agents, sizes, finishes and binders applied to the surface of fibers used to improve resin adhesion and handling can critically affect hygrothermal performance and should be carefully selected and documented.

Hygrothermal Behavior

Daniel R. Ruffner, The Boeing Company

Processing

Fabrication processing can affect the hygrothermal behavior of composites, primarily as a function of the resulting quality of the completed composite. Oven cures have become more common with cost considerations, but with only vacuum pressure for consolidation, void volume typically increases. Collection of liquid moisture in voids is a common reason for the appearance of non-Fickian diffusion from weight gain data. Resin content and fiber volume differences also change absolute weights, since the resin is typically the primary component absorbing moisture.

Regardless of the fabrication process, every thermosetting composite material undergoes some sort of time-and-temperature cure cycle profile where the chemical changes such as chain extension and crosslinking occur. The pressure applied during the cure cycle can be set aside for this discussion, for while the pressure applied during cure can result in physical changes such as consolidation or development of voids, for common composite-cure processes, it has a negligible effect on the chemical changes occurring during cure.

Since the cure cycle is where chemical changes are occurring, differences in cure cycles can result in differences in the chemical end-state for the resin matrix. While some nominal degree of variation in cure cycles is unavoidable and typically negligible, substantial differences can significantly influence many composite responses, including hygrothermal behavior. A simple case is the result of unreacted curing agent being trapped in the matrix. Since curing agents can be hygroscopic, small changes in the quantity of residual curing agent can result in relatively large differences in the amount of moisture absorbed by the resin. Other chemical changes in parameters such as molecular weight and cross-link density can also occur, with similar results.

The final dwell in a cure cycle is commonly 2 h at 120 to 180 °C (250 to 350 °F) for many epoxies. While there can be some effects from the time and temperature profile leading up to the final dwell, called path dependence, the profile usually becomes critical only with extreme deviations or specific materials. Many changes in composite performance can be attributed to changes in the final dwell time and temperature, including hygrothermal behavior such as moisture weight gain.

The percent weight gain of moisture as a function of cure-cycle final dwell time and temperature for a 120 °C (250 °F) curing glass/epoxy material can be seen in Fig. 1. This response surface shows that the material absorbs the most moisture with a cure cycle of about 110 °C (230 °F) for about an hour. This would be a strong indication of an undercure resulting from use of this dwell, although the material may still be acceptable for some applications. With relatively small increases in time and/or temperature for the final dwell, the moisture absorption can be substantially reduced. More dramatic reduction in moisture absorption with substantially higher time or temperature must be weighed against other chemical and mechanical changes that are also a function of cure, such as those seen in Fig. 2 for elevated-temperature wet compression strength.

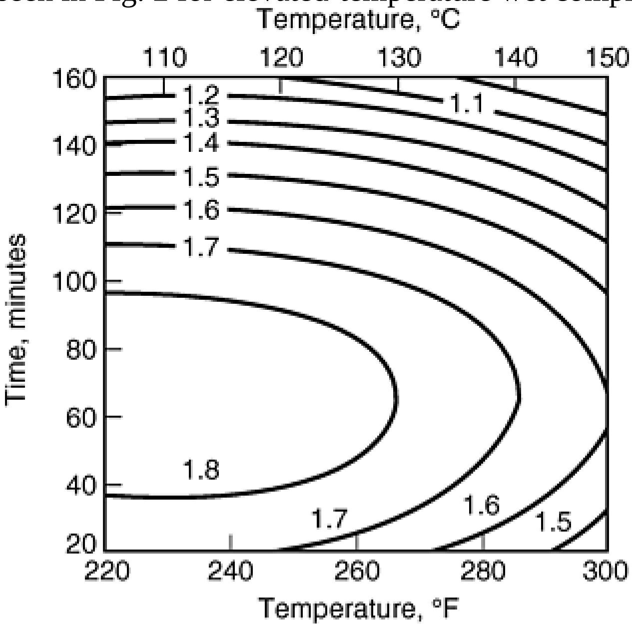

Fig. 1 Moisture absorption at saturation (weight percent) as a function of cure cycle final dwell time and temperature (120 °C, or 250 °F, cure glass/epoxy)

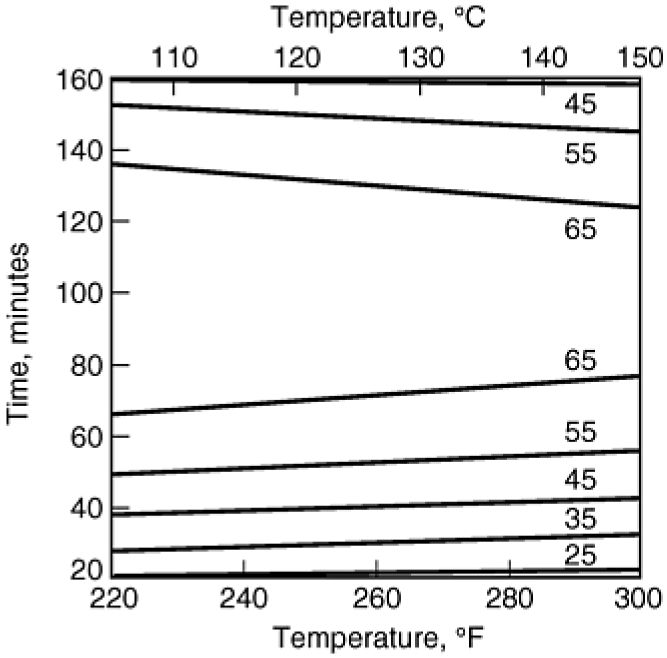

Fig. 2 Elevated temperature wet compression strength (ksi) as a function of cure cycle final dwell time and temperature (120 °C, or 250 °F, cure glass/epoxy)

Daniel R. Ruffner, The Boeing Company

Diffusion

Moisture absorption for composite materials is primarily a diffusion-based process. Diffusion is classically described as Fickian. For some materials a time effect has been noted, and modified Fickian models have been proposed in response. Characterization of the diffusion-based process of moisture absorption has been the focus of a great deal of work. Some work is concerned with achieving saturation, typically a worst-case moisture exposure, for material characterization. When the moisture absorption, seen as weight gain, slows to a predetermined level, the coupon or part is ready for testing.

Even if the aim of a particular project is just to assure saturation of particular parts or coupons, a more basic understanding can assist in determining the time frame necessary to achieve the saturation desired and confirm assumptions made about the moisture absorption of the material. This ability becomes critical for thicker structure where saturation within the service life is not anticipated.

Two primary factors govern diffusion behavior: the rate at which the moisture is absorbed and the final saturation level achieved. The rate at which moisture absorption occurs is typically a function of the temperature to which the material is exposed, not the moisture level or relative humidity exposure. The saturation moisture absorption achieved after long exposure to the temperature and humidity condition is usually governed by the moisture level or relative humidity to which the material is exposed. Thus the temperature and moisture level work together to determine the rate and ultimate quantity of moisture absorbed by the material.

Many examples of composite materials demonstrating non-Fickian behavior have been reported in the literature. While this behavior may not exclude a material for a particular application, it frequently indicates non-diffusion processes of interest. The diffusion process describes the physical absorption of moisture in a material. If other processes occur in parallel, they can change the moisture absorption process and the associated weight gain. If only diffusion is assumed to be occurring, the weight gain profile could appear non-Fickian. An example of Fickian weight gain can be seen in Fig. 3, along with several non-Fickian profiles.

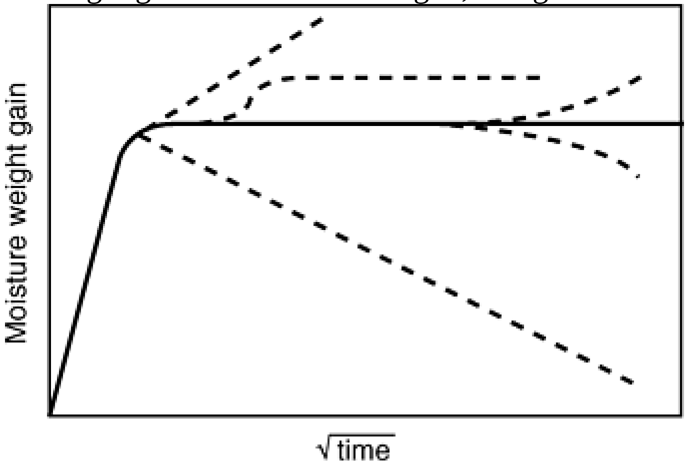

Fig. 3 Fickian (solid line) and common non-Fickian moisture weight gain profiles

Since diffusion only covers the physical absorption of moisture, if the material has locations for liquid moisture to collect, a dual mechanism is in place. One common feature that allows the collection of liquid moisture in the laminate is voids or porosity. Another is failure of the bond between the fiber and resin, allowing collection of fluid at this interface. Chemical changes to the resin such as hydrolysis can also change the moisture absorption.

One frequent cause of non-Fickian behavior is use of a conditioning temperature near or exceeding the glass-transition temperature, T_g of the resin. Many resin and composite properties change substantially and sometimes unpredictably near or exceeding the T_g. Unless the composite is for some reason actually being considered for

use in these conditions, the conditioning temperature should almost always be at least 10 to 15 °C (20 to 30 °F) below the T_g anticipated for the composite at the end of conditioning. Epoxies can lose 20 °C (35 °F) in T_g temperature for each 1% of moisture weight gain. The T_g may also be cure dependent, as seen in Fig. 4 for the cure final dwell time and temperature. Exceeding this T_g limit can result in substantially different mechanisms and failure modes and irreversible moisture absorption. Thus the appearance of non-Fickian behavior may actually be an indication of undesired initial or aged conditions for the composite and deserving of further investigation.

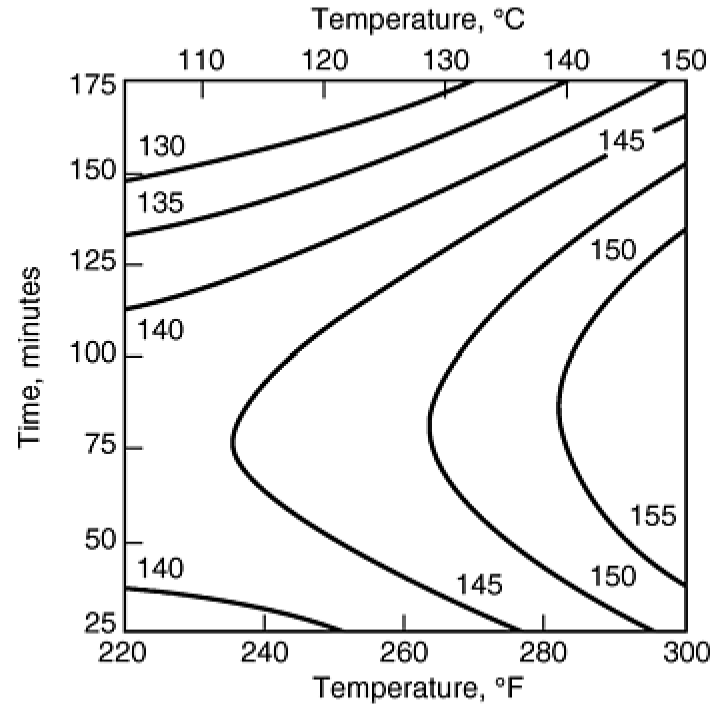

Fig. 4 Glass transition temperature (in degrees Celsius, as determined by differential scanning calorimetry) as a function of cure cycle final dwell time and temperature (120 °C, or 250 °F, cure glass/epoxy)

Hygrothermal Behavior

Daniel R. Ruffner, The Boeing Company

Hygrothermal Testing and Conditioning

Separate coupons are typically used to assess fundamental hygrothermal behavior. When they are conditioned alongside mechanical test coupons or even parts to assess moisture absorption, they are termed traveler coupons or travelers. To avoid the coupon configuration from affecting the observed behavior, the traveler should reflect the as-processed material for the other coupons or parts as closely as possible. If coupons are being used just to monitor moisture absorption to saturation, they should reflect the thickest portion of the coupons or parts. If diffusion through the thickness of the structure is anticipated as the primary mode, then the width and length of the coupon should be at least 10 times the thickness. For determination of fundamental hygrothermal properties, a range of coupon thicknesses may be used.

If there were no fiber or interface effects, then neat resin and composite results would be comparable. Since this is rarely completely true, composite samples should be used, although additional samples of neat resin can be used to further discern the nature of the moisture absorption and effects.

To achieve a reference dry state prior to conditioning so the full moisture absorption can be characterized, coupons are first dried until weight losses are negligible. It is critical that this drying- (and subsequent

conditioning-) temperature exposure does not further the cure of the resin beyond what will be seen for the fielded structure. As a rule, the drying and conditioning temperature should be at least 10 to 15 °C (20 to 30 °F) below the maximum cure temperature used.

The drying can be performed in a desiccator with or without vacuum or in an oven with or without desiccant or vacuum to speed drying. Commonly 65 °C (150 °F) for at least 48 h is employed. If the traveller coupons are being used just to assure saturation, and have seen the same history as the mechanical coupons or parts they represent, the drying step is frequently omitted.

Exposure to 70 °C (160 °F) at 85 to 95% relative humidity for 30 to 60 days is an informal standard for aerospace application and is a good starting point for evaluation. Determining the conditions of saturation is important. As saturation is approached, the rate of moisture absorption decreases exponentially, and the additional moisture absorbed in reaching full saturation becomes insignificant. Several different metrics are used, including three consecutive 24 h measurements, each of which represents less than 1 or 2% of the total weight gain. Typically at least three coupons are used, and the moisture loss during weight gain measurement is considered insignificant.

Frequently water immersion is used to speed the moisture absorption. While this may be appropriate, especially for receiving inspection functions, care must be taken to correlate moisture absorption in humid air to immersion. It is common for longer exposures to immersion to create degradation worse than that normally experienced in the field. Immersion in 30 °C (86 °F) water is used to simulate long-term exposures, while immersion from 90 °C (195 °F) to boiling is used for rapid conditioning, such as for receiving inspection of materials. Immersion temperatures of about 60 °C (140 °F) for 14 days or more have been used for conditioning of coupons before material-characterization mechanical testing.

Some have conditioned with exposure to steam up to 150 °C (300 °F), but unless this is representative of actual service, it typically induces excessively conservative degradation. For a given humidity level for most polymer matrices, there is an upper-limit temperature beyond which the degradation extent and mechanism change dramatically.

Coupons that can be fully dried after completion of saturation can provide additional insight on the degradation mechanism(s) at work. If the moisture-absorption weight gain can be completely reversed on drying, then only physical changes are indicated (although it is possible for leaching losses to match moisture weight gain from physically bound or chemically reacted water).

If it cannot be fully reversed, then chemical degradation such as through hydrolysis is indicated. Substantial chemical changes do not provide confidence in the long-term durability of the material or indicate excessively accelerated aging.

Mechanically loading or pressurizing coupons while they are being conditioned has shown to have some influence but is not commonly considered. Finally, “pulse” loading of the moisture has been performed to further accelerate conditioning to saturation. A higher temperature and/ or pressure is used for the initial conditioning to encourage the more rapid absorption of moisture. The remainder of the conditioning is then performed at the standard condition. Validated moisture-absorption models can be especially useful when such complex hygrothermal histories are used for conditioning or to represent actual service conditions.

Nondestructive test methods such as pulse- echo ultrasonics have been used to gage the absorption of moisture. Correlation of laboratory results can then be used to gage the condition of the fielded structure. This can also be correlated with visually observable changes in the material, as well as fractographic examination such as that performed in a scanning electron microscope.

Hygrothermal Behavior

Daniel R. Ruffner, The Boeing Company

Degradation Mechanisms and Failure Modes

An understanding of the degradation mechanisms and failure modes is a critical part of using accelerated aging to predict long-term behavior of the material. Effects can be seen in the fiber, in the matrix, and at the interface or interphase between.

While hygrothermal degradation of the fiber itself is not common for most glass and carbon fiber reinforcement applications, it is characteristic for aramid fibers, which may absorb more moisture than the resin. Degradation of the resin can take several different forms. Physical changes such as plasticization are largely reversible. Chemical changes such as hydrolysis or chain scission are usually more severe and irreversible. Cracks, peeling, and other surface modifications can be experienced, as well as leaching of components such as unreacted curing agent.

The interface between the resin and fiber can be attacked, destroying the fiber bonding and allowing water to collect. Since the collection of liquid water is not a diffusion-based process, this can make the moisture weight gain appear non- Fickian. A distinct phase that has shared characteristics with the fiber bond and the resin can be created in the composite, which can experience different effects.

The ratio of reversible moisture weight loss by drying after saturation to total moisture weight absorption at saturation can be used as a rough measure of the ratio of reversible to irreversible mechanisms. This can be somewhat misleading if there are competing mechanisms, such as leaching of material for weight loss with permanent weight gain from moisture captured in a chemical degradation mechanism.

A final mechanism is the swelling and volumetric stress that can be developed with moisture absorption. While typically only a significant factor for relatively thick coupons and some parts, it can generally be treated analytically in the same manner as thermal- and cure- induced volumetric changes and stresses.

Hygrothermal Behavior

Daniel R. Ruffner, The Boeing Company

Properties

The effect of moisture absorption can be negligible or dominate the application of the material. Hygrothermal effects can range from damping characteristic improvements, strength degradations, and little change to moduli. If effects are present, lesser differences are usually seen on fiber-dominated properties versus resin- dominated properties. Exceptions occur when the interface between the fiber and resin is attacked, preventing load transfer.

Physical and chemical effects to the composite have already been discussed in some detail, so mechanical property effects are primarily discussed here. The effect of hygrothermal conditioning can be a function of not just the property but also a function of loading conditions and rates. Thermal spike and freeze/thaw cycles have been used as part of the conditioning process to represent field usage. Changes in toughening mechanisms can occur, leading to changes in failure modes from tough to brittle. Fatigue, creep and impact properties can also be adversely affected. In some cases, the variability of a particular property will be affected, with or without changes to the mean value. Many mechanical property effects will be highly correlated. In many cases, it is not necessary to exactly characterize the effect but only to establish that for this particular property, it is not a worst case condition.

A comparison of wet- and dry-test results for a glass/epoxy material can be seen in Fig. 5. For compression and shear, the moisture exposure induces some level of reduced strength regardless of temperature. For tensile strength, a reduction is seen at elevated temperature, but there is no effect at room temperature. At cold temperatures the dry condition appears to be more critical than the wet condition. As is frequently seen for many materials and applications, hot/ wet is the most critical condition for each of the properties shown.

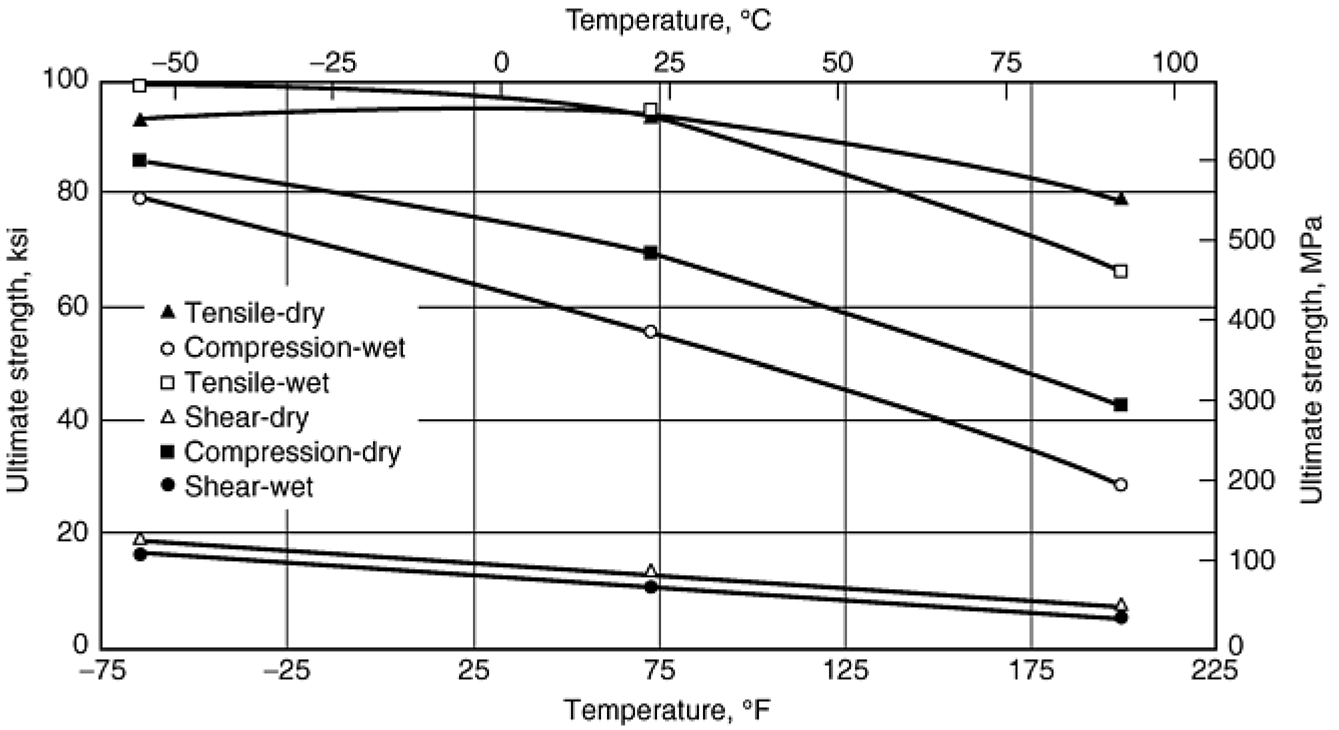

Fig. 5 Mechanical properties for dry and moisture saturated glass/epoxy material as a function of test temperature

There is an obvious test-temperature dependence on the extent of the hygrothermal effect. In addition, drying of the coupon during test can have a substantial effect on the results in a nonconservative manner. Unsteady-state temperature and moisture conditions are being experienced while the coupon is being heated to the test temperature. Weighing the coupons immediately after test and using a model to determine the actual moisture state at the time of failure can be useful.

Fatigue and Life Prediction

Jeffrey R. Schaff, United Technologies Research Center

Introduction

DURABILITY AND DAMAGE TOLERANCE are significant concerns for safety and product liability in the design of composite structures. This is particularly true for components that experience dynamic loading, such as rotorcraft blades, propellers, turbine blades, and so on. Although advancements have been made in composite life prediction methods, these methods are not sufficiently mature to predict the fatigue life of full-scale components with only coupon fatigue data. As a result, components are largely designed and certified through a series of tests that are supported by analysis. In practice, the cost and risk of designing and certifying a robust structure can be significantly reduced based on a building-block approach, where the design is validated in coupon and sub-component through full component testing. The building-block approach is discussed in the article "Overview of Testing and Certification" in this Volume. Simplifying analyses and guidelines are used in a supporting role to address fatigue in the design and development process in meeting specific durability and damage tolerance requirements.

Fatigue is defined as the degradation of the integrity of a material as a result of external conditions that vary with time. These external conditions are usually in the form of a fluctuating mechanical load and stress, but can also be in other forms, such as a thermally induced cyclic stress or cyclic exposure to moisture. The integrity of the material is commonly measured in terms of mechanical properties, such as stiffness and strength. The loss in stiffness of a material may create an instability in a structural component, and loss in strength is directly associated with the failure of a component. Such a failure can occur at a small fraction of the static strength of a material. In this sense, fatigue in composite materials is observed through accumulation of damage that initiates and progresses during cyclic loading and exposure to environment. The cyclic loading causes damage, reducing the strength until the material can no longer sustain even the service loading, that is, the load for which the material was designed.

In comparison with metals, advanced composites exhibit superior fatigue performance due to their high fatigue limit and resistance to corrosion. Fatigue damage in composite materials is very complex, due to several damage mechanisms occurring at many locations throughout a laminate. Damage is observed in a series of mechanisms, such as matrix cracking, fiber fracture, longitudinal cracking, crack coupling, and delamination growth. As a result of this damage, composite components generally do not fail due to a single, large macrocrack (as do metals), but rather fail due to a series of interdependent damage events.

In the design of composite structures for durability and damage tolerance, the primary concerns are out-of-plane failures, such as delamination, material degradation associated with environment, stability under compression loading, large degree of scatter in fatigue life, and bearing failure of joints. This article offers introductory discussion on fatigue damage process, methodologies assessing fatigue behavior, and life prediction models. For detailed discussions of fatigue and life prediction of composite materials, the reader is encouraged to refer to 1, 2 3.

Fatigue Damage

Knowledge of the individual damage mechanisms and their progression is key to understanding the fatigue behavior of composite materials. For illustration purposes, the damage mechanisms are introduced for a quasi-isotropic laminate under tension-compression fatigue loading. For a more detailed discussion of damage process, see Ref 1. Damage is defined by several localized mechanisms. Further complicating matters, these damage mechanisms are abundant, that is, they occur at many unpredictable locations throughout the laminate. There are five major damage mechanisms: matrix cracking, fiber breaking, crack coupling, delamination initiation, and delamination growth. Figure 1 illustrates the damage state versus percent of life for the three phases of damage progression.

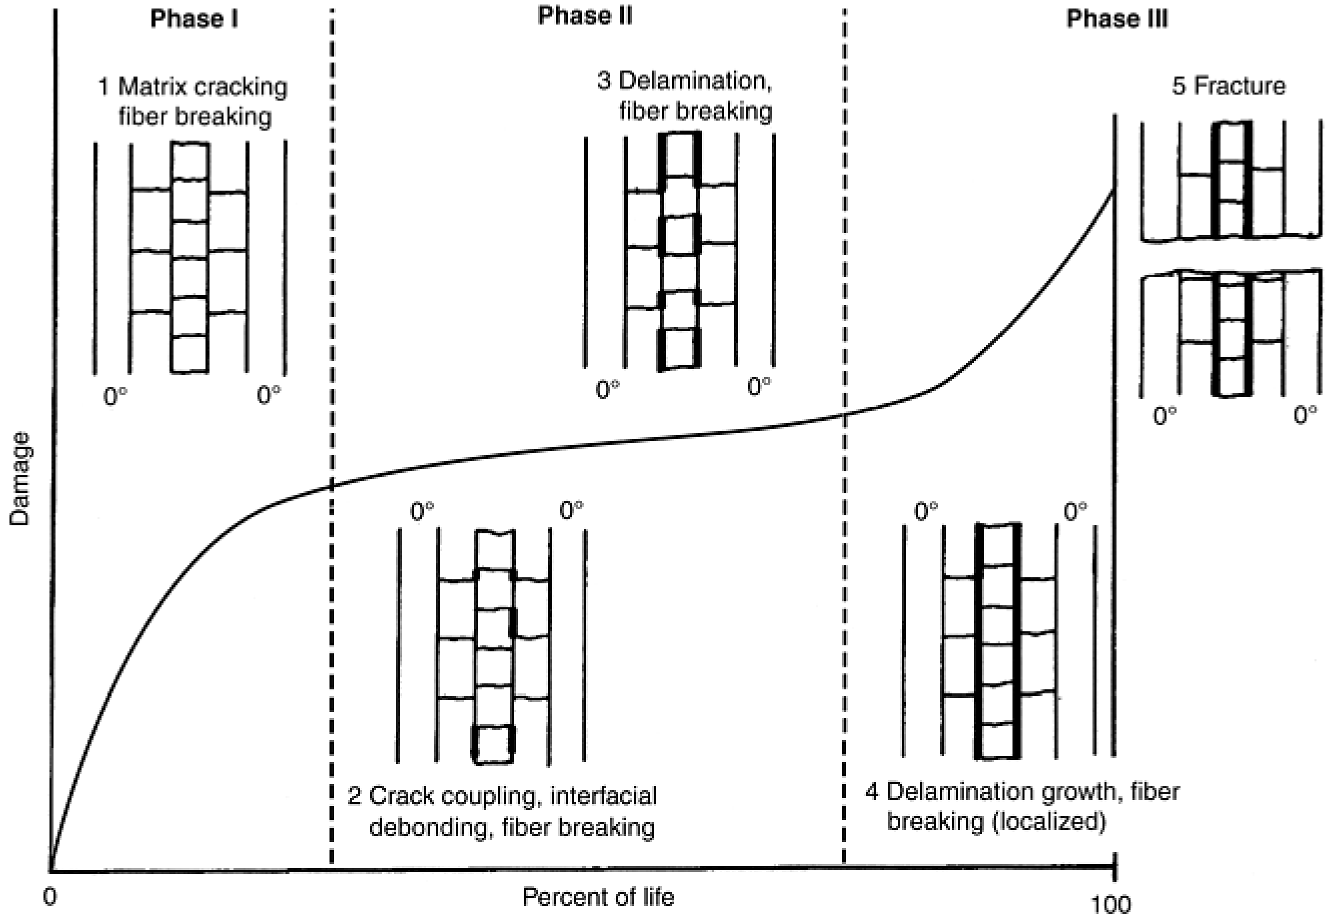

Fig. 1 Three phases of fatigue damage represented on a damage curve. Phase I, matrix cracking; Phase II, fiber fracture, crack coupling, and start of delamination; Phase III, delamination growth and final fracture. Five damage mechanisms are illustrated. Adapted from Reifsnider (Ref 1)

Phase I: Matrix Cracking. In the first phase, the damage consists primarily of matrix cracks. Overall, the damage in this phase is relatively small and occurs in the first 10 to 25% of life (Ref 4). The loss in stiffness is typically less than 10% of the original stiffness, and the strength loss is negligible. However, future damage events are strongly dependent on matrix cracking, which initiates during the first phase. Matrix cracks grow from flaw sites continuously distributed throughout the laminate. As the fatigue loads fluctuate, matrix cracks develop in the off-axis 45° and 90° plies. These matrix cracks are more likely to initiate under tensile loads and

will occur first in the 90° plies. Figure 2 shows the crack pattern in a $[0°/90°/\pm45°]_s$. The matrix crack runs through the thickness of the 90° plies and terminates at the 0° plies. Measurement of matrix cracks in controlled fatigue experiments suggests the crack density reaches a saturation state that can be described by the ply thickness and material properties (5, 6 7).

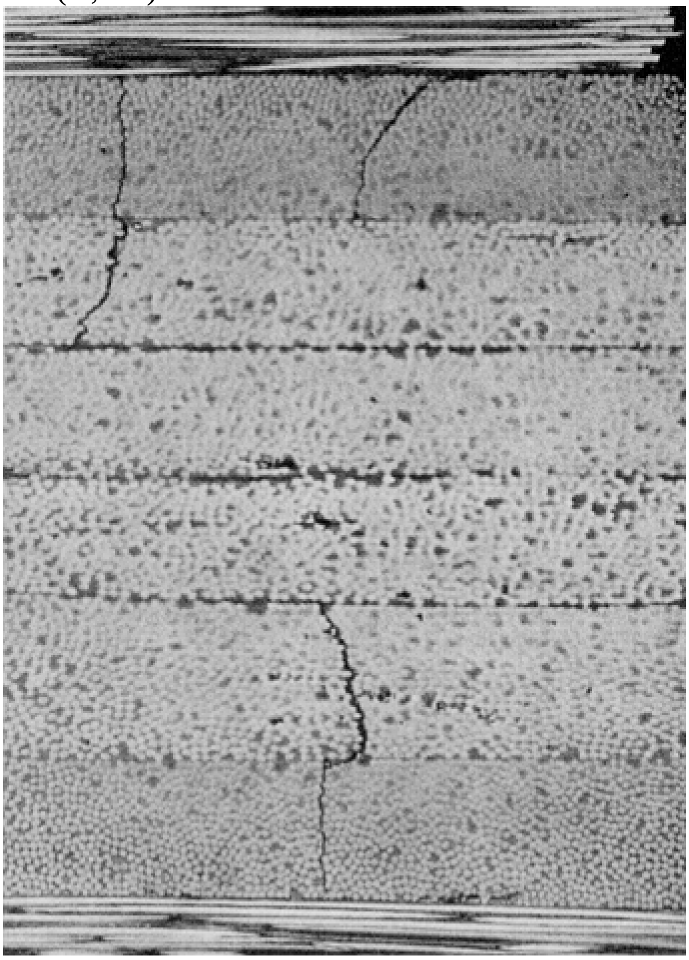

Fig. 2 Micrograph showing crack pattern in matrix of $[0°/90°/\pm45°]_s$ graphite/epoxy laminate under a static load of 483 MPa (70 ksi). Cracks in 90° plies have linked to those in +45° plies, but have not propagated to the 0° plies.

Phase II: Fiber Fracture, Crack Coupling, and Delamination Initiation. The second phase consists primarily of fiber fracture, local debonding, and delamination initiation, and occurs over the next 70 to 80% of the life of the laminate. Damage develops at a slower rate than in Phase I. As the load increases, stress concentrations develop at the intersection of the matrix cracks and the 0° fibers where these cracks are blunted. These stress concentrations cause fibers to fracture in the adjacent plies. Large tensile stresses located at the tip of the matrix cracks induce longitudinal cracks in the direction of the 0° fibers and perpendicular to the matrix cracks. This damage mechanism is called crack coupling and includes the combination of matrix cracks and longitudinal cracks. Crack coupling is illustrated in Fig. 3 using a cross-ply laminate that has been subjected to a fatigue loading. In this figure, transverse matrix cracks and longitudinal cracks are visible. In the later stages of Phase II, delamination initiation becomes the dominant damage mechanism. Strong interlaminar stresses develop at the intersection of matrix cracks and longitudinal cracks, creating a favorable situation for delamination initiation.

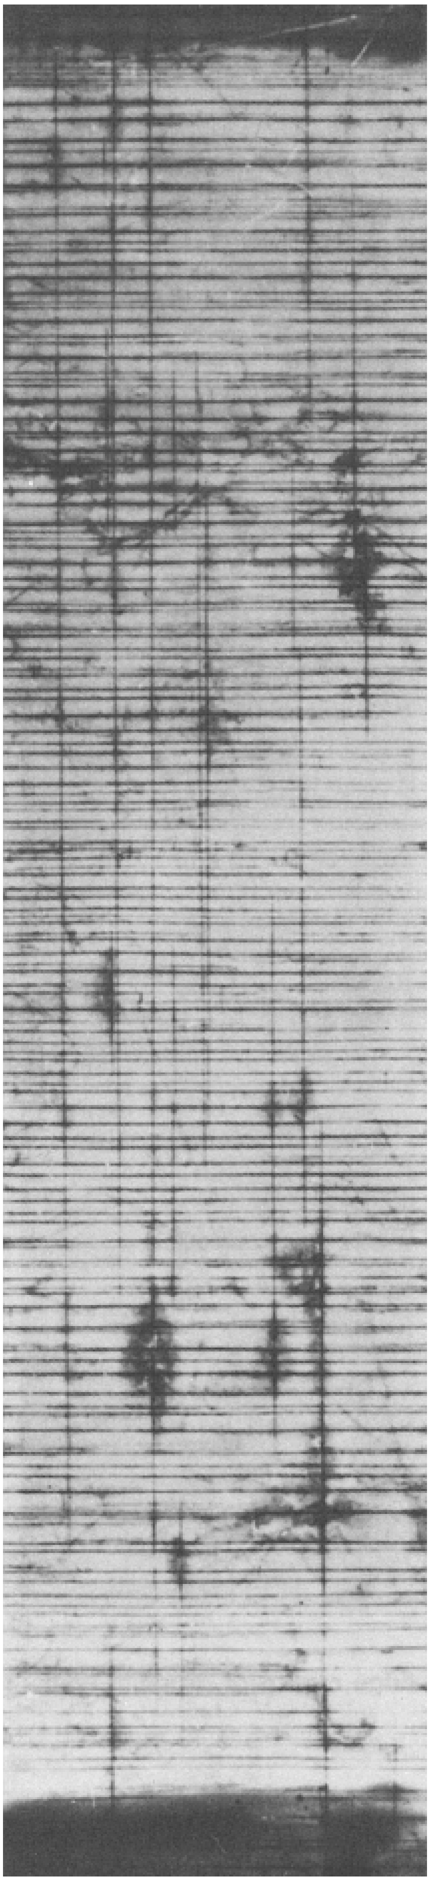

Fig. 3 Radiograph of graphite/epoxy laminate using image-enhancing penetrant to reveal transverse and longitudinal cracking and local delaminations

Phase III: Delamination Growth and Fracture. In the final phase of fatigue damage, internal stresses cause the damage mechanisms to increase in intensity. The longitudinal cracks grow, thereby isolating the 0° fibers. Also, the delaminations continue to grow between ply interfaces. Delaminations separate the main laminate into a series of sublaminates. In this phase, a rapid decay of stiffness has been experimentally observed (Ref 8). Eventually, the strength of the laminate is reduced enough to cause catastrophic failure. Note that compression fatigue loads may accelerate the delamination growth, due to buckling of the sublaminates.

Fatigue and Life Prediction

Jeffrey R. Schaff, United Technologies Research Center

Fatigue Methodologies

As with metals, there are two classical approaches for design and analysis of fatigue- loaded composite components: safe life and damage tolerance. The damage tolerance approach assumes that all engineering components contain flaws. These flaws are considered allowable if the defects, or defect growth, do not affect structural performance. Defect growth is predicted using empirical crack growth laws and linear elastic fracture mechanics (Ref 9). The safe life or fatigue life technique involves characterization of the total fatigue life to failure in terms of cyclic stress or strain range. In this technique, engineering components are designed for a certain life-based on empirical stress (or strain) versus life (*S-N*) curves and on cumulative damage growth laws (Ref 9). A variation of these approaches, sometimes referred to as enhanced safe life, characterizes *S-N* relationships where the test specimens purposely contain potential manufacturing defects and in-service damage. The best source of current practices on durability and damage tolerance is MIL-HDBK-17, Volume 3 (Ref 3).

Safe Life and *S-N* Relationships. The *S-N* curve was first implemented by Wohler in the 1860s to understand the effect of stress on the fatigue life of railroad axles. The *S-N* curve quantifies the relationships between

fatigue life and applied stress amplitude. The curve is developed using constant stress amplitude fatigue tests at several stress levels. Each *S-N* curve represents one loading type, as defined by its stress ratio, $R=\sigma_{min}/\sigma_{max}$, where σ_{min} and σ_{max} are the minimum and maximum stress, respectively. In the safe life approach, the *S-N* relation is used in design to establish a maximum allowable stress (or strain) and/or to predict statistically based minimum fatigue life with a cumulative damage fatigue model. There are significant shortcomings of the safe life approach. First, the damage mechanisms and damage processes of Fig. 1 are combined into a single, phenomenological damage parameter. Furthermore, the structural composite produces a multiaxis stress state due to its anisotropy and multiaxis loading, whereas the *S-N* relationships are indicative of a simplified stress state, especially for unidirectional coupons. Thus, test results obtained from coupons cannot easily be directly applied to complex structures, due to differences in manufacturing, loading, environment, and damage states. However, even with these limitations, well-planned *S-N* experiments can be very useful for studying many variables in design.

A typical *S-N* curve is graphically represented in Fig. 4 for a series of T300/934 graphite/epoxy laminates under tension-compression loading. The influence of composite lay-up can be inferred from inspection of Fig. 4 by comparison of the fatigue behavior for unidirectional $[0]_{16}$, cross-ply $[0/90]_{4s}$, angle-ply $[\pm 45°]_{4s}$, and quasi-isotropic $[0°/\pm 45°/90°]_{2s}$ laminates. Although some correlation has been made between unidirectional fatigue behavior and that of multidirectional laminates, it is best to characterize laminates of interest rather than infer *S-N* curves from unidirectional data. This is in part due to the acceleration of damage associated with off- axis matrix cracking and crack coupling. Compared with metals, the curves of the composite offer relatively high fatigue threshold, and the slope is relatively low due to insensitivity of the graphite fiber to fatigue. For practical laminates, the slope of the *S-N* curve tends to increase, becoming less negative as the percentage of off- axis plies increases (Ref 11).

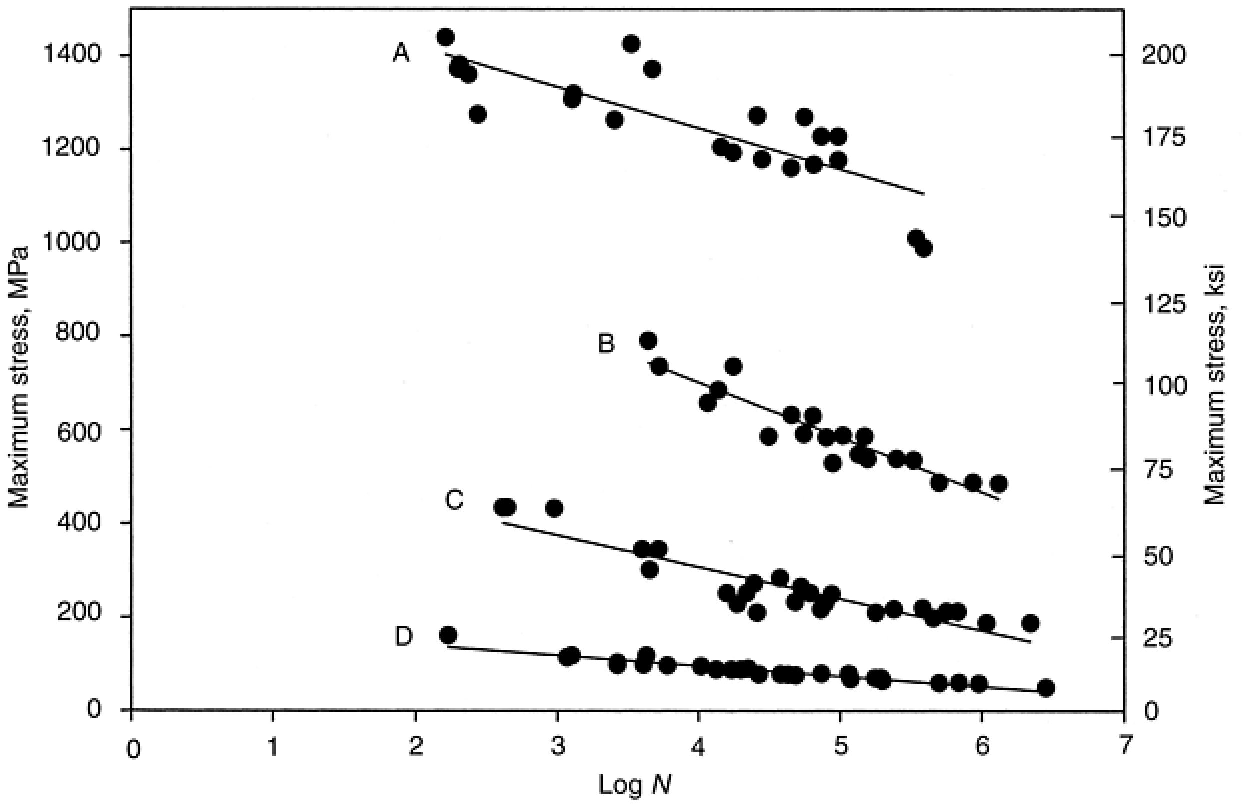

Fig. 4 *S-N* curves for T300/934 graphite/epoxy laminates. Log life in cycles, *N*, vs. maximum load. Loading is equal tension-compression, $R=-1.0$. Curves are A, unidirectional $[0°]_{16}$; B, cross-ply $[0°/90°]_{4s}$; C, quasi-isotropic $[0°/\pm 45°/90°]_{2s}$; D, angle-ply $[\pm 45°]_{4s}$. Adapted from Ref 10

The effect of loading can be determined upon comparison of *S-N* curves for stress ratios, *R*, reflecting tension-tension, compression-compression, and tension-compression loading. Study of fatigue data consistently suggests that tension-compression loading is the most severe, followed by compression-compression and tension-tension (12, 13 14). A master diagram is a graphical means of simultaneously presenting fatigue lives for many stress ratios. In a master diagram, the stress amplitude, $\sigma_{amp}= (\sigma_{max}-\sigma_{min})/2$, is plotted as the ordinate,

and the mean stress, $\sigma_m = (\sigma_{max}+\sigma_{min})/2$, is plotted as the abscissa. Stress ratio is introduced through lines of constant stress ratio, *R* ($R=\sigma_{min}/\sigma_{max}$). These stress ratio lines have a slope of $(1–R)/(1+R)$ and radiate from the origin. These lines are separated into four distinct load types: tension-tension (T-T), tension-dominated tension-compression (T-C), compression-dominated tension-compression (C-T), and compression-compression (C-C). Figure 5 illustrates the master diagram for T300/5308 [0°/45°/90°/–45°]$_{2s}$ laminates.

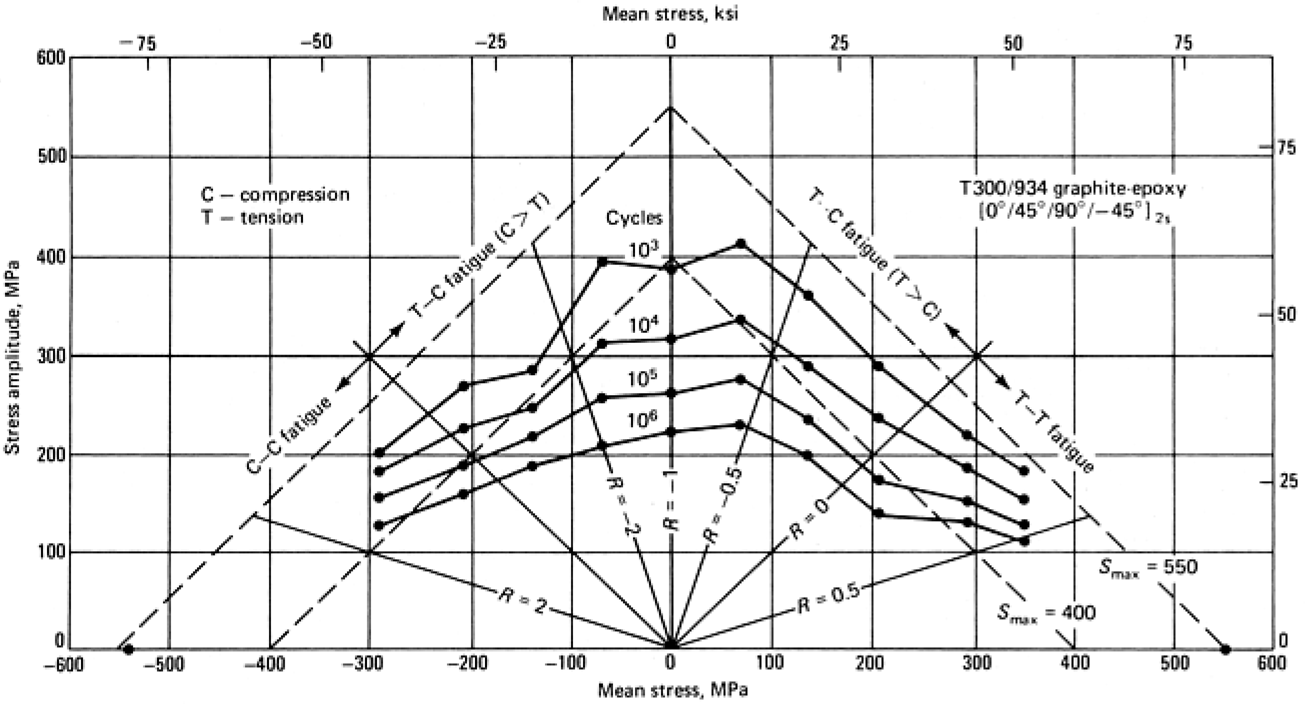

Fig. 5 Master diagram for [0°/+45°/90°/–45°]$_{2s}$, T300/5208 graphite/carbon quasi-isotropic laminate. Maximum stress, S_{max}, are dotted lines. Stress amplitude, S_{amp}= (S_{max}–S_{min})/ 2, vs. mean stress, S_m= (S_{max}+S_{min})/2. $R=S_{min}/S_{max}$

For a case where the stress was cyclic and varied between 400 MPa (58 ksi) tension and compression, the mean stress is 0. The stress ratio (*R*) is–1. The family of all cases of cyclic loading where the compression stress equals the tensile stress would fall on the vertical axis, where *R*=–1 and the mean stress would be 0. Cases where the tensile load is greater than the compressive load fall to the right of this line, as do pure tensile loads. More compressive loads and pure compressive loads fall to the left. Note the dotted lines indicating the maximum stress ($S_{max}=\sigma_{max}$) on the master diagram.

Recall that a primary concern in the fatigue of composites is delamination. However, the *S*-*N* data of Fig. 4 and 5 represent in-plane axial loading and provide little use in characterizing interlaminar failure. Thus, it is prudent to develop *S*- *N* relationships between interlaminar stresses and interlaminar failure. Experience has shown that three- or four-point short beam shear testing can be used to correlate cyclic interlaminar shear stress with delamination. The test method for noncyclic loads is discussed in "Out-of-Plane Analysis" in this Volume. This can be supplemented with interlaminar normal stress fatigue behavior if interlaminar tension stresses are expected. The axial tension-tension and short beam shear *S*-*N* curves are plotted in Fig. 6 for unidirectional graphite/epoxy laminates. ASTM D 3479 and D 2344 provide test practices for an axial tension-tension fatigue specimen and for a static strength by short beam shear specimen, respectively.

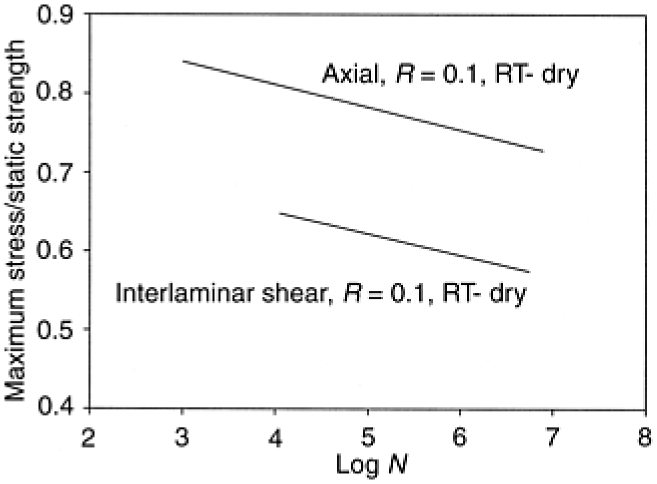

Fig. 6 *S-N* curves for 6350/AS unidirectional laminates. RT, room temperature (Ref 15)

The fatigue data of Fig. 4 and 6 can be characterized by the following common expressions in semilog or power form, respectively:

$$S = A + B \log N \quad \text{(Eq 1)}$$

$$KS^{b} N = 1 \quad \text{(Eq 2)}$$

where *S* is the applied stress parameter; *N* is the fatigue life; *A* and *B* are parameters for Eq 1; and *K* and *b* are parameters for Eq 2. The *S-N* curves of Fig. 4 are reported in Table 1 in the form of Eq 1. "B" corresponds to the slope of the line and "A" corresponds to the y-intercept.

Table 1 *S-N* parameters for T300/934 laminates, *R* =–1.0

Curve(a)	Laminate	A, MPa	B, MPa
A	Unidirectional	1597	–87.7
B	Cross-ply	1170	–117
C	Quasi-isotropic	578	–67.3
D	Angle-ply	186	–22.5

Source: Ref 10

In developing *S-N* curves, the stress level, stress ratio, and environment should bound the anticipated in-service exposure. Typically, tests are performed at three to five stress levels for a given *R* ratio, where 6 to 10 replicates are preferred at each stress level to quantify the statistical variations of life. Furthermore, fatigue behavior should characterize both in-plane and out-of-plane failure modes.

Failure of composite specimens under identical conditions produces a high degree of scatter, in comparison with metals. Thus, statistical treatment of the fatigue data is of particular interest. The distribution of static strength and fatigue life can be described mathematically by a two-parameter Weibull function (Ref 16). A two-parameter Weibull density function is given by:

$$f(x) = \frac{\beta}{\alpha}\left(\frac{x}{\alpha}\right)^{\beta-1} \exp\left[-\left(\frac{x}{\alpha}\right)^{\beta}\right] \quad \text{(Eq 3)}$$

where α is the scale parameter and β is the shape parameter. The scale parameter, α, represents the location of the 63.2 percentile of the distribution. The Weibull parameters are determined to mathematically fit the experimentally determined distributions by well-established techniques, such as the maximum likelihood method (Ref 17). The shape parameter for composite materials is typically between 14 and 40 for static strength and between 1.4 and 4.0 for fatigue life. For comparison, shape parameter for commonly used metals is approximately 7.0, indicating a greater degree of scatter for composites. The same information can also be cast into another form, called a cumulative Weibull distribution function. This function is a cumulative sum of the density function and is given by:

$$F(x) = 1 - \exp[-(\frac{x}{\alpha})^{\beta}] \quad \text{(Eq 4)}$$

where $F(x)$ is the probability that x exceeds α. Equations 3 and 4 describe the fatigue life distribution for a single loading. Given data at three stress levels for a given *R*-ratio, the *S*-*N* relations of Eq 1 and 2 can be expressed in terms of Weibull scale parameter by substituting N=α. This provides a statistical representation of the *S*-*N* curve. Examples of Weibull fatigue life distributions are summarized in Table 2 for selected data reported in Ref 18.

Table 2 Fatigue life distributions using Weibull function

Laminate	*R*	σ_{amp}			
		MPa	**ksi**	**Log α**	**β**
Glass/epoxy cross-ply	0.05	183	26.5	2.775	2.4
	0.05	160	23.2	3.453	4.2
	0.05	137	19.9	4.249	2.0
	0.05	115	16.7	5.342	1.7
Graphite/epoxy	0.1	179	26.0	5.968	1.3
quasi-isotropic	0.1	167	24.2	6.108	4.5
	0.1	159	23.1	6.591	1.8
	–1.0	344	49.9	4.434	1.7
	10	155	22.5	5.988	2.4
Graphite/epoxy angle-ply	0.1	82.7	12.0	4.214	3.7
	0.1	71.8	10.4	4.942	5.7
	0.1	54.9	7.96	6.061	6.0
	–1.0	109.7	15.91	4.740	7.1
	10	88.0	12.8	5.192	3.4

For selected data from Schoff and Davidson (Ref 18), $R = \sigma_{min}/\sigma_{max}$; σ_{amp}, stress amplitude; Log α, log life; β, shape factor

Often the *S*-*N* curves are used in the design process to establish maximum stress (or strain) values called allowables. In fatigue these are established for both in-plane stresses as well as interlaminar stresses. An A- or B-basis allowable specifies a maximum allowable stress representing a probabilistic statement equal to 95% lower confidence bound that the probability of survival is at least 0.99 for *A*-basis or 0.90 for *B*-basis. The calculation of stress allowable is reported in Shyprykevich (Ref 19) and the MIL-HDBK-17. Additional sources of *S*-*N* fatigue data are listed in Table 3.

Damage Tolerance Approach. The damage tolerance approach has evolved from metals to composite applications within the aerospace industry among others. Damage tolerance is defined as the ability of a structure to sustain design loads in the presence of damage caused by fatigue, corrosion, environment, accidents, and other sources, until such damage is detected, through inspections or malfunctions, and repaired. This approach measures the safe operation of the structure through linkage of damage state, schedule inspections, likelihood of detection, and damage progression. Thus, damage tolerance is an integral part of fatigue and life prediction. Detailed discussion of this approach and analysis is provided in the articles “Damage Tolerance” and “Fracture Mechanics of Composite Delamination” in this Volume.

In the damage tolerance approach, prediction of damage growth and future damage states is aided by composite fracture mechanics analysis. The dominant mechanism leading to failure in metals is crack growth. The *Paris law*, which is a primary tool to predict flaw growth in metals, relates the rate of growth of a macrocrack to the change in stress-intensity factor induced by the loading. The Paris law is written in the form:

$$\frac{da}{dN} = C(\Delta K)^{m} \qquad \text{(Eq 5)}$$

where da/dN is the crack growth rate; C and m are empirical constants; and ΔK is the stress-intensity factor range. Recalling the complex damage states of Fig. 1, the damage of a composite is not well characterized as a single, dominant crack. In most composites there are many microcracks and delaminations. In some cases in which there is a dominant macrocrack or delamination, the Paris law may be used for an approximation of life to a defined crack size. In this case, the stress-intensity factor (ΔK) is replaced in Eq 5 by strain energy release rate (ΔG). In a similar manner, interlaminar fracture models can be used to determine if a delamination will initiate and grow from a flaw. For the special case where the dominant failure mechanism is delamination, interlaminar fracture methods based on strain energy release rate and virtual crack closure principles, as proposed by O'Brien (Ref 25) and summarized by Martin (Ref 26), have shown promise.

Regardless of which approach is taken, the damage tolerance requirements are ultimately satisfied in practice by testing full-scale components with engineered defects to a statistically based lifetime.

Fatigue and Life Prediction

Jeffrey R. Schaff, United Technologies Research Center

Delamination

Fatigue is generally not considered the limiting factor in design, due to high fatigue thresholds. This is particularly true for static structures. Consider airframe structures in aerospace applications, where the structure is designed to satisfy damage tolerance criteria, which results in low stress levels in these structures. It is generally accepted that fatigue does not represent a design constraint in these composite structures. The exceptions are structures that are subjected to high cycle fatigue or dynamic loading, components that are prone to delamination, or structures not designed for damage tolerance.

Delamination is a critical issue in fatigue and generally results from high interlaminar normal and shear stresses. Figure 7 shows structural elements in which high interlaminar stresses are common. Experience has shown these elements to be prone to delamination. These elements include free edges, termination of plies in taper regions, radius of stiffeners or channel sections, closeout regions of sandwich structures, and skin-stiffener attachments. Either by testing or analysis, the elements of Fig. 7 must be designed to limit the occurrence of delamination. Analysis consists of three-dimensional finite-element analysis (FEA) or specialized solutions for elements of Fig. 7. In particular, interlaminar normal stresses that result in an opening mode fracture should be minimized. In testing, the building-block approach is strongly recommended. A relatively large number of tests are performed at the coupon level to establish design allowables for different loading and environments. A smaller number of tests at the element and subcomponent level are required to demonstrate the reliability of the manufacturing and structural concept.

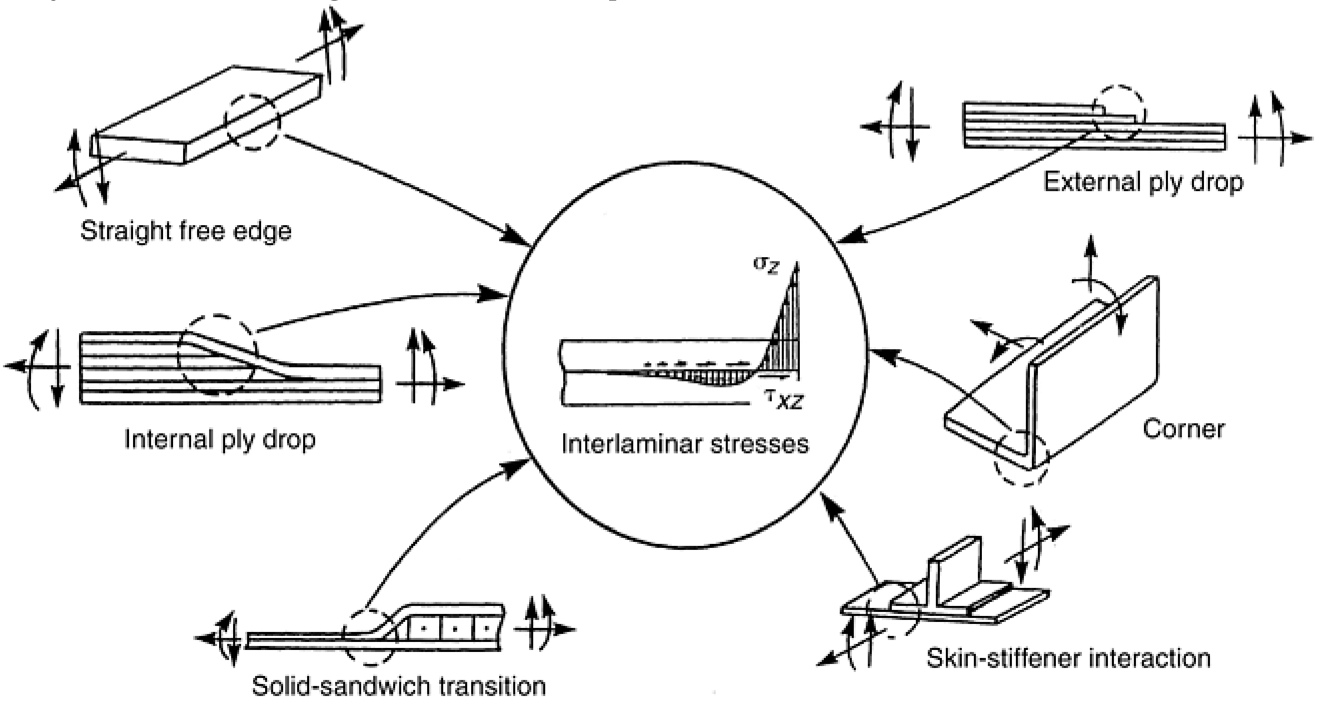

Fig. 7 Structural configurations with high interlaminar stresses. σ_z is tensile stress and τ_{xz} is shear stress.

The work of Dexter and Baker (Ref 23) is perhaps the best reference on environmental effects on composite structures. In this work, the effect of moisture and aging was characterized in a ten- year study of laboratory coupons as well as a fifteen-year study of in-service flight exposure of helicopter structures.

Fatigue and Life Prediction

Jeffrey R. Schaff, United Technologies Research Center

Life Prediction Models

For purposes of this review, fatigue models for composite materials under cyclic loading are classified broadly as either *mechanistic* or *phenomenological*. In a mechanistic-based approach, the damage is modeled discretely,

thus allowing direct prediction of initiation and growth of damage. For example, O'Brien (Ref 25) suggests the application of linear fracture mechanics and FEA to predict the initiation of delamination. These models are useful in damage tolerance assessments and are further discussed in the article "Fracture Mechanics of Composite Delamination" in this Section. Phenomenological fatigue methodologies, which generally define damage in terms of macroscopically measured properties such as strength or stiffness, are easily incorporated into existing design practices. These models are simply applied to multistress-level loading and are traditionally associated with safelife.

Palmgren-Miner Rule. Perhaps the most simple life prediction model is the Palmgren- Miner rule (Ref 27, 28):

$$\sum_{i=1}^{m} \frac{n_i}{N_i} = 1 \qquad \text{(Eq 6)}$$

where m is the number of different stress levels; n_i is the number of stress cycles at level i; and N_i is the number of cycles to failure at the stress amplitude corresponding to level i. The fatigue life, N_i, is determined from the appropriate S-N curve. The Palmgren-Miner rule assumes that damage can be quantified as the ratio of the number of cycles at an applied stress amplitude divided by the fatigue life at that stress amplitude. In general, the Palmgren-Miner rule provides poor predictive capability for composite materials (Ref 18, 21).

Advanced Residual Strength Models. Advancements in life prediction have been largely in the development of stiffness- and strength- based fatigue models. Talreja (Ref 29) developed a continuum damage model relating stiffness to local damage states. Strength-based fatigue models applied to composite materials originated with the works of Halpin et al. (Ref 30) and were advanced by Yang and Du (Ref 31). These models were modified by Reifsnider et al. (Ref 32) and incorporated into MRLife, a composite analysis code that uses normalized strength relations for a given ply based on unidirectional static and fatigue properties. MRLife allows selection of failure criteria, strength degradation functions, and stiffness degradation functions. The strength-based residual strength model has shown good predictive capability for spectrum fatigue loading (Ref 18). It is considered as a good alternate life prediction model to the Palmgren-Miner rule.

Figure 8 presents the residual strength relation that is used by the model for constant amplitude fatigue. The solid line in the figure "tracks" the Weibull scale parameter for residual strength, that is, the 63.2 percentile of the strength distribution, as the scale parameter for strength decreases with increasing cycling. The equation of this line is given by:

$$R(n) = R_0 - (R_0 - S_p)\left(\frac{n}{N}\right)^{v} \qquad \text{(Eq 7)}$$

where $R(n)$ is the residual strength scale parameter after n cycles; R_0 is the static strength scale parameter; S_p is the peak stress *magnitude* of the constant amplitude loading; N is the scale parameter for the fatigue life distribution; and v is the strength degradation parameter.

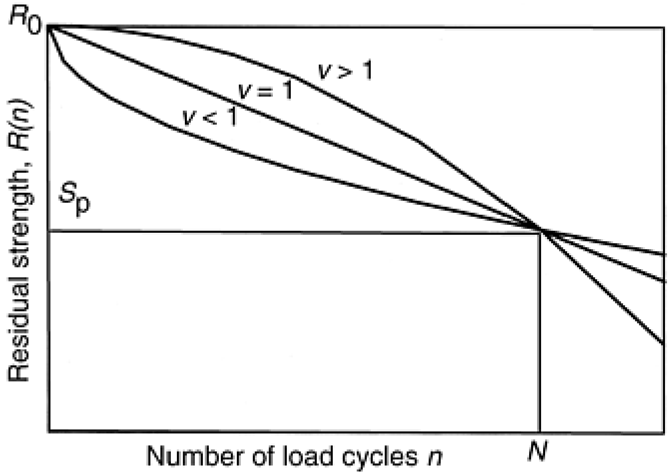

Fig. 8 Residual strength, $R(n)$, relation for constant amplitude loading. R_0 is the original static tensile or compressive strength; S_p is the peak stress magnitude; v is a strength degradation parameter.

For constant amplitude loading with a positive mean stress, S_p is the maximum stress; for constant amplitude loading with a negative mean stress, S_p is the magnitude of the minimum stress. R_0 is the scale parameter for the distribution of static strength. The scale parameter for the fatigue life distribution, N, is found by an S- N curve

or from a master diagram similar to Fig. 5. The strength degradation parameter, v, controls the overall shape of the residual strength relation. It is obtained by comparing the predicted and observed life distributions for constant amplitude fatigue loading. When $v >> 1$, "sudden death" behavior is simulated; when $v = 1$, a linear strength degradation is simulated; and when $v < 1$, the behavior of those laminates that experience an early, sudden loss in strength is simulated. The values of R_0, N, and v are dependent on laminate lay-up, materials system, geometry, and the type of loading (i.e., uniaxial, biaxial, shear, etc.). Therefore, model characterization tests must be performed for each variation. Initially, the strength distribution is equal to the static strength distribution. During fatigue loading, the entire distribution experiences a degradation in strength. As cycling continues and the mean strength degrades, the residual strength of the weaker structures will fall below the maximum applied stress, and failure will occur. The probability of failure during constant amplitude fatigue loading, that is, the probability that the residual strength is less than the peak stress, S_p, may also be expressed in the form of a Weibull distribution as:

$$P[\hat{R}(n) \le S_p] = 1 - \exp[-(S_p / R(n))^{Bf(n)}] \quad \text{(Eq 8)}$$

where $B_f^{(n)}$ is a yet-to-be-determined Weibull shape parameter for residual strength. Substituting the residual strength relation, Eq 7, into Eq 8 gives:

$$P[\hat{R}(n) \le S_p] = 1 - \exp \times [-(\frac{S_p}{R_0 - (R_0 - S_p)(\frac{n}{N})^v})^{Bf(n)}] \quad \text{(Eq 9)}$$

A review of the fatigue data in open literature indicates that strength data becomes increasingly scattered with increasing fatigue loading prior to static testing. In Eq 9, this is controlled by the Weibull shape parameter, B_f. Smaller values of B_f correspond to broader, more dispersed, distributions. In Eq 9, B_f is assumed to initially equal the static strength shape parameter, B_s, and to linearly degrade to the limiting value of the fatigue life shape parameter, B_l.

Life predictions by strength-based fatigue models are compared to experimental results reported by Schutz and Gerharz (Ref 14) for uniaxial loading of $[0_2°/\pm45°/0_2°/\pm45°/90°]_s$ graphite/epoxy test specimens. Comparisons are made for a loading spectrum simulating the stress history on upper wing skin at wing root of fighter aircraft. The load spectrum contains sixteen load levels and a peak compressive stress of 652.5 MPa (94.6 ksi). The models were characterized with fatigue life data at three stress ratios:–1.0,–1.66, and–5.0. Experimental and theoretical fatigue life results are shown in Fig. 9. The predictions demonstrate good correlation with experiment and better agreement than that of Yang and Du (Ref 31). The Palmgren-Miner rule was unconservative by factor of three in prediction of the mean fatigue life. Overall, strength-based fatigue models have shown better predictive ability for mean life than the Palmgren-Miner rule.

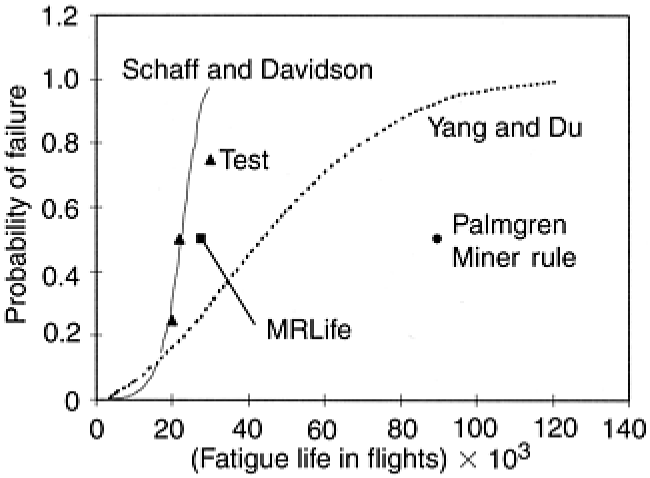

Fig. 9 Comparison of prediction and observed results for spectrum fatigue data of Schutz and Gerharz (Ref 14), Schaff and Davidson (Ref 18), Yang and Du (Ref 31), MRLife (Ref 32), and Palmgren-Miner rule (Ref 27, 28)

Damping Properties

Introduction

VIBRATIONAL AND DAMPING CHARACTERISTICS OF composites are important in many applications, including ground-based and airborne vehicles, space structures, and sporting goods. In response to a transient or dynamic loading, structures can experience excessive vibrations that create high noise levels, stress fatigue failure, premature wear, operator discomfort, and unsafe operating conditions. An understanding of various theoretical and experimental aspects to vibration in composites is essential to the efforts to avoid or eliminate these potential problems.

In the past, the damping capacity of conventional engineering materials has not generally provided sufficient energy dissipation to limit resonant or near-resonant amplitudes of vibration. The position has been further aggravated by the development of high-strength alloys of aluminum and titanium, which generally have lower damping than those provided by their weaker counterparts. Conventional structures have many additional sources of energy dissipation, such as bolted and riveted joints, lubricated bearings, and so on. In space

applications, because of the absence of a surrounding fluid or gas, aerodynamic damping is essentially zero, thus removing an important source of energy dissipation, especially in thin-sheet structures. However, when using composite materials, it is usually necessary to use adhesively bonded joints, because bolts and rivets tend to pull out. This seriously reduces structural damping, which makes material damping far more important. This situation can be alleviated in fiber-reinforced materials by making a suitable choice of components so that the damping derives essentially from the matrix and fiber-matrix interface. It is therefore more important to understand the mechanisms of damping in composites and to appreciate their significance than is the case for metallic materials.

The main sources of internal damping in a composite material arise from microplastic or viscoelastic phenomena associated with the matrix and from relative slipping at the interface between the matrix and from relative slipping at the interface between the matrix and the reinforcement. Thus, excluding the contribution from any cracks and debonds, the internal damping of the composite will be influenced by:

- The properties and relative proportions of matrix and reinforcement in the composite (the latter is usually represented by the volume fraction of the reinforcement, V_f)
- The size of the inclusions
- The orientation of the reinforcing material to the loading axis
- The surface treatment of the reinforcement

In addition, loading and environmental factors, such as amplitude, frequency, and temperature, may affect damping.

To cover the dynamic properties of all composite materials is beyond the limited scope of this article. Only those advanced composites used in stress-bearing situations in modern engineering are discussed. Unreinforced polymers are not covered here, except as a component of the composite, nor are composites with randomly oriented fibers, nor those containing nonfibrous reinforcements. The damping and moduli of short-fiber composites have been reviewed by S.A. Suarez et al. (Ref 1). Because modulus and damping are interrelated, both are considered.

The vibration properties of concern are the damping and the dynamic modulus, which are defined in Fig. 1. When subjected to a stress cycle, all materials show a nonsingular relationship between stress and strain. The modulus is given by the mean of the stress-strain loop. For most materials, there is little ambiguity in this definition, because the loop is almost indistinguishable from a straight line. The area, ΔU, of the loop represents the work done against "internal friction" and is the amount of energy dissipated during the cycle.

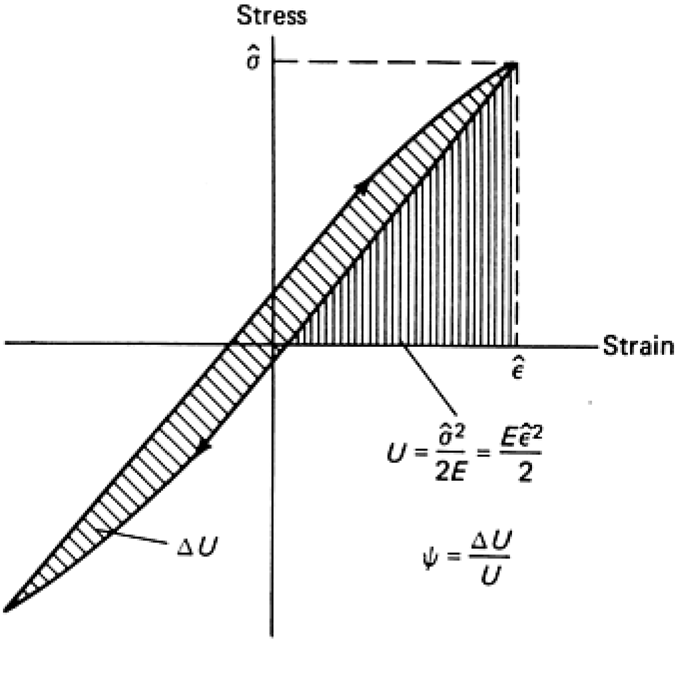

Fig. 1 Definition of specific damping capacity, Ψ. ΔU, energy dissipated per cycle; U, maximum stored energy

It can be seen from Fig. 1 that the maximum strain energy stored per unit volume in the cycle is $U = \sigma^2/2E = E^2_{\in}/2$. The specific damping capacity, Ψ, of the material is defined as:

$$\Psi = \frac{2\pi}{Q} = 2\delta = 2\pi\eta = 4\pi C = 2\pi\left(\frac{f_2 - f_1}{f_n}\right)_{3dB} \quad \text{(Eq 1)}$$

where Q is the quality (amplification) factor, δ is the logarithmic decrement, η is the loss factor, C is the proportion of critical damping, f_n is the natural frequency (Hz), and f_1 and f_2 are the half- power (3 dB) points.

Finally, it must be emphasized that just as there are many possible sources of energy dissipation in structures, most apparatuses for measuring damping need some method of applying the cyclic loads, measuring the dynamic response, and locating the specimen in some frame of reference. Many authors have not been sufficiently careful in making such measurements with metals and composites. Whereas thermoplastics often have substantial amounts of damping, structural metals and composites do not. It is therefore crucially important that any damping data used should be from an impeccable source. All things being equal, the lowest damping values quoted for a given material are likely to be the nearest to the truth. Not only should damping measurements be carefully made, but the apparatus must be purged of extraneous losses by calibrating it with some metal of very low damping properties (such as high-strength titanium or aluminum alloys).

Damping Properties

Unidirectional Composites

The basic building block of layered composite structures is a single lamina of unidirectionally reinforced material. All the fibers are considered to be parallel and lying in the direction of the major axis of the specimen.

Longitudinal shear involves the twisting of a bar of an aligned composite. Thus, the longitudinal shear modulus of carbon-fiber-reinforced plastic (CFRP) or glass-fiber-reinforced plastic (GFRP) is principally a function of the matrix shear modulus, the fiber shear modulus, and the volume fraction of fibers. None of the existing micromechanics theories accurately fits the experimental data (Ref 2), but the numerical prediction of D.F. Adams and D.R. Doner (Ref 3) gives good agreement. From the type of curve shown in Fig. 2, it is possible to determine the fiber volume fraction, V_f, if the matrix shear modulus, G_m, is known, and vice versa.

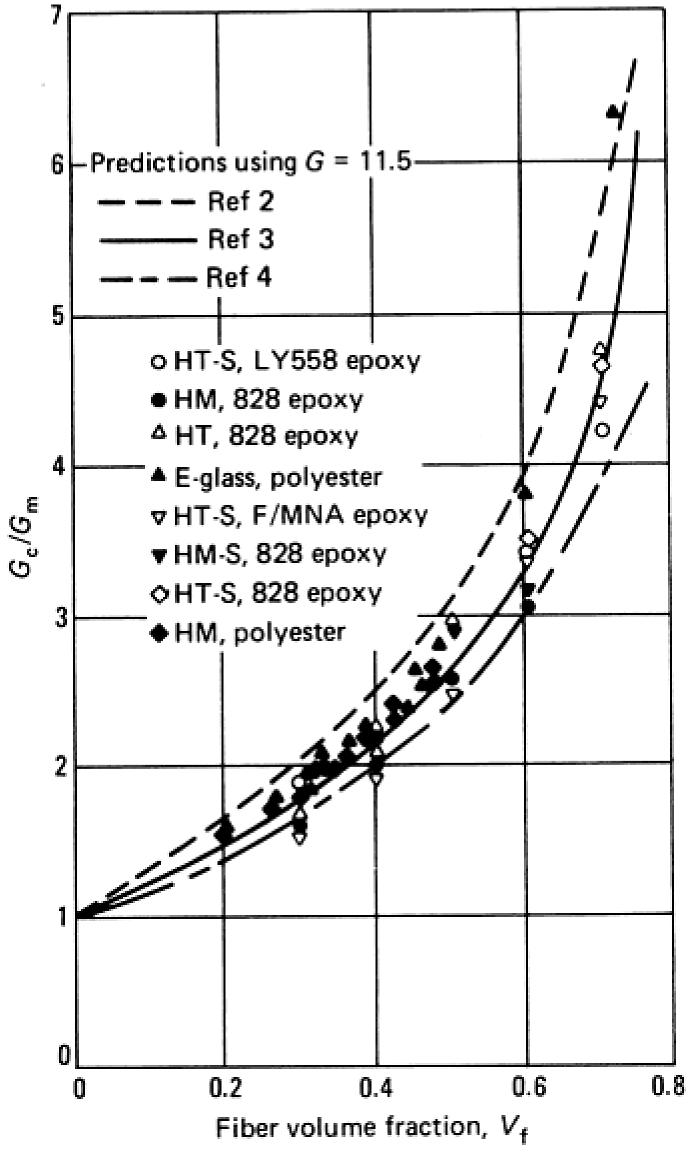

Fig. 2 Variation of reduced composite longitudinal shear modulus (G_{LT}/G_m) with fiber volume fraction (V_f)

For longitudinal shear loading, it can be shown that for viscoelastic materials (Ref 4):

$$\Psi_{LT} = \frac{\Psi_m(1-V_f)\{(G+1)^2 + V_f(G-1)^2\}}{[G(1+V_f)+1-V_f][G(1-V_f)+1+V_f]} \quad \text{(Eq 2)}$$

where f and m represent fiber and matrix, V_f is the fiber volume fraction, G is the ratio of the shear modulus of the fiber to that of the matrix, and Ψ is the specific damping capacity. For many fiber-matrix combinations, G is of the order of 10, which leads to a composite specific damping capacity that is not influenced very much by the fiber volume fraction. This relationship is shown in Fig. 3 for a typical carbon-fiber- reinforced composite, along with an alternative solution proposed by R.D. Adams and D.G.C. Bacon (Ref 2). To allow a comparison of these predictions with the variety of experimental data, the damping values have been nondimensionalized. To explain the lower damping measured in their torsional tests, R.D. Adams and D.G.C. Bacon cited effects that were due to fiber misalignment and dilatational strains in the materials that contribute little to the damping but add significantly to the stored strain energy. Thus, if the damping capacity or shear modulus of the matrix is known, it is possible to estimate the damping and shear modulus of a composite with a given volume fraction. Alternatively, by using curves such as those in Fig. 3, or the similar ones given by R.G. Ni and R.D. Adams (Ref 5), it is possible to estimate the properties of a composite with a given volume fraction if those at some other volume fraction are known.

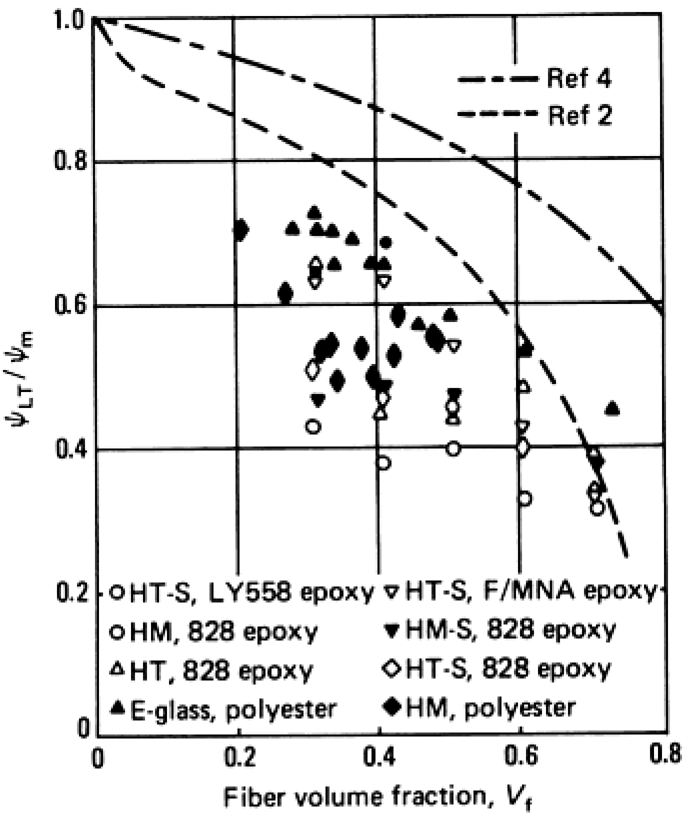

Fig. 3 Variation of the ratio of longitudinal shear damping (Ψ_{LT}) to the matrix damping (Ψ_m) with volume fraction (V_f)

Longitudinal Tension/Compression. The longitudinal Young's modulus, E_L, (the tensile modulus in the direction of the fibers in a unidirectional composite) is given by the rule of mixtures and is:

$$E_L = E_f V_f + E_m(1 - V_f)$$

where E_f and E_m are the fiber and matrix Young's moduli, and V_f is the fiber volume fraction. This rule is well obeyed experimentally, as shown in Fig. 4, and may be used as a check on any parameter, provided the others are known. This relationship was derived for normal axial loading (tension or compression), but also applies in flexure, provided that shear effects can be neglected. The scatter of the experimental results in Fig. 4 is mainly due to fiber misalignment, which is usually worse at low volume fractions. Other errors can be due to incorrect assessment of the volume fraction. It is also possible to predict the damping capacity of a unidirectional material when it is stressed in the fiber direction by using the rule of mixtures and assuming that all the energy dissipation occurs in the matrix. This gives the equation:

$$\Psi_L = \Psi_m(1 - V_f)\, E_m/E_L$$

where E is Young's modulus and L represents longitudinal tensile/compressive properties of the composite.

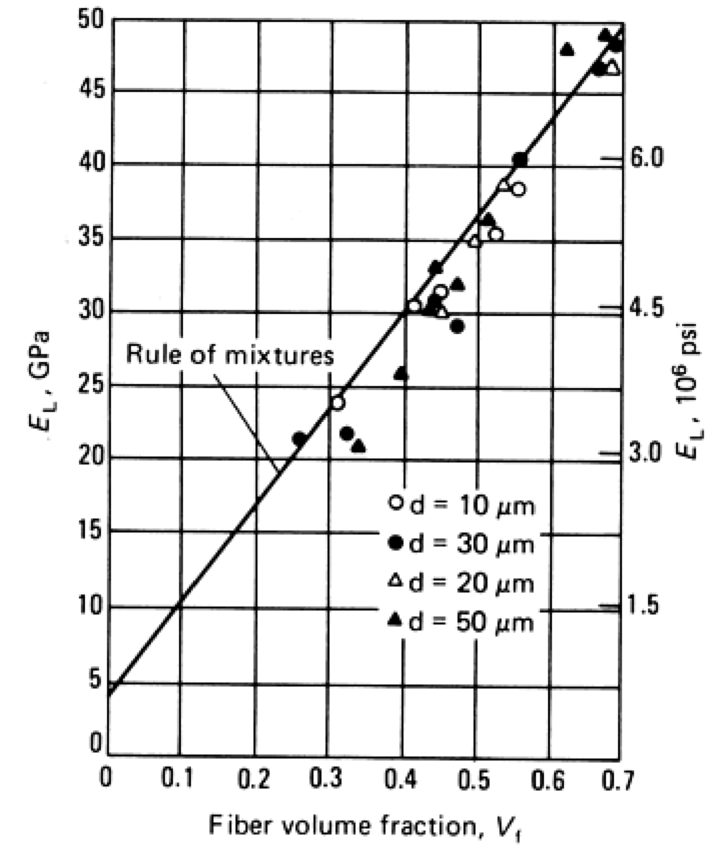

Fig. 4 Longitudinal Young's modulus (E_L) against fiber volume fraction (V_f) for different glass fibers

However, it is found that this expression considerably underestimates the measured value of Ψ_L, even when considerable effort has been made to eliminate extraneous losses (Fig. 5). Basically, there are several factors contributing to the discrepancy. First, the smaller the fiber diameter, the larger the surface area of fiber per unit volume. R.D. Adams and D.F. Short (Ref 6) showed that for 10, 20, 30, and 50 μm (390, 790, 1200, and 1950 μin.) diam glass fibers in polyester resin, there was a consistent increase in Ψ_L with reduction in fiber diameter. Second, the problem of misalignment is not insignificant, as is shown subsequently for angle-ply composites. Third, any structural imperfections, such as cracks and debonds, lead to interfacial rubbing and, hence, to additional losses. Finally, the unidirectional lamina is very often loaded in flexure rather than uniform in-plane tension or compression. Thus, although the effect of shear is negligible in stiffness measurements, this is less true for damping because shear damping is essentially that of the matrix, and Ψ_{LT} is of the order of 50 to 100 times larger than Ψ_L.

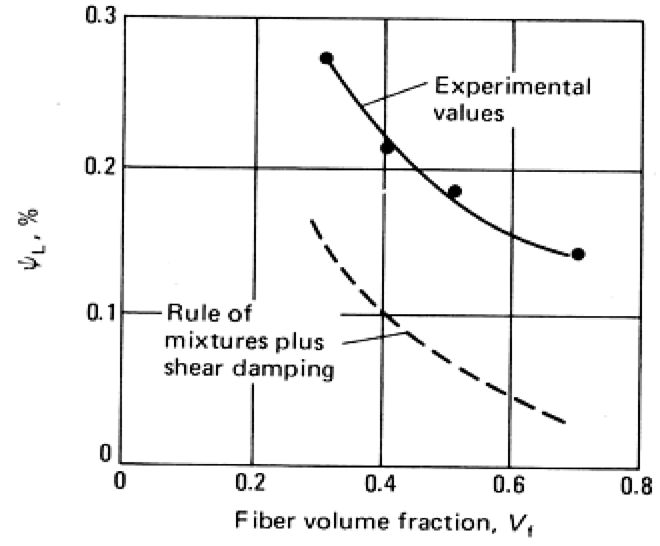

Fig. 5 Variation of flexural damping (Ψ_L) with fiber volume fraction (V_f) for HT-S carbon fiber in epoxy resin

Although only a small percentage of the energy is stored in shear, it can make a substantial contribution to the total predicted value of damping. Figure 6 shows that as the aspect ratio of a beam was reduced from 90 to 50, the shear damping contribution was increased. Further, by subtracting the shear damping from the experimental values, the effect of aspect ratio is essentially eliminated.

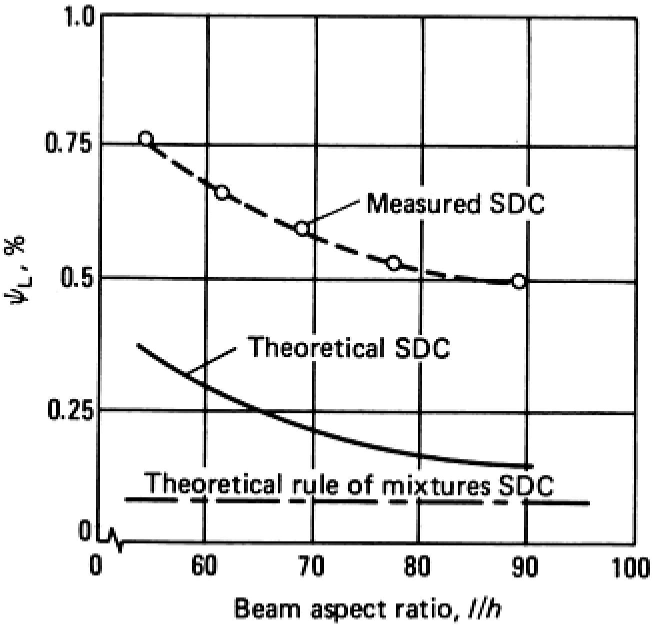

Fig. 6 Variation of flexural damping (Ψ_L) with aspect ratio *l*/*h* (*l*, length; *h*, thickness) for high-modulus carbon fiber in DX209 epoxy resin $V_f = 0.5$. SDC, shear damping contribution

The difference remaining between the rule of mixtures prediction and the "experimental minus shear" values was mainly due to the combination of misalignment internal flaws, and fiber diameter. It has been suggested that the discrepancy can be explained by the composite being modeled such that it considers damping of the fibers. Unfortunately, this is unlikely to be a realistic solution because the damping of the fibers is extremely small. R.D. Adams (Ref 7) has directly measured the longitudinal shear damping of a variety of single carbon fibers and found values of the order of 0.13% specific damping capacity. This gives a loss factor of the order of 2×10^{-4}. In tension/compression, the graphite microfibrils that make up the carbon-fiber structure will be preferentially stressed in their strong direction, with much less interfacial slipping than might occur in torsion. Thus, the longitudinal damping (tension/compression) ought to be at least an order of magnitude lower than that measured in torsion, giving a loss factor of approximately 2×10^{-5}. There is, therefore, no way in which damping of this level can reasonably be used to explain the discrepancies in the micromechanic models. On the other hand, it is known that aramid fibers possess quite high damping levels, even in tension/compression, and might therefore offer an exception to the previous generalization.

Transverse Tension/Compression. In the transverse direction, damping is, as in shear, very heavily matrix-dependent. Again, there is no reliable micromechanics theory for predicting Ψ_L. Experiments covering a wide variety of fibers, from E-glass to high-modulus carbon, showed that transverse damping is largely independent of both fiber type and surface treatment. Volume fraction, like longitudinal shear, does have a significant effect on Ψ_L. Some experimental results to illustrate this point are given in Fig. 7. Figure 8 shows the transverse Young's modulus, E_T, which, like G_{LT} (Fig. 2), is seen to increase markedly with volume fraction. The theoretical curve is based on the expression proposed by S.W. Tsai and H.T. Halpin (Ref 8), and the values are for a glass composite for which it has been assumed that the longitudinal and transverse moduli of the glass fibers are identical (that is, the fiber is isotropic). This cannot be assumed for carbon fibers, which are highly anisotropic.

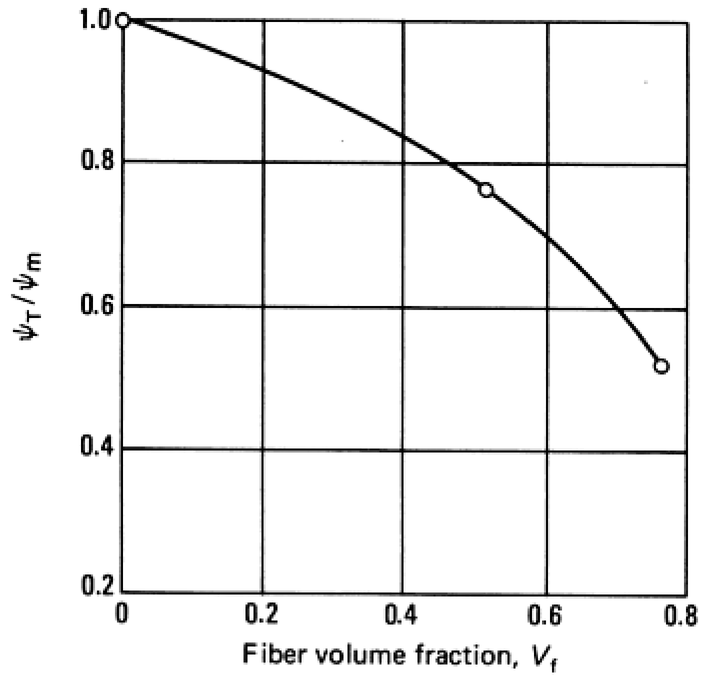

Fig. 7 Variation of ratio of transverse damping (Ψ_T) to matrix damping (Ψ_m) with fiber volume fraction (V_f). Results from GFRP specimens in flexure

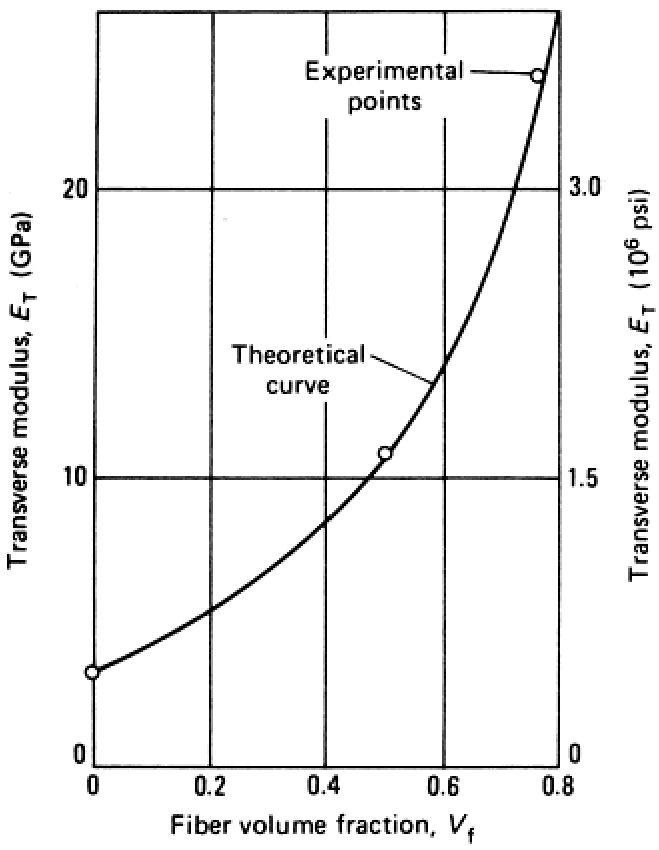

Fig. 8 Variation of the transverse modulus (E_T) with fiber volume fraction (V_f) of GFRP in flexure. E_{fT}= 70 GPa (10 × 10^6 psi). E_m= 3.21 GPa (0.466 × 10^6 psi)

General Comments on the Simple Loading of Laminae. While the various micromechanics theories, including those proposed by S. Chang and C.W. Bert (Ref 9), are sufficiently accurate for predicting moduli, they are generally poor at predicting damping. This is because the various theories do not contain some of the important factors (such as microcracks, misalignment, and surface area) that contribute to the damping of unidirectional materials while having little effect on the moduli. Without the development of some very complex models, it is

unlikely that the situation can be changed in the near future. The only safe feature is that, with the possible exception of aramid fibers, there is essentially no damping in the fibers themselves.

R.G. Ni and R.D. Adams (Ref 5) used a combination of micromechanics and experimental results to produce a series of predictive curves for the variation of the unidirectional moduli and damping values with fiber volume fraction. They also showed the importance of using the correct volume fraction for this basic data. Thus, when predictions of the damping for laminated plates are being made, it is important to know the volume fraction of both the plates and the unidirectional material used in making the prediction. Guides were given for converting data, and an example showed the errors that can occur if the corrected data are not used. It is suggested that the Ni and Adams approach is far more suitable in practical terms than trying to evolve increasingly complex micromechanics models. A further practical point is that it is difficult to make representative pure resin (matrix) specimens, the results of which are necessary for any micromechanics prediction. This is because the resins used for making preimpregnated fiber sheets or tapes (prepregs) contain volatiles that are difficult to remove from the bulk without creating bubbles or causing other chemical changes in the cured blocks.

Off-Axis Loading. When the specimen axis, and thus the direction of loading, is at an angle, θ, to the fiber direction in a unidirectional composite, an off-axis situation exists.

R.D. Adams and D.G.C. Bacon (Ref 10) derived closed-form expressions for the damping, Ψ_θ, of a unidirectional beam with fibers at an angle to that of the specimen axis. Figure 9 shows the theoretical and experimental values of Ψ_θ for a CFRP beam, together with the separate theoretical contributions from stresses in the L, T, and LT directions. Figure 9 also shows the separate contributions from direct stresses in the direction of the fibers Ψ_L, transverse to the fibers Ψ_T, and in shear, Ψ_{LT}. The theoretical prediction and experimental measurements of the variation of Young's modulus, E_θ, with angle, are also shown in Fig. 9. Excellent agreement between theory and experiment is shown for both modulus and damping.

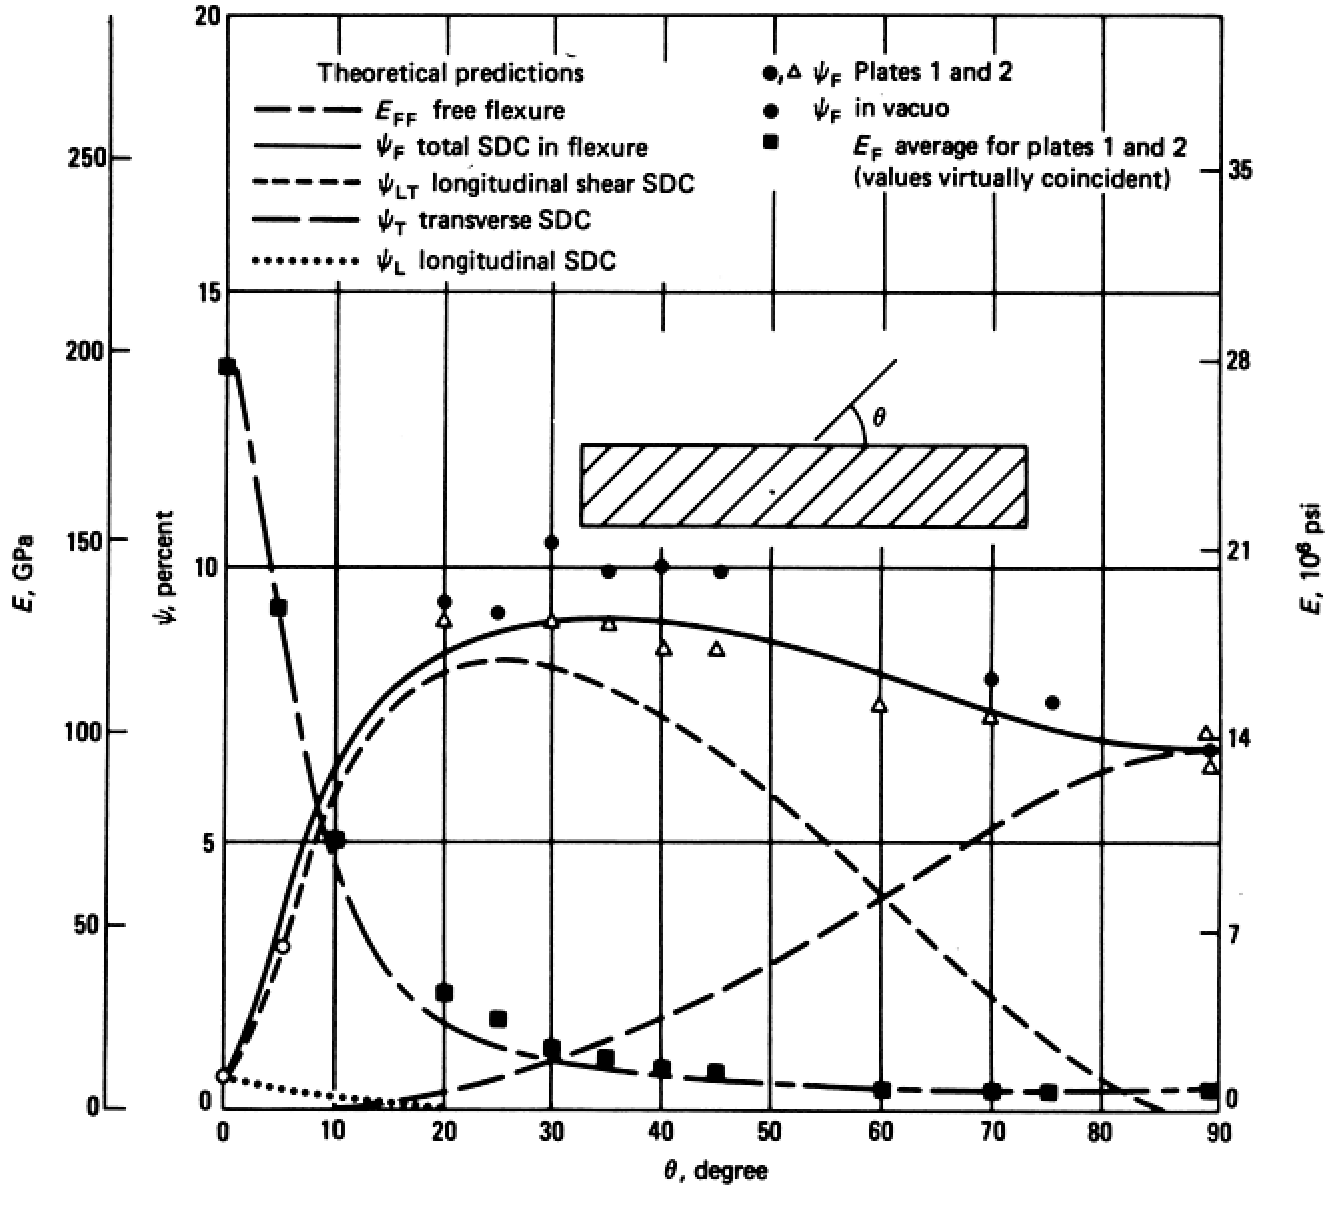

Fig. 9 Variation of flexural Young's modulus (*E*) and Damping (Ψ) with fiber orientation (θ) for high-modulus carbon fiber in DX209 epoxy resin. V_f= 0.5

R.D. Adams and D.G.C. Bacon showed that, for a carbon composite in which $E_L >> G_{LT}$, $E_L >> E_{LT}$, $\Psi_L << \Psi_T$, and $\Psi_L << \Psi_{LT}$, then to a very good approximation over the range $5° < \theta < 90°$:

$$\Psi_\theta = \frac{1}{s_{11}}\left[\frac{\Psi_T}{E_T}\sin^4\theta + \frac{\Psi_{LT}}{G_{LT}}\sin^2\theta\cos^2\theta\right]$$

where S_{11} is the compliance in the direction of the specimen axis.

Beams Cut From Laminated Plates

In practice, structures made from composites contain a series of layers of unidirectional fibers such that each layer has some predetermined orientation with respect to the defined dimensions of the structure (Fig. 10). The orientations and transverse dispositions of the fibers depend on the loads to be carried (strength) and the deflections that can be tolerated (stiffness). For any arrangement of layers, it is now possible to predict not only structural strength and stiffness, but also inherent damping. Laminated plate theory is used to evaluate the contributions to damping made by each layer. Beams are a special case of plates, but are often treated

separately because the theory of vibrating beams is much easier than that of plates. In an article of this length, the theory can only be outlined. A fuller treatment is given by R.G. Ni and R.D. Adams (Ref 11).

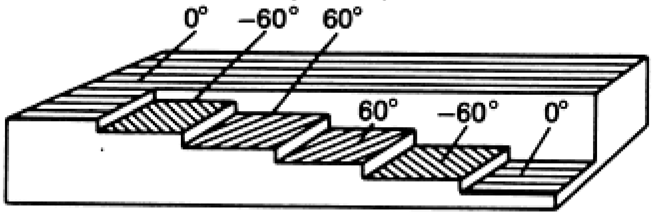

Fig. 10 Lamina stacking arrangement for (0°,–60°, 60°)$_s$ laminate. The suffix *s* indicates symmetry of stacking about the midplane.

The constitutive equation relating stresses, σ, and strains, ϵ, in the k^{th} lamina is (using standard notation for composites):

$$\begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_6 \end{bmatrix}_k = \begin{bmatrix} Q_{11} & Q_{12} & Q_{16} \\ Q_{12} & Q_{22} & Q_{26} \\ Q_{16} & Q_{26} & Q_{66} \end{bmatrix}_k \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_6 \end{bmatrix}_k$$

where the values Q_{ij}^k are the stiffness matrix components in the specimen system of axes 1, 2, 3 of the k^{th} lamina, and are obtained from the values in the axes related to the fiber direction *x*, *y*, *z* by using the appropriate geometric transformation. For a beam specimen, the stresses σ_2 and σ_6 (transverse and interlaminar shear) can generally be neglected in comparison with σ_1 although M.M. Wallace and C.W. Bert cite cases where this may not always be so (Ref 12).

With the appropriate geometric transformation, these stresses can be converted from the specimen axes to the fiber directions. It is then possible to calculate the stresses in the fiber direction σ_x (that is, σ_L), normal to it σ_y (that is, σ_T), and the shear components σ_{xy} (that is, σ_{LT}). The total energy stored in the *x* (or L) direction, Z_L, for example, can then be calculated, and the energy dissipation in this layer and in this direction can then be given by:

$$\Delta Z_L = \Psi_L \cdot Z_L$$

For the beam, the overall specific damping capacity, Ψ_{ov}, is then given by the total energy dissipated divided by the total energy stored:

$$\Psi_{ov} = \frac{\Sigma \Delta Z}{\Sigma Z} = \frac{\psi_L Z_L + \psi_T Z_T + \psi_{LT} Z_{LT}}{Z_L + Z_T + Z_{LT}} \qquad \text{(Eq 3)}$$

If the elastic moduli and damping coefficients are known for the unidirectional material, it is possible to calculate the overall damping of a beam. R.G. Ni and R.D. Adams (Ref 11) gave the theory for generally laminated beams and obtained excellent agreement with the measured results.

Whereas specimens with all the layers at θ will twist as they are bent, the twisting can be restrained internally by using several layers at ±θ. The damping contributions can again be assessed, and the measured values accounted for (Ref 10, 11). Figure 11 shows theoretical predictions and experimental measurements for the modulus and damping of a series of CFRP beams made with ten layers of high-modulus carbon fibers in epoxy resin, alternately at ±θ. Note that the modulus is higher than that of the off-axis specimens because of the internal restraint, while the damping is generally lower.

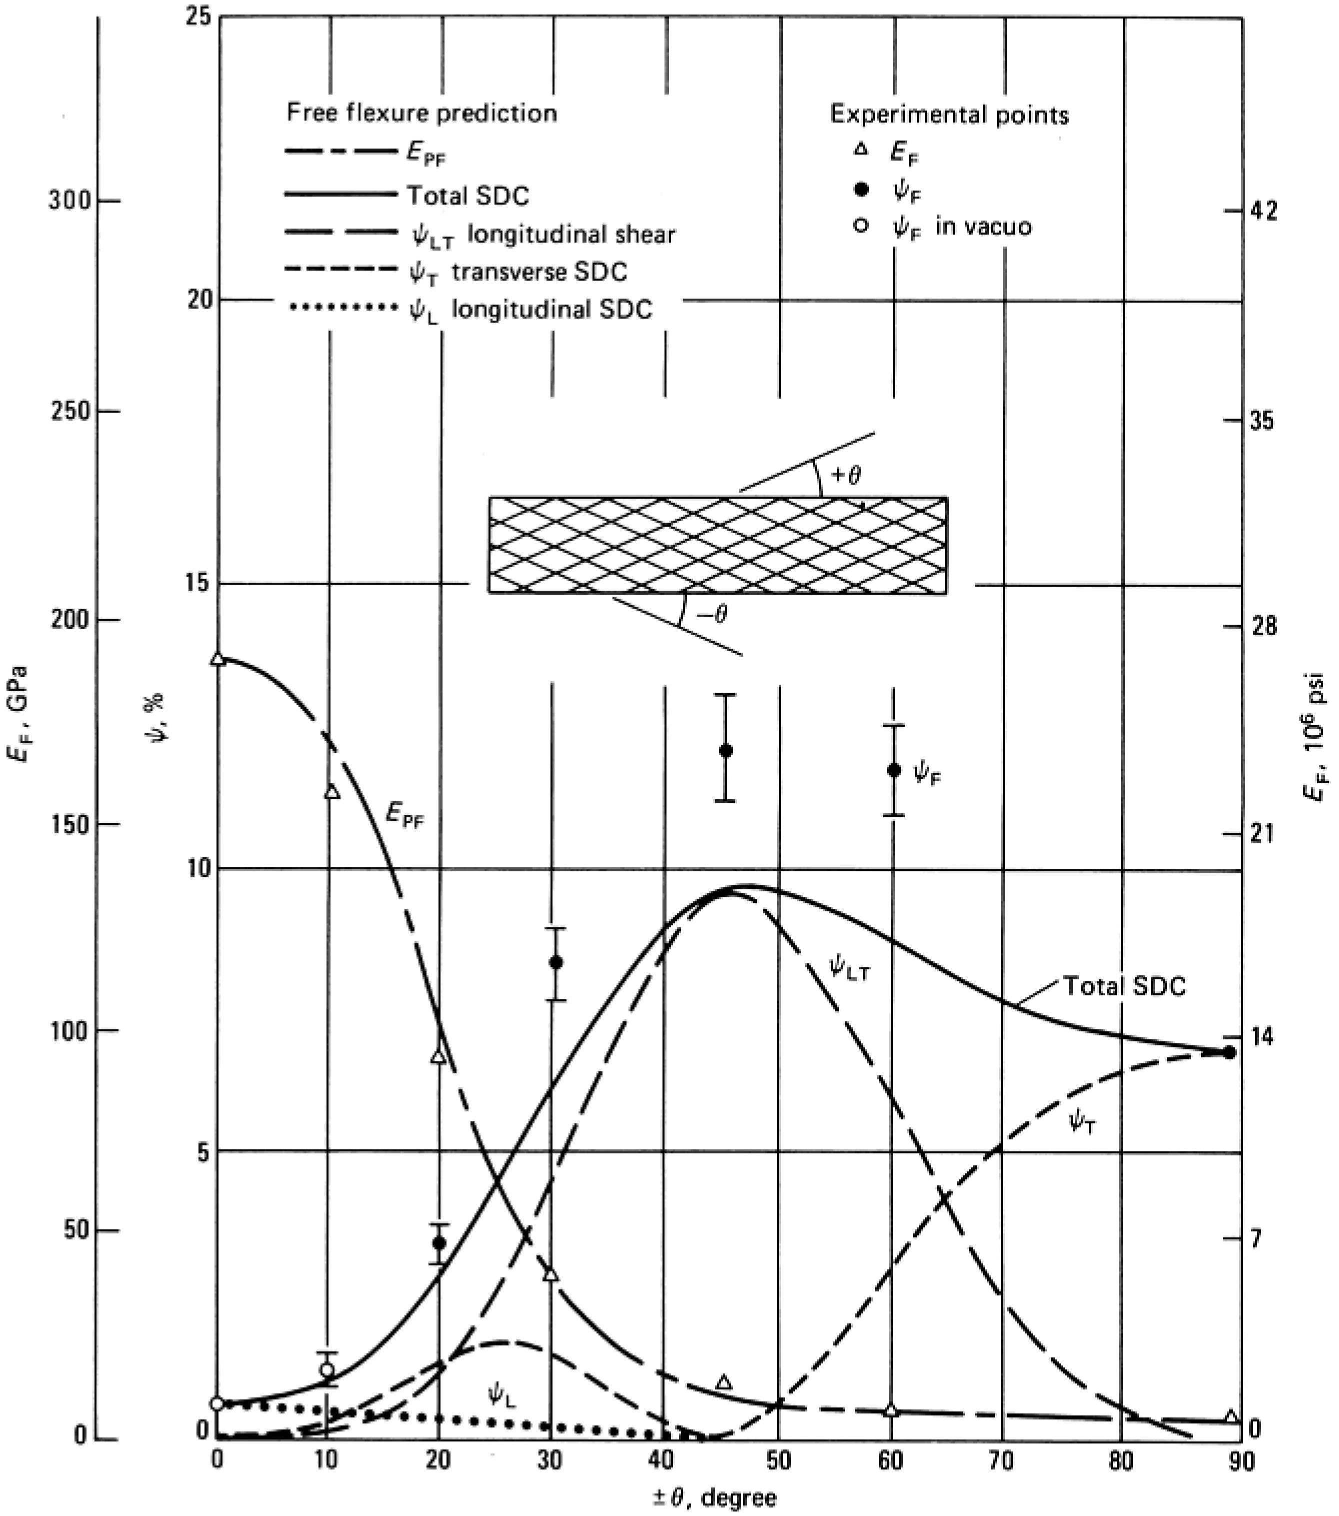

Fig. 11 Variation of flexural Young's modulus (E_f) and damping (Ψ) with ply angle ±θ for high-modulus carbon fiber in DX209 epoxy resin. V_f= 0.5

More generally, laminated composites, as shown in Fig. 10, are commonly used in practice. Fortunately, the same method as that just described can be used to predict damping. Figure 12 shows the excellent agreement between theory and experiment for the variation of damping (and stiffness) with θ of a symmetrical, high-modulus, graphite-fiber-reinforced epoxy plate. Beam specimens were cut at angles from–90° to +90° relative to the fiber direction in the outer layer of this (0°,–60°, +60°)$_s$ plate.

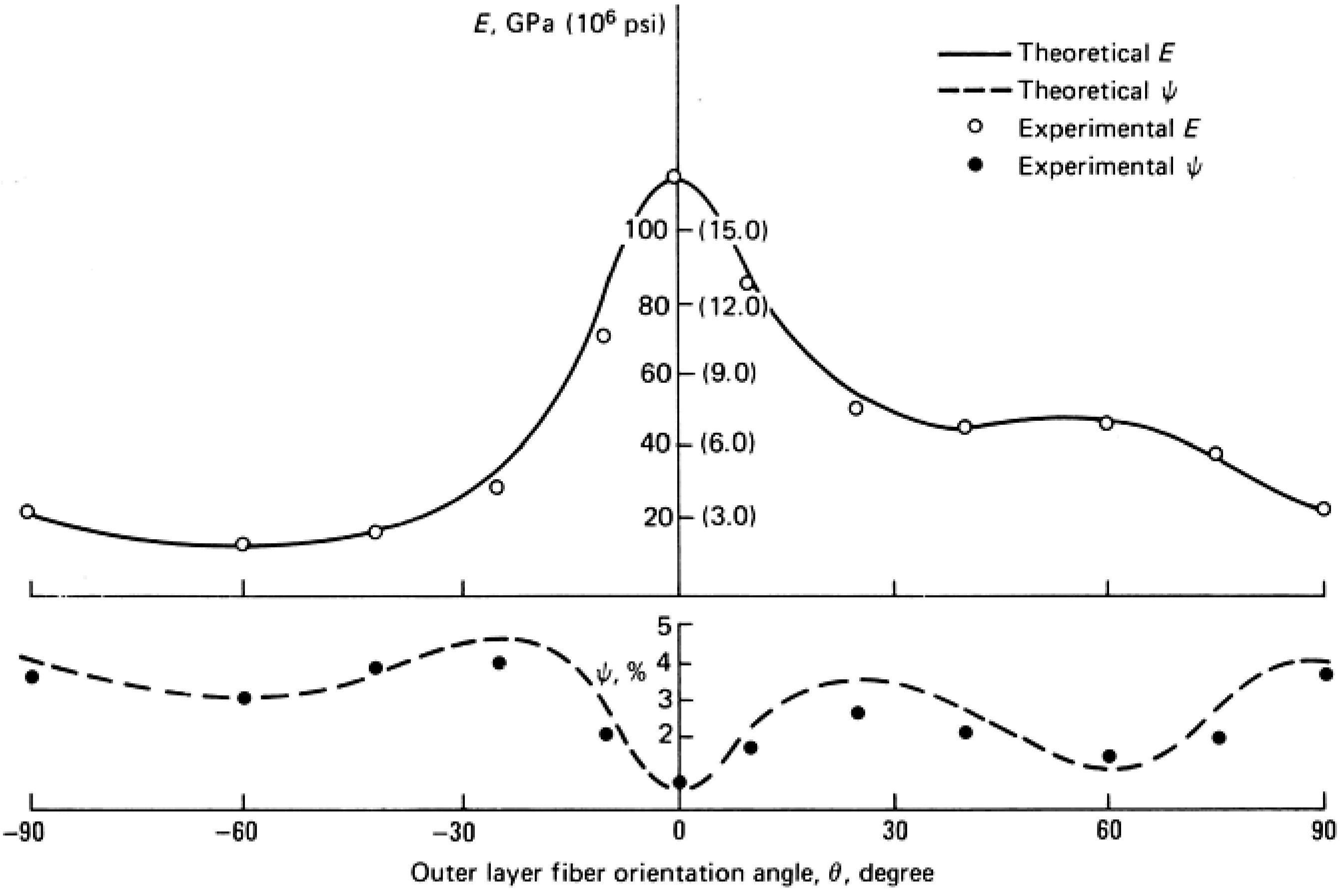

Fig. 12 Variation of flexural modulus (*E*) and damping (Ψ) with outer layer fiber orientation angle (θ) for 0°,–60°, 60°)$_s$ made from high-modulus carbon fibers in DX210 epoxy resin

Laminated Plates

Fiber-reinforced plates of various shapes and different boundary conditions (free, clamped, and hinged) commonly occur in practice. Designers need to be able to predict the stiffness parameters and damping values of such plates for conditions such as aeroelasticity, acoustic fatigue, and so on. Much attention has been devoted to stiffness predictions, but very little to damping. The objective here is to develop a suitable mathematical model that can be used to predict the damping values of plates laminated from fibers of various types at various orientations. Such is the mathematical complexity of the equation of motion of plates (even those made from isotropic materials) that closed-form solutions exist only for special cases, such as hinged

(simply supported) rectangular plates and circular plates (involving Bessel functions). The solution is therefore best obtained using finite- element techniques, which can readily accommodate different shapes, thicknesses, and boundary conditions. Some examples are given by P. Cawley and R.D. Adams (Ref 13).

All the plates discussed here are midplane symmetric, which eliminates bending-stretching coupling. It is, however, possible to include this effect in the analysis if asymmetrical laminates are used.

The first ten modes of vibration of a typical plate can be adequately described by using a coarse finite-element mesh with six elements per side (6 × 6 = 36 elements for a rectangular plate). The essence of the technique is first to determine the values of strain energy stored because of the stresses relative to the fiber axes of each layer of each element. Use of modulus parameters determined from unidirectional bars makes it possible to determine the total energy stored in each layer of each element. These are then summed through the thickness to give the energy stored in each element (related to the strains and the mean elasticity matrix for the element). It is then possible to use standard finite- element programs and avoid the mathematical complication of working in terms of the standard plate equations. This approach provides the stiffness of the plate, the maximum strain energy, *U*, stored in any given mode of vibration, the natural frequencies, and the mode shape. The energy dissipated in an element of unit width and length situated in the k^{th} layer can also now be determined. This is done by transforming the stresses and strains to the fiber directions and using the damping properties of 0° bars. The energy dissipated in the element in the k^{th} layer is integrated over the whole area of the plate, and contributions of each layer are summed to give ΔU, the total energy dissipated in the plate. The overall specific damping capacity, Ψ_{ov}, is then given by $\Psi_{ov}=\Delta U/U$. Alternatively, the damping can first be summed through the thickness of the damped element to give a damped element stiffness matrix. This can then be treated by standard finite element techniques (Ref 14).

It is useful to express in the mathematical terms the technique described previously. The maximum strain energy, *U*, is obtained as for an undamped system as follows:

$$U = \frac{1}{2}\int_v \{\varepsilon_{ij}\}^T \{\sigma_{ij}\} dV \quad \text{(Eq 4)}$$

where ϵ_{ij} and σ_{ij} are the strains and stresses related to the fiber direction, and *V* refers to the volume.

This equation may be reduced to a standard form as:

$$U = \tfrac{1}{2}\{\delta\}^T [K]\{\delta\} \quad \text{(Eq 5)}$$

where {δ} is the nodal point displacement matrix. Here, five degrees of freedom for each nodal point and eight nodal points for each element are used, and [*K*] is the stiffness matrix. In the evaluation of the maximum strain energy, *U*, the Young's modulus of 0° and 90° unidirectional fiber-reinforced beams, E_L, E_T, and the shear modulus of a 0° unidirectional rod, G_{LT}, are used, Now:

$$\Delta U = \int_v \delta(\Delta U) dV \quad \text{(Eq 6)}$$

where $\delta(\Delta U)$ is the energy dissipated in each element, and is defined as:

$$\delta(\Delta U) = \delta(\Delta U_1) + \delta(\Delta U_2) + \delta(\Delta U_{23}) + \delta(\Delta U_{13}) + \delta(\Delta U_{12})$$

$$\delta(\Delta U_1) = \tfrac{1}{2}\Psi_L \varepsilon_{11}\sigma_{11} \delta(\Delta U_2) = \tfrac{1}{2}\Psi_T \varepsilon_{22}\sigma_{22}$$

and

$$\delta(\Delta U_{23}) = \tfrac{1}{2}\Psi_{TT}\varepsilon_{23}\sigma_{23}$$

$$\delta(\Delta U_{13}) = \tfrac{1}{2}$$

$$\Psi_{LT}\epsilon_{13}\sigma_{13}$$

$$\delta(\Delta U_{12}) = \tfrac{1}{2}$$

$$\Psi_{LT}\epsilon_{12}\sigma_{12}$$

where subscript 1 denotes the fiber direction, while 2 and 3 denote the two directions transverse to the direction of the fibers, and Ψ_L, Ψ_T, and Ψ_{LT} are the associated damping capacities that are also obtained from tests on unidirectional beams.

We may now reduce Eq 7 to matrix form as:

$$\Delta U = \frac{1}{2}\int_v \{\varepsilon_{ij}\}^T [\Psi]\{\sigma_{ij}\} dV \qquad \text{(Eq 7)}$$

where:

$$[\Psi] = \begin{bmatrix} \psi_L & 0 & 0 & 0 & 0 \\ 0 & \psi_T & 0 & 0 & 0 \\ 0 & 0 & \psi_{TT} & 0 & 0 \\ 0 & 0 & 0 & \psi_{LT} & 0 \\ 0 & 0 & 0 & 0 & \psi_{LT} \end{bmatrix}$$

Using the same method as with Eq 4, Eq 7 may be reduced to:

$$\Delta_U = \frac{1}{2}\{\delta\}^T [K_d]\{\delta\} \qquad \text{(Eq 8)}$$

where {δ} is the same matrix as in Eq 4 and was obtained from the finite-element results. The stiffness matrix of the damped system is [K_d], and it may be evaluated separately. D.X. Lin, R.G. Ni, and R.D. Adams described this method in much more detail (Ref 14).

Some results are given for theoretical predictions and experimental measurements on several plates made from glass or high-modulus carbon fibers in DX210 epoxy resin. The plates were made of 8 or 12 layers of preimpregnated fiber to give different laminate orientations; details of the plates used are given in Table 1. The material properties used in the theoretical prediction are given in Table 2. All the values in this table were established either by using beam specimens cut from a unidirectional plate (longitudinal and transverse damping and Young's moduli) or cylindrical specimens (for measuring the shear modulus and damping in torsion). It should be noted that the value of the torsional damping of a bar with fibers at 90° to the axis, Ψ_{23}, is not important in the prediction, because changing it from 6% to 15% gave no significant difference to the overall theoretical results. In the prediction, Ψ_{23} is taken as the same value as Ψ_{12}, which is the value of torsional damping of a unidirectional rod in longitudinal shear. Because of variations in the fiber volume fraction of the plates, the material properties used in the theoretical prediction were each corrected from a standard set given for 50 vol%, using the method of R.G. Ni and R.D. Adams (Ref 11). The plates were vibrated in the free-free condition (with all the edges freely supported). Although hinged or clamped edges can be readily incorporated into the finite element model, they are not easy to reproduce in an experiment. Figures 13 and 14 show, for the first six free-free modes, the theoretical prediction and experimental results of CFRP plates for various fiber orientations. On the whole, there is good agreement between the predicted and measured values. Mode 6 in plate 3 could not be obtained experimentally because the input energy from the transient technique used for measuring the frequency and damping (Ref 15) was insufficient. Figures 15 and 16 give the results for GFRP plates in free-free vibration. All show good agreement between prediction and measurement.

Table 1 Plate data

Plate number	Material	No. of layers	Density, g/cm^3	V_f	Ply orientation
1	CFRP[(a)]	8	1.446	0.342	$(0°, 90°, 0°, 90°)_s$ [(b)]

The effect of air damping and the additional energy dissipation associated with the supports affect the results of the very low damping modes, such as mode 4 of plate 1, mode 4 of plate 3, and so on. These are essentially beam modes in which the large majority of the strain energy is stored in tension/compression in the fibers and not in matrix tension or shear. However, the results for all the plates used are satisfactory, even when the specimens have imperfections, such as slight variations in thickness and the nominal angle of the fibers (±2° to (±3° error). It can be said that the more twisting there is, the higher the damping. For instance, for an eight-layer cross-ply (0°/90°) GFRP plate (Fig. 15), the two beam-type modes, that is, modes 2 and 3, appear to be similar, but the relationship of the nodal lines to the outer fiber direction means that the higher mode has much less damping than the lower one. The other modes of vibration of this plate all involve much more plate twisting, and hence matrix shear, than do modes 2 and 3, and so the damping is higher.

Design Considerations for Plates. It is important for designers to realize the significance of these results, which show that for all the plates, the damping values are different for each mode. For instance, for the all-0° square GFRP plate in Fig. 17, the damping of the first mode was over 14 times that of the sixth mode. Also, it should be noted that some modes may have much less damping than others, especially when most of the fibers are in one direction. If such a low-damping mode has its natural frequency close to or in the frequency range of any excitation, it may well lead to excessive motion and cause fatigue, noise radiation, component malfunction, and so on.

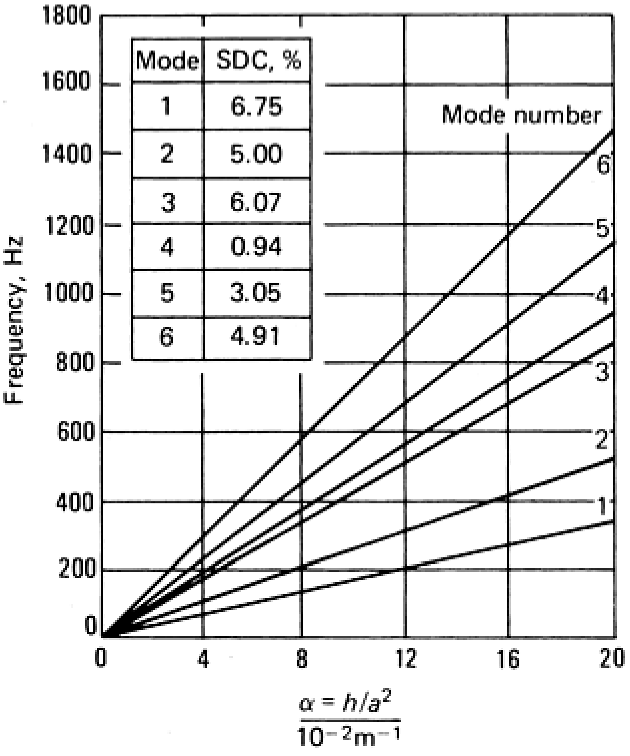

Fig. 17 Variation of natural frequencies and damping with the ratio of thickness to the area of a square plate (all 0°) GFRP. V_f= 0.50

D.X. Lin, R.G. Ni, and R.D. Adams (Ref 14) showed how the prediction of natural frequencies and damping values could be simplified for geometrically similar structures by using a series of design charts. First, the damping is a function only of the mode shape. Thus, for a series of square plates with a given fiber orientation, the damping value of each mode is constant, irrespective of the dimensions of the plate. It should be noted that the damping of epoxy and similar high-performance resins is not frequency-dependent in the way that is normally associated with thermoplastics, except near the glass transition temperature, which would normally be outside the design range, even though aerospace structures have wide temperature range of operation. Furthermore the natural frequencies can all be scaled from a series of simple numbers, or read off a design chart. Figure 17 shows such a chart for an all-0° GFRP plate that has a volume fraction of 0.50. For a given mode, the natural frequency of the *t*th mode, f_i, is given by $f_i=k_i\, h/a^2$, where h is the plate thickness and a is its side length. Thus, it is possible, by using charts such as those in Fig. 17, to determine quickly and accurately the natural frequency and damping of any of the first six modes of a square plate with that particular fiber arrangement.

Because the volume fraction can also change, it is necessary to construct a further series of graphs to allow for this. Figure 18 shows the variation of natural frequency and damping of an all-0° GFRP plate with volume fraction. Again, the damping will not change with plate dimensions (h and a), although it does decrease as the volume fraction increases. Figure 18 is based on a plate for which h/a^2= 0.032 m^{-1}. Now, because:

$$f_i=k_i\, h/a^2$$

k_i must be some function of *inter alia*, the volume fraction. Thus:

$$\frac{f_i}{f_i'}=\frac{h}{h'}\left(\frac{a'}{a}\right)^2$$

and by cross-correlating from charts such as those given in Fig. 17 and 18, it is possible to predict the damping and frequency of a given mode as *h*, *a*, and V_f vary (Ref 14).

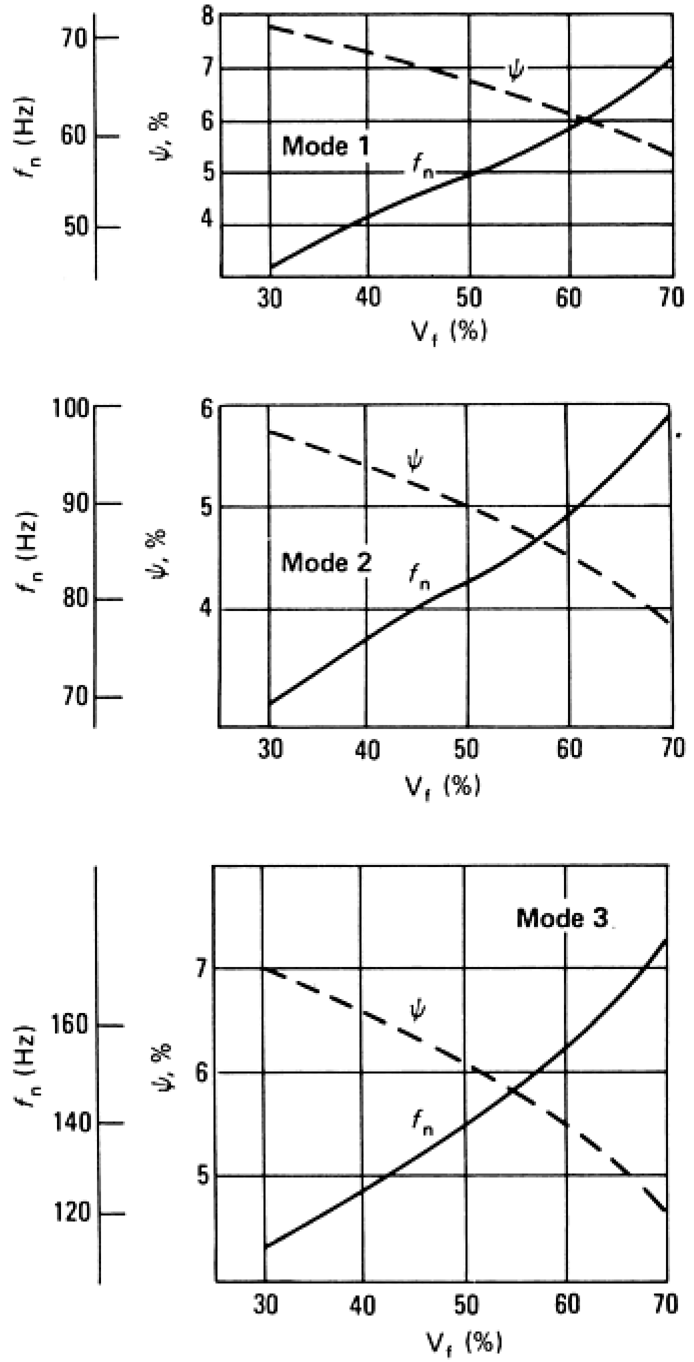

Fig. 18 Variation of natural frequencies (f_n) and damping (Ψ) of a GFRP (all 0°) plate with fiber volume fraction (V_f). $\alpha = h/a^2 = 0.32$ m^{-1}

Woven Fibrous Composites

Woven fiber-reinforce plastics are becoming increasingly important because they have the following advantages over laminates made from individual layers of unidirectional material:

- Improved formability and drape
- Bidirectional reinforcement in a single layer
- Improved impact resistance
- Balanced properties in the fabric plane

The woven composite is formed by interlacing two sets of threads, the warp and the weft, in a wide variety of weaves and balances.

Figure 19 shows the damping results obtained by cutting a series of beans at various angles, θ, from a 16-ply plate of CFRP. The fibers were woven to a balanced five-harness satin weave pattern in which one weft thread was interwoven with every fifth warp thread. This weave is the most widely used in laminates, because it gives higher mechanical properties than do plain and twill weaves, due to reduced crimping. The damping increases from about 1% at θ= 0° and 90° to a maximum of about 6% at θ= 45°. R.G. Ni and R.D. Adams' prediction (Ref 11) for a 0°/90° cross-ply made from unidirectional laminae is also shown on Fig. 19, and is in reasonable agreement with the experimental data for the woven material. The damping of the woven material is modified because the twisting of the specimens is restrained internally by the perpendicular arrangement of the warp and weft threads.

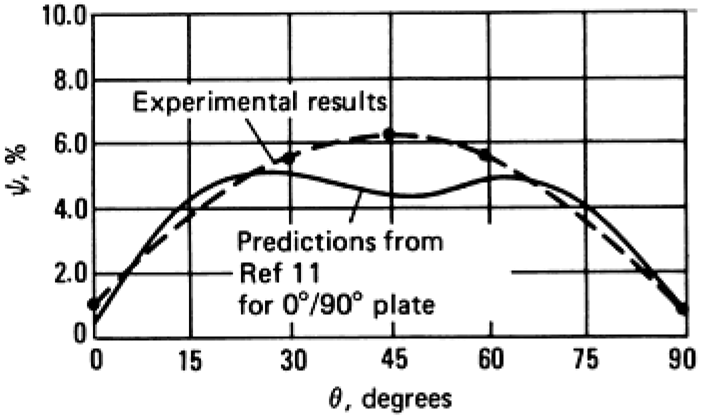

Fig. 19 Variation of specific damping capacity(Ψ) for a series of beams cut at various angles (θ) from a woven 16-ply CFRP plate

While further work is necessary to characterize the various weaves, it appears that the results will, at first approximation, be similar to those for laminates made from unidirectional laminae with the same in-lane fiber orientations.

Sandwich Laminates

To maximize the stiffness of GFRP laminates, it is common to add thin skins of CFRP. R.G. Ni, D.X. Lin, and R.D. Adams (Ref 16) made mathematical predictions of the dynamic properties of such hybrid laminates. They obtained excellent agreement between their experimental results and their theoretical predictions for the damping and moduli of plates, and of beams cut from these plates. These authors also showed how to maximize both the stiffness of a laminate from the ratio of the amounts of glass and carbon, and their relative costs.
The theoretical analysis showed that the effect of the core material on the flexural modulus and damping of this type of hybrid is generally not great. This allows some freedom in choosing the orientation of the GFRP core, and even in the selection of core materials.

Effect of Temperature

Many composites are based on polymeric matrices, usually epoxy resins, for which there are temperature-dependent damping capacities and moduli. While the influence of frequency on damping and modulus is not as strong for epoxies as it is for the high-damping polymers, as used in constrained-layer and similar damping treatments, it is not negligible. Figure 20 shows the change of E_L, E_T, and G_{LT} of a unidirectional CFRP composite over the range of–50 to +200 °C (–60 to +390 °F). (The matrix material was DX209 epoxy resin cured for 2 h at 180 °C (355 °F) and postcured for 6 h at 150 °C (300 °F).) A logarithmic scale was used, and it can be seen that the 2 matrix-dependent moduli, E_t and G_{LT}, were significantly reduced at temperatures above 150 °C (300 °F). Indeed, the transverse specimen (90° orientation) could not be tested at temperatures above 150 °C (300 °F), as it sagged under its own weight. In contrast, the 0° modulus was essentially unaffected until the matrix became shear soft, at which point the deformation became more by shear than by bending and fiber deformation. Figure 21 shows damping on a logarithmic scale and the much higher damping levels that are available in shear and transverse loading than in longitudinal tension/compression. The Ψ_L damping is due not only to increased matrix damping, according to the rule of mixtures, but also to the enhanced shear deformation referred to previously. The damping peak, at about 180 °C (360 °F), represents classical viscoelastic behavior. Testing beyond 200 °C (390 °F) was impossible because of charring.

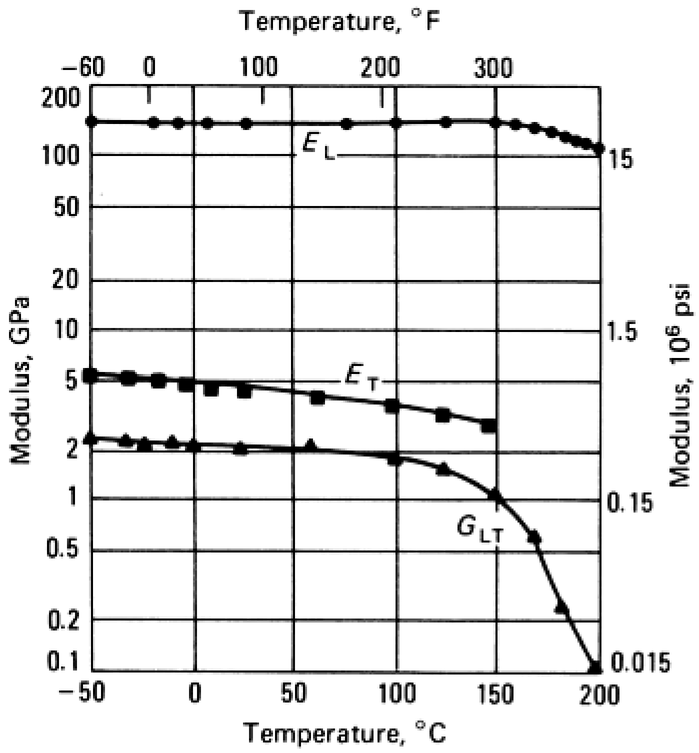

Fig. 20 Variation of longitudinal modulus (E_L), transverse modulus (E_T), and longitudinal shear modulus (G_{LT}) with temperature for high-modulus carbon fibers in DX209 epoxy resin. V_f= 0.5

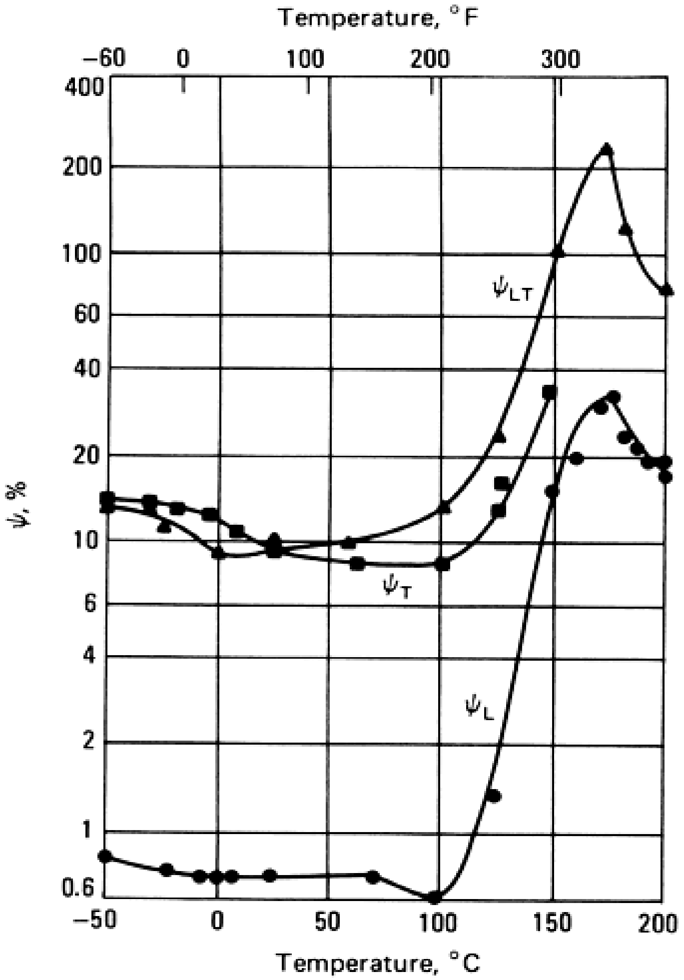

Fig. 21 Variation of longitudinal damping (Ψ_L), transverse damping (Ψ_{LT}) with temperature for high-modulus carbon fibers in DX209 epoxy resin. V_f= 0.5

At lower temperatures, the β relaxation phenomenon comes into effect. This is illustrated in Fig. 22 for a cryogenic grade, woven glass-fiber- reinforced epoxy material.

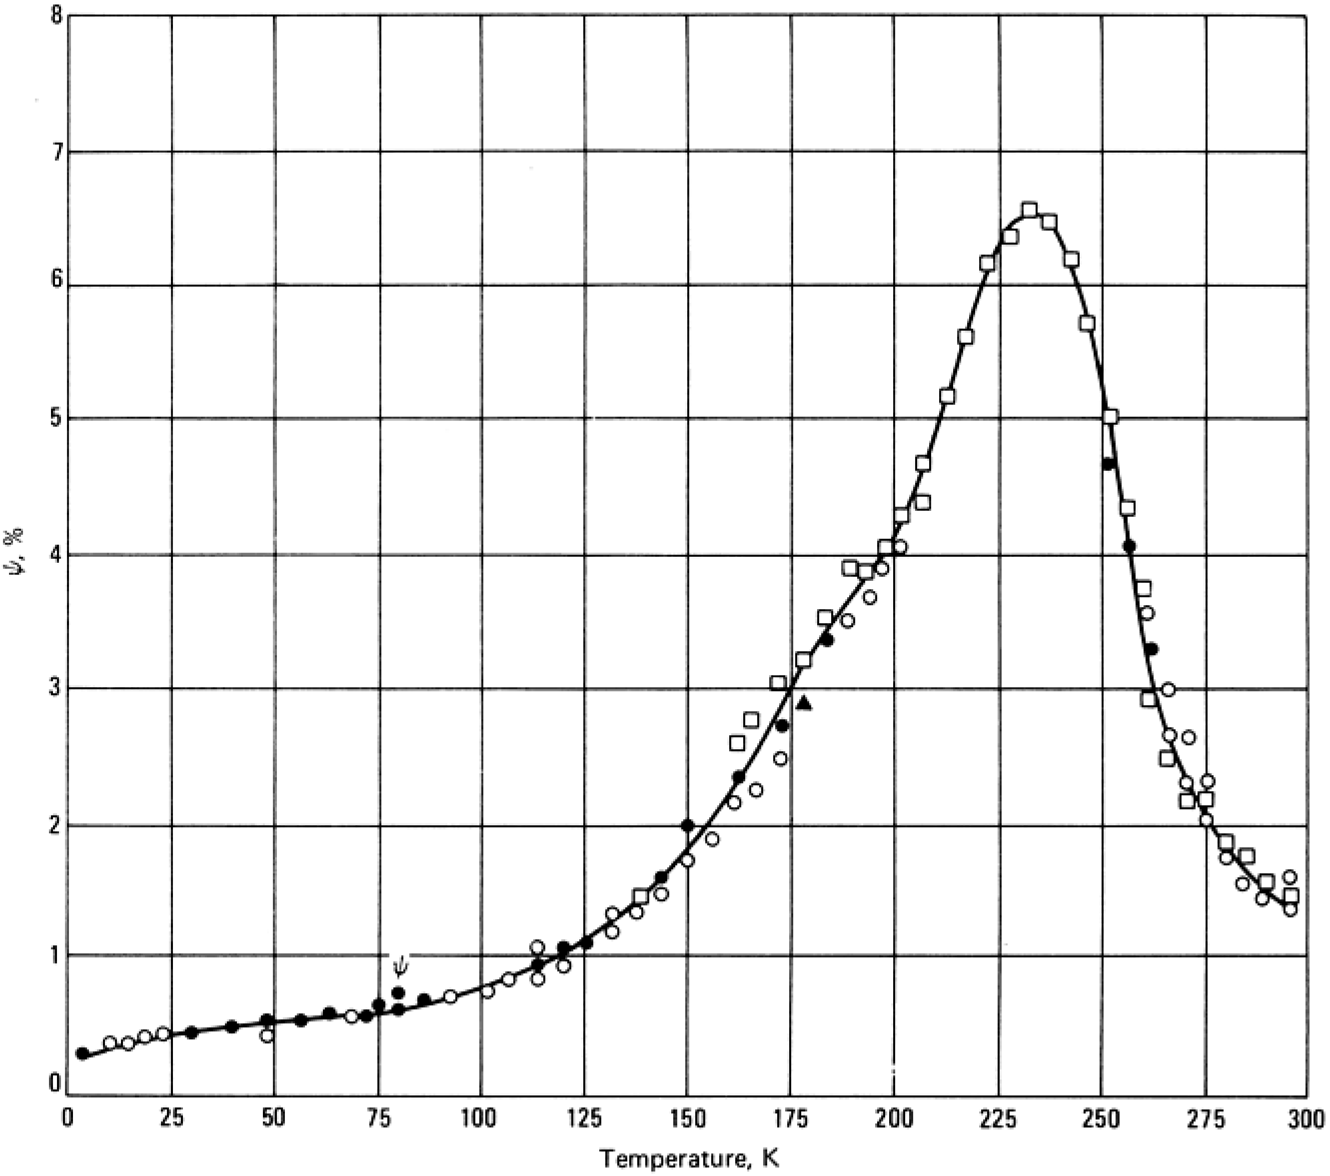

Fig. 22 Variation of specific damping capacity (Ψ) with temperature for a glass cloth-epoxy specimen

To achieve a wide range of resin properties, a standard resin was modified by the addition of a flexibilizer. By varying the proportions of resin to flexibilizer, precondensates with different glass transition temperatures were formed. Shell Epikote 828 (Shell Oil Co.) was used as the standard resin and flexibilized by the addition of Epikote 871 in the proportions 1:1 and 2:1 (828/ 871) by weight to give FO (pure 828), F50 (50% flexibilizer), and F33 (33% flexibilizer). The resin was made into prepreg with type II (high- tensile strength) carbon fiber and laminates prepared from it. Figure 23 shows that increasing the flexibilizer content increases the damping and decreases the glass transition temperature.

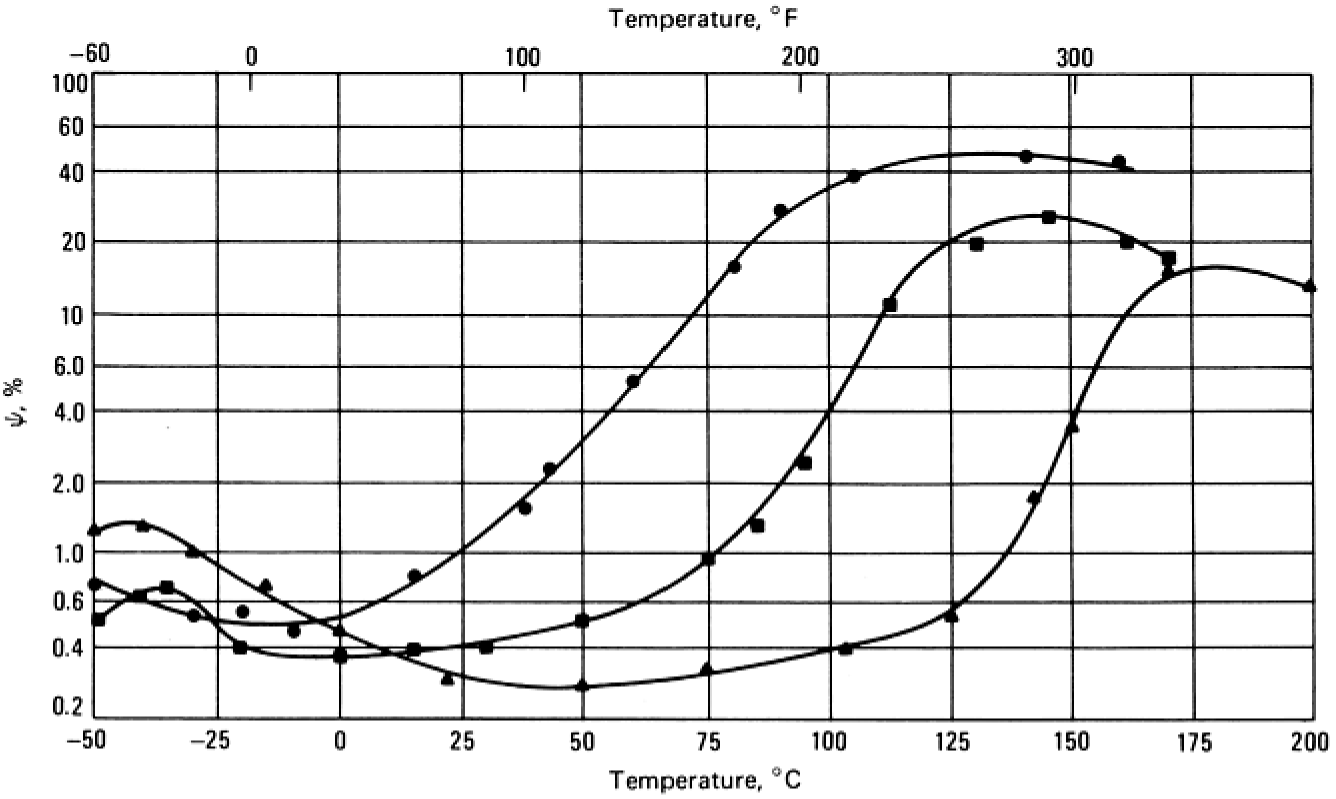

Fig. 23 Variation of specific damping capacity (Ψ) with temperature for 0° unidirectional composite made from Epikote flexibilized resin. V_f= 0.5

Figure 24 shows the combined effect of fiber orientation and temperature on the flexural damping of a series of beams cut at various angles from a unidirectional plate (type II carbon fibers in DX209 epoxy resin). The damping results of specimens with angles of 0° to 40° are presented in Fig. 24; specimens from 50° to 70° (not shown) showed very little difference in behavior. The frequency of vibration used in measuring the glass transition temperature varied from 324 Hz for the 0° specimen to 120 Hz for the 40° specimen. There was a reduction of the peak temperature of about 10 °C over the range of fiber angles of 0° to 20°.

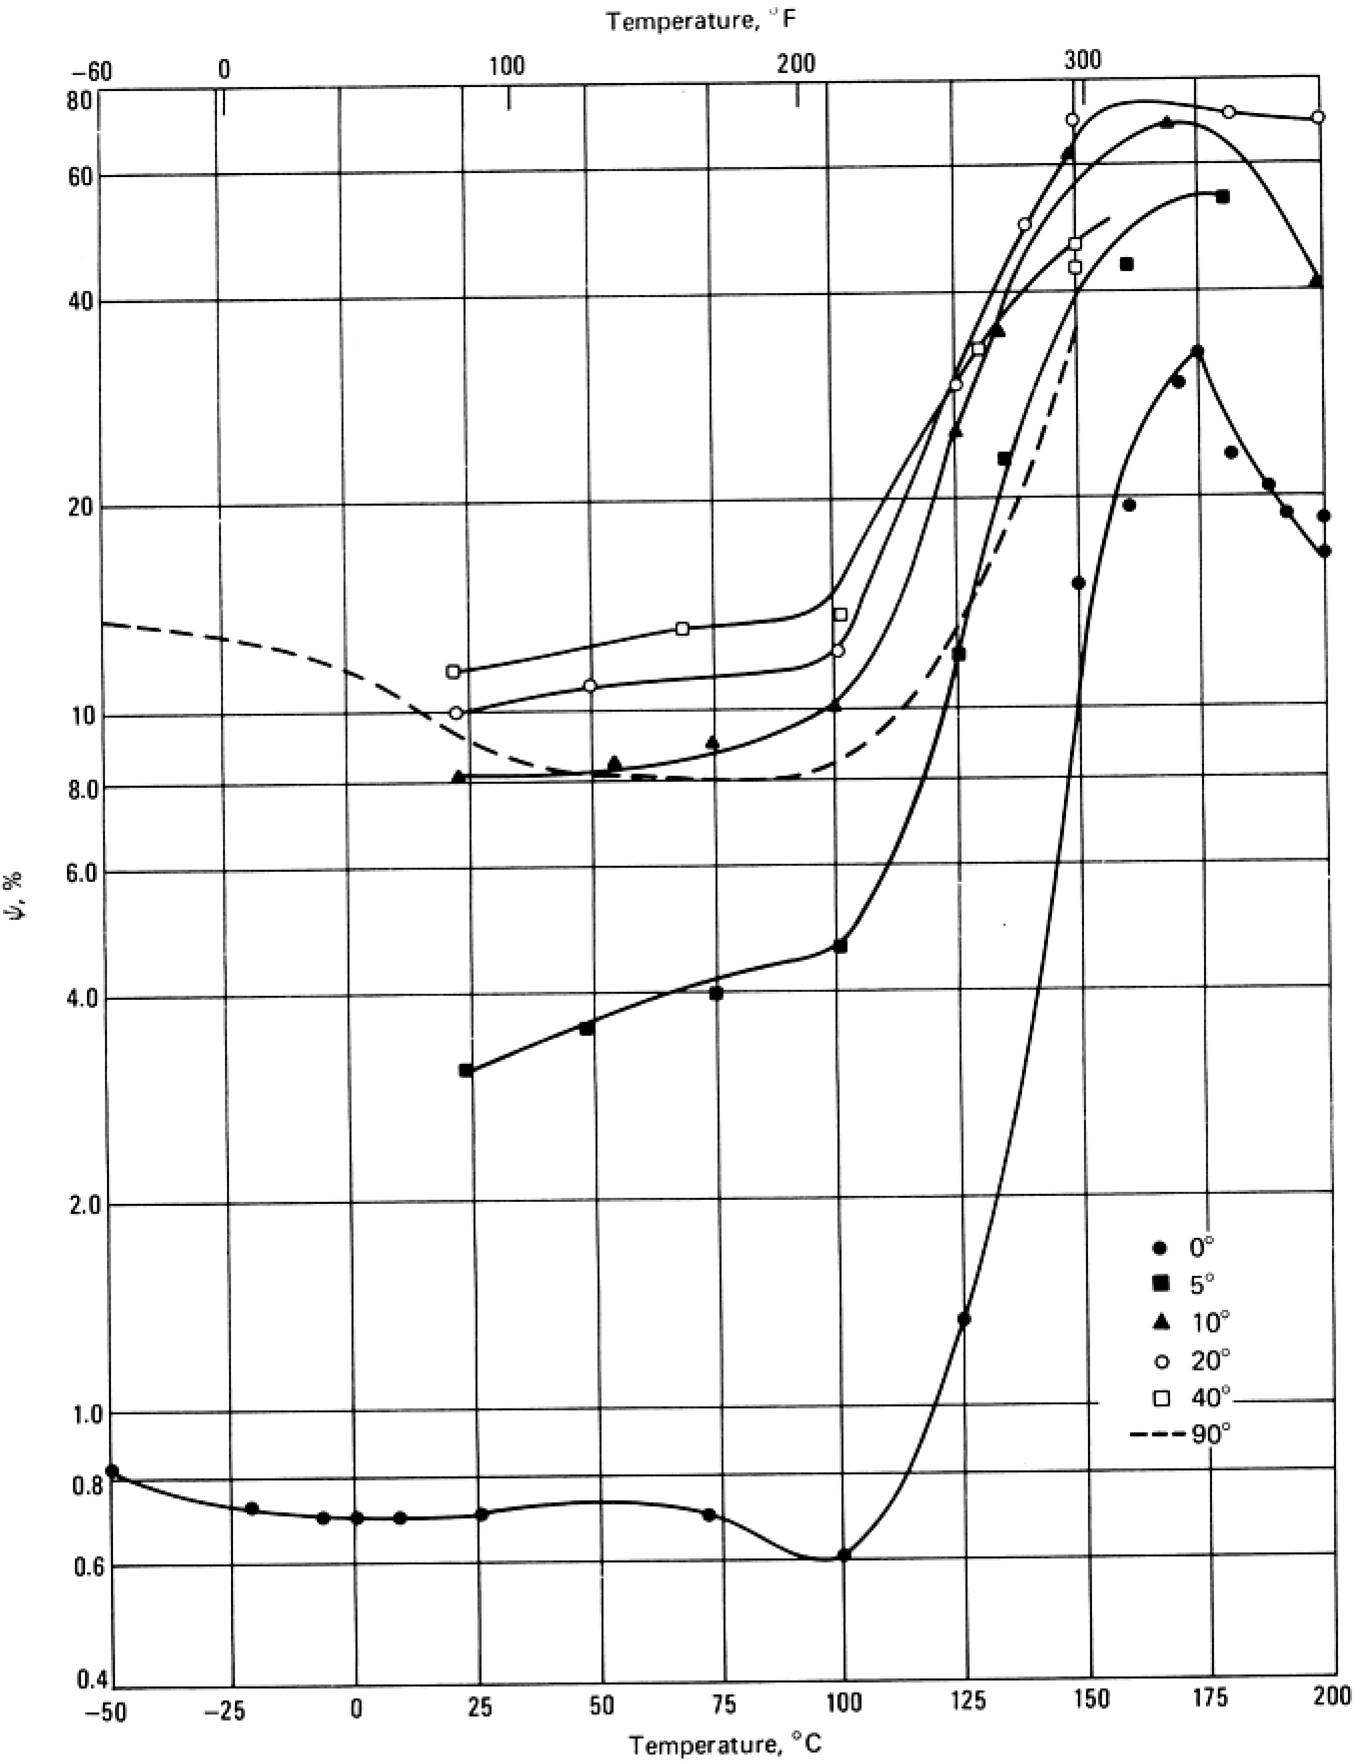

Fig. 24 The effect of fiber orientation on the variation of specific damping capacity (Ψ) with temperature for high- modulus carbon fibers in DX209 epoxy resin. V_f= 0.5

The damping properties near the relaxation peaks for a range of frequencies are given for ±10° and ±20° specimens (Fig. 25). In both cases, there is a reduction of the damping peak with increase of frequency. A

comparison of traces with approximately the same frequency at the peak (that is, 249 Hz, ±10° and 235 Hz, ±20°), showed that the damping was almost identical, at about 53% SDC, but that the peak temperature for the ±20° specimen was nearly 20 °C (36 °F) below that of the ±10° specimen. The contribution of shear damping for the ±20° specimen is much larger than is that for the ±10° specimen (Fig. 11), and the longitudinal tensile component is almost negligible. However, due to the fairly high flexural modulus of the ±10° specimen, *E*±10, and its relatively low torsion modulus, *G*±10, there will be shear deformation in flexure. The difference between the two types of shears is one of direction; the flexural shear is denoted by σ_{zx} where z is perpendicular to the plane of the laminate, and the shear that is due to the fiber angle is denoted by σ_{xy}. For 0° specimens, σ_{zx} and σ_{xy} lie in the plane of symmetry, and the effect will be identical, but for more complex laminates involving adjacent laminae at different angles, the result is not as obvious.

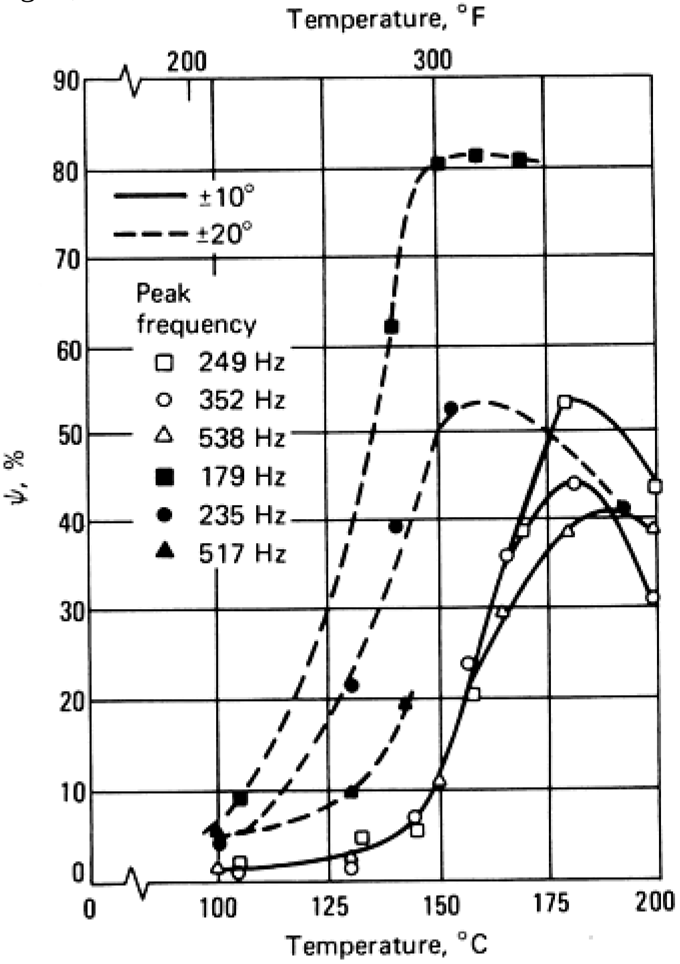

Fig. 25 Variation of specific damping capacity (Ψ) with temperature for ±10° and ±20° angle-plies made from high-modulus carbon fibers in DX209 epoxy resin. V_f= 0.5

The effect of temperature on flexural modulus depends to a large extent on the lay-up; where the fiber angle is near 0°, there is only a small reduction at high temperatures, but at larger fiber angles (20 to 90°), the modulus can decrease by more than an order of magnitude.

Relationship Between Damping and Strength

If improving damping properties of a laminate at no detriment to its mechanical properties is an objective, it is interesting to examine the differences between ±15° angle plies and 0°/90° cross plies. In flexure, the strengths and moduli are almost identical for the range of fibers, whereas the damping of the angle plies is double that of

the cross plies. In torsion, the shear moduli of angle plies are largely dependent on the fiber modulus and are much larger than the cross-ply shear moduli, the values of which are nominally independent of fiber modulus. The damping of angle plies is, in this latter case, less than half that of the cross plies.

Thus, different lamination geometries and fiber moduli can be arranged to give some common properties between laminates while having very different properties in other modes. In design, this gives greater flexibility to cater for strength and stiffness in one direction, with optional properties in others, according to requirements, than can possibly be achieved with isotropic materials. The damping properties of laminates can now be added to these design parameters (Ref 17).

Composites Versus Metals

To put the damping of composites in context, a comparison should be made with the damping of metals. Figure 26 shows the variation of damping with cyclic stress amplitude for a range of common structural metals. The metallic specimens were tested in axial vibration (tension/ compression) using the apparatus described by R.D. Adams and A.L Percival (Ref 18); more details of the results are given in Ref 19 and 20. Composites provide slightly higher damping than steels, but significantly less than conventional high-damping alloys. On the other hand, low-weight high-strength alloys such as aluminum and titanium give extremely low damping; values of less than 0.01% SDC have been reported (Ref 21).

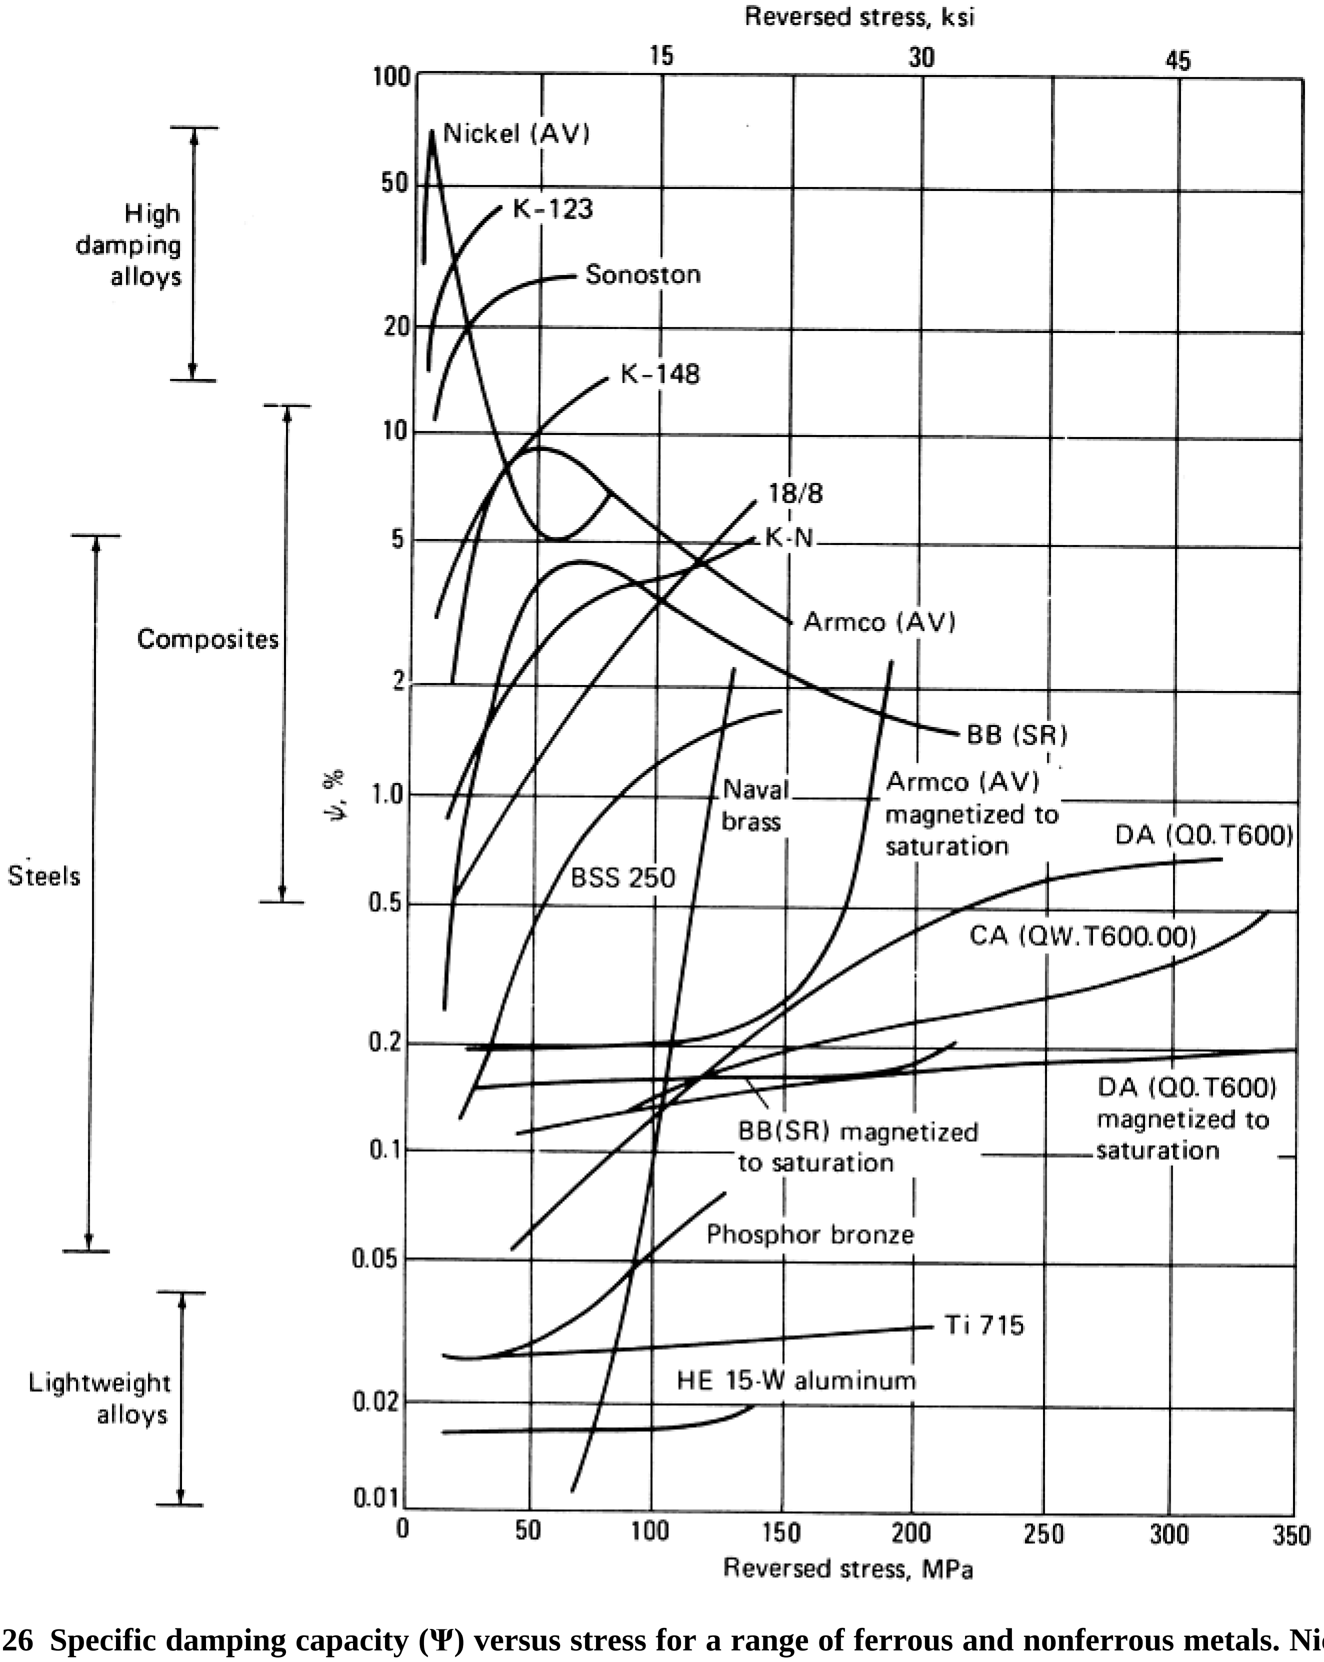

Fig. 26 Specific damping capacity (Ψ) versus stress for a range of ferrous and nonferrous metals. Nickel (AV), annealed in vacuum. K-123, K-148, K-N, grades of cast iron. 18/8, stainless steel. Bolted and Bonded Joints

L.J. Hart-Smith, The Boeing Company

Introduction

THE STRUCTURAL EFFICIENCY of a composite structure is established, with very few exceptions, by its joints, not by its basic structure. Joints can be manufacturing splices planned at predetermined locations in the structure or unplanned repairs that could be needed anywhere in the structure. Consequently, unless a specific application needs no provision for repairs or uses throw-away unrepairable components, the correct sequence for design is to first locate and size the joints, in fiber patterns optimized for that task, and then fill in the gaps (the basic structure) in between.

This sequence is a marked departure from normal practice for conventional ductile metal alloys and is necessitated by the relative brittleness of fiber-reinforced composites. Yielding of ductile metals usually reduces the stress concentrations around bolt holes so that there is only a loss of area, with no stress concentration at ultimate load on the remaining (net) section at the joints. With composites, however, there is no relief at all from the elastic stress concentration if the holes or cutouts are large enough. Even for small holes in composite structures, the stress- concentration relief is far from complete, although the local disbonding (between the fibers and resin matrix and local intraply and interply splitting close to the hole edge) does locally alleviate the most severe stress concentrations.

The reason for emphasizing the importance of joints in the design of composite structures is that the availability of large computer optimization programs and the highly deficient treatment of residual thermal stresses within the resin in most of the composite laminate theories have combined to create the illusion that optimized composite structures will necessarily be highly orthotropic and tailored precisely to match the load conditions and stiffness requirements. (There are no terms in most theories to allow for separate residual thermal stresses in the fibers or matrix of the monolayer, which serves as the building block for cross-plied laminate theories. The omission is due to the artificial homogenization of distinctly two-phase composite materials into mathematically simpler one-phase models. Fortunately, there is finally one mechanistic theory—see the article “Characterizing Strength From a Structural Design Perspective” in this Volume and Ref 1 and 2—in which there is a proper distinction between the fiber and resin constituents in fiber-polymer composites. Separate characterization of each failure mechanism in each constituent has shown that only a few true materials properties are needed to explain what appear to be many different loading conditions at the laminate and lamina level. The progressively more widespread use of this approach will lead to far less reliance on empiricism and costly testing than has been necessary in the past.)

If composite structures were highly orthotropic and precisely tailored, the task of designing joints in composites would be much more difficult than it is now. The capability of bolted joints in such highly orthotropic materials is often unacceptably low. Hence, the laminate can never be loaded to the levels suggested by lamination theory for unnotched laminates.

Fortunately, or unfortunately, depending on one’s point of view, the strength of composite structures with both loaded and unloaded holes depends only slightly on the fiber pattern (for nearly quasi-isotropic laminates); the stress-concentration factor increases almost as rapidly as the unnotched strength for slightly orthotropic patterns. Indeed, throughout the range of fiber patterns surrounding the quasi-isotropic lay-up, the bearing strengths and gross-section strengths are almost constant, which simplifies the design process considerably. A valid case can often be made for a small amount of orthotropy, within the shaded area in Fig. 1, particularly when there is a preferred load direction or stiffness requirement that must be met. The farther a laminate pattern is outside the shaded area, the more likely it is to fail prematurely by through-the-thickness cracks parallel to the maximum concentration of fibers.

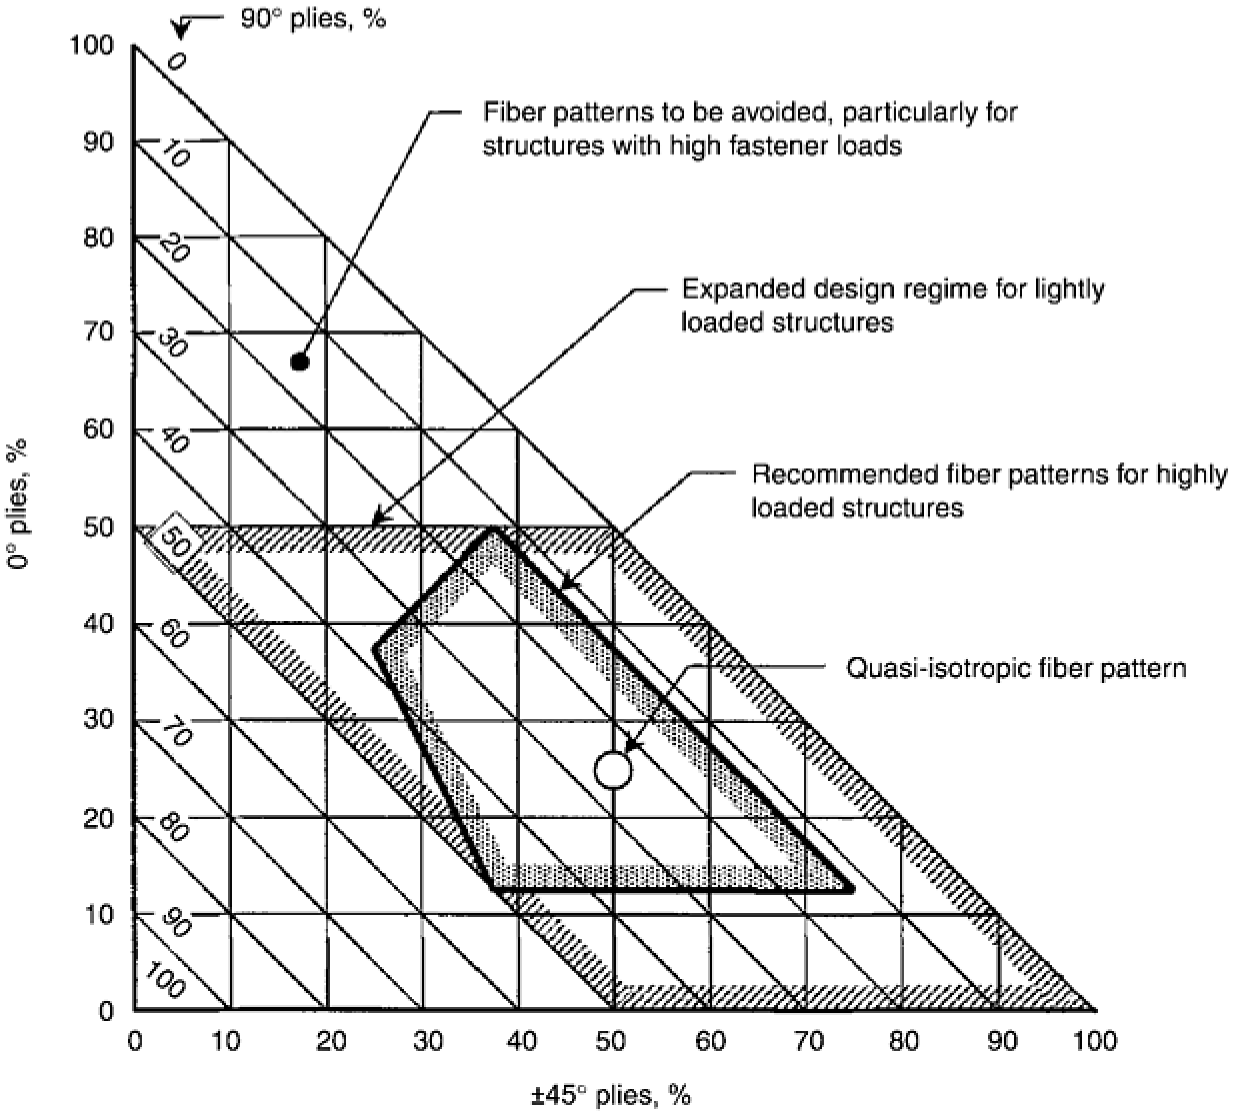

Fig. 1 Selection of lay-up pattern for fiber-reinforced composite laminates. All fibers in 0°, +45°, 90°, or–45° direction. Note: lightly loaded minimum gage structures tend to encompass a greater range of fiber patterns than indicated, because of the unavailability of thinner plies.

Even for those few truly non-strength-critical uses of highly orthotropic fiber patterns, such as space structures with zero coefficient of thermal expansion and one-shot missiles, there must be a transition to nearly quasi-isotropic patterns around any bolt holes; the structural efficiency of bolted joints in highly orthotropic laminates is known to be inadequate. Therefore, the material presented here is applicable to all sensible composite structures, although it deliberately excludes mechanical joints in highly orthotropic materials. If joints were assessed in terms of an efficiency comparing the strength of the joint with the strength of the same unnotched laminate, far stronger composite structures would be designed than have been when this consideration has been overlooked. As is explained later, it is extremely difficult to attain a 50% joint efficiency (even with multirow bolted joints); even an efficiency of 40% in a single-row joint requires the use of the most appropriate pitch-to-diameter (*w*/*d*) ratio. Attention is confined to uniaxial membrane loading, because most of the relevant test data on bolted joints are similarly restricted, and because the analysis methods for off-axis loading and applied bending moments are still being developed.

The design of joints in nearly quasi-isotropic composites is straightforward, once the notion of joint efficiency as a function of geometry is accepted, although it is also necessary to allow for nonlinearities in the material behavior; linearly elastic analyses are far too conservative. The analysis of adhesively bonded joints using elastic-plastic adhesive models has advanced to the stage at which it can legitimately be called a science. The design of straightforward bonded joints has been reduced to following a few procedures and obeying a few simple design refinements to prevent premature failures due to induced peel loads. The design and analysis of the more complex stepped-lap bonded joints needed for much thicker and more highly loaded bonded structures

is facilitated by the use of digital computer programs based on nonlinear continuum- mechanics solutions. Even the determination of the design load level for bonded joints is easy, regardless of the nominal applied loads. In no case should the strength of the joint be allowed to fall below that of the surrounding structure; otherwise, the bonded joint would have no damage tolerance and could act as a weak-link fuse. Fortunately, with the strong ductile adhesives typically used by the aerospace industry, the bond is inevitably stronger than the adherends for properly designed joints between thin members. Even for thicker structures, the bond can always be made stronger than the structure by using enough steps in the joint. It has been recognized that it is also necessary to prevent the accumulation of irreversible damage in the adhesive layer by using a sufficiently complex joint geometry to ensure that the application of design limit load does not exceed the linear elastic capability of the adhesive. Recent progress in the prediction of bonded joint strength and resistance to delamination in composite laminates includes the ability to include both shear and peel loads, as well as residual thermal stresses from curing at high temperatures, in the failure criteria (see Ref 2).

The design and analysis of bolted or riveted joints in fibrous composites, however, remains very much an art, because of the need to rely on empirical correction factors in some form or other. Mechanically fastened joints differ from bonded composite joints in one further aspect: the presence of holes ensures that the joint strength can never exceed the local laminate strength. Indeed, after years of research and development, it appears that only the most carefully designed bolted composite joints will be even half as strong as the basic laminate. The simpler bolted joint configurations will attain no more than a third of the laminate strength. However, because the adhesively bonded repair of thick composite laminates is often impossible or impractical (Ref 3), there is a real need for bolted composite structures quite apart from the greater ease of assembly at mechanically fastened manufacturing breaks between subassemblies. A further problem with the design of bolted composite structural joints is that fibrous composites are so brittle that there is virtually no capability for redistributing load, as is afforded by yielding of ductile metals. Consequently, it is very important to calculate accurately the load sharing between fasteners and to identify the most critically loaded one. There is a common misconception that one should always strive for the benign failures associated with bearing-critical bolted joints, because tension-through-the-holes failures are so abrupt. What is not widely appreciated is that the latter failure modes are also associated with far higher bolted composite joint strengths. Also, it is all but impossible to design a multirow bolted joint that *will* fail by bearing.

(The preference for bearing-critical joints also extends to mechanically fastened joints in metallic structures at some aircraft factories. While this might be attainable for virgin structures, the higher bearing stress needed to reduce the net- section stresses inevitably results in the earlier initiation of fatigue cracks at the fastener holes. In the presence of such cracks, late in the life of structures, failure by tension through the reduced net section will undercut any bearing failures, thwarting the original design approach. The point is that specific failure modes are associated with different joint strengths and lives, and that these associations need to be acknowledged when selecting joint geometries.)

Obviously, one can avoid the strength limitations of bolted or riveted composite joints by using such techniques as local pad-ups to thicken chordwise bolt seams on wing skins, for example, and glass softening strips in the skins over the spar caps. However, such an approach precludes the possibility of making repairs with mechanical fasteners throughout the remaining unprotected structure, unless one is prepared to accept a substantial reduction in strength.

This article starts with a discussion of adhesively bonded joints, covering the keys to durability, the elastic-plastic mathematical model for the adhesive in shear, the simple design rules for thin bonded structures, the computer programs for the more highly loaded stepped-lap joints, and the two-dimensional effects associated with load redistribution around flaws and with damage tolerance. Additional information is available in the article “Secondary Adhesive Bonding of Polymer-Matrix Composites” in this Volume.

Mechanically fastened joints are then discussed, starting with the elastic-isotropic geometric stress-concentration factors, the empirically established correlation factors to convert these elastic values to those observed in the composites at failure, the identification of optimal joint proportions for single-row joints, and the design and analysis of the stronger multirow joints, with particular regard to the bearing-bypass interaction. Additional information is available in the article “Mechanical Fastener Selection” in this Volume and in Ref 4 and 5.

Bolted and Bonded Joints

L.J. Hart-Smith, The Boeing Company

Fundamentals of Shear Load Transfer through Adhesively Bonded Joints

Adhesively bonded joints can be strong in shear but are inevitably weak in peel, so the objective of good design practice is to arrange the joint to transfer the applied load in shear and to minimize any direct or induced peel stresses. The details of the design vary with the load intensity (and, hence, the thickness of the adherends), as shown in Fig. 2. The thinner members can be joined effectively by simple, uniformly thick overlaps, while thicker members require the more complex stepped-lap joints.

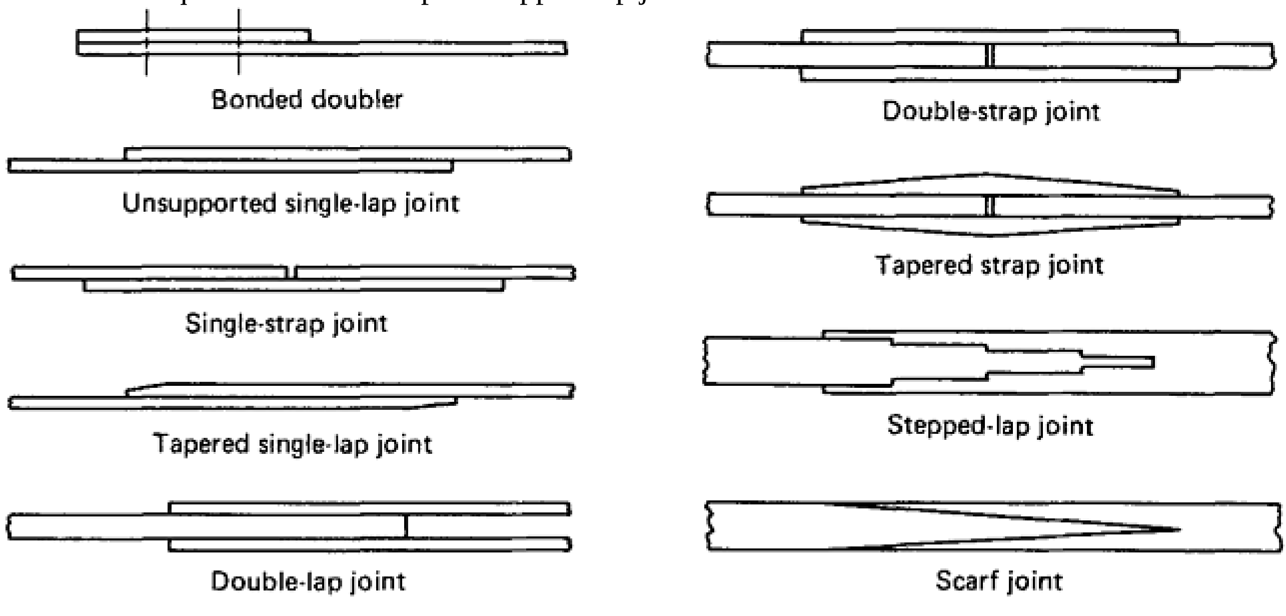

Fig. 2 Adhesively bonded joint types

For each of the joints shown in Fig. 2, the potential shear strength of the bond—that is, the strength that the bond could have developed had the adherends not failed first—exceeds the direct strength of the adherends outside the joint, up to a determinable thickness. This characteristic is shown in Fig. 3, which also shows the loss of bond strength that is sometimes associated with flaws in or damage to the bond. Even with such degradation, the bond will be stronger than the members outside the joint, up to some lesser adherend thickness.

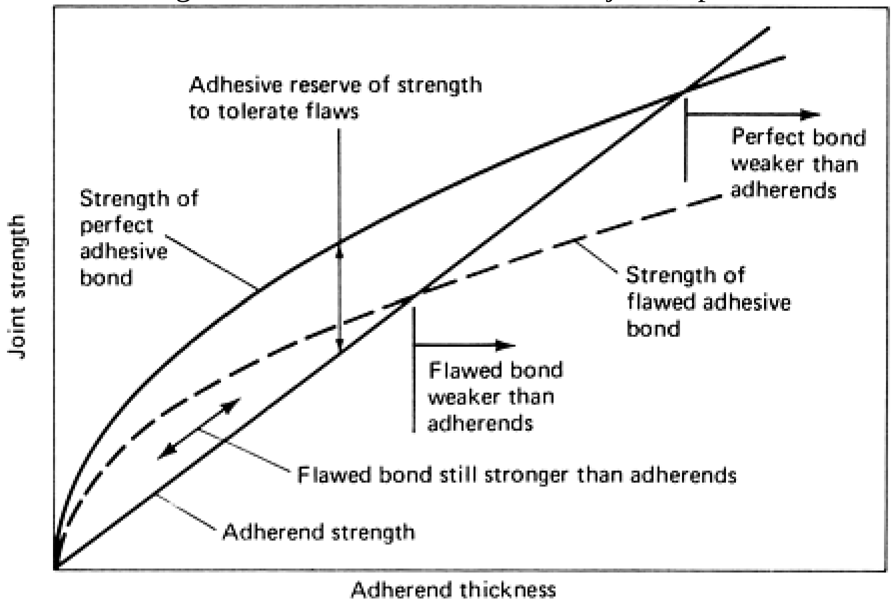

Fig. 3 Relative strength of adhesive and adherends, as affected by bond flaws. τ_p is the maximum shear stress, σ_∞ is the remote skin stress.

The key point of Fig. 3 is that for adherend thicknesses greater than that for which the bond and member strengths are equal, there can be absolutely no tolerance with respect to flaws, porosity, or damage. The slightest imperfection would lead to catastrophic unzipping of the entire bond area if sufficient load were applied. That is why it is so important that bonded joint strengths *must* exceed those of the adherends, even to the point of exceeding the strength by at least 50% to permit the occurrence of minor manufacturing flaws or imperfections. Subject to that proviso, bonded joints between thin members have a remarkable insensitivity to very large local flaws, as explained in Ref 6. In this context, the term “thin” is adjusted to suit the complexity of the joint and refers to those sensible designs for which the nominally perfect bond is stronger than the members being joined. Such a design philosophy for bonded joints should always be followed, even when the nominal applied loads are less than the strength of the members. Otherwise, there will always be the possibility of a local flaw that is large enough to convert the nominally perfect bond into a weak-link fuse. A flaw in an underdesigned joint shares the characteristics of a through crack in a metal sheet, as shown in Fig. 4, except that it is much harder to find. Figure 4 refers equally to metal and composite structures, except that, for the latter, load redistribution around the bond flaw may also cause delaminations in the composite panel or possibly result in the unzipping of the bond.

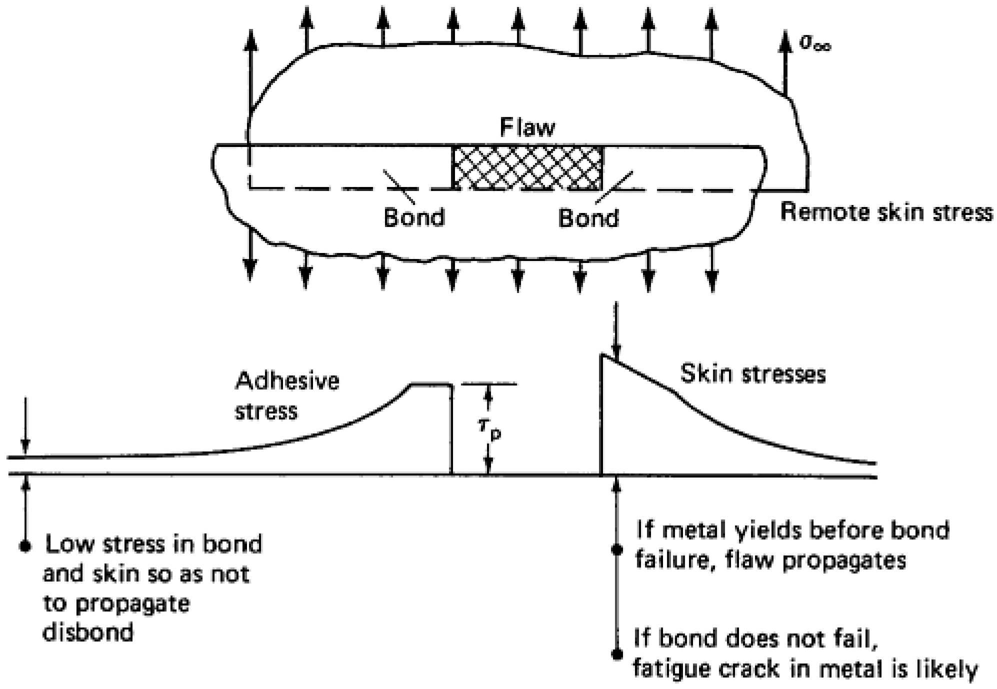

Fig. 4 Redistribution of load at flaws in bond

Adhesive bonds must also be resistant to the environment in which they operate, which is typically thermal or chemical. This need has been demonstrated in the many in-service failures of secondary and, in at least two cases, primary bonded metal structures on U.S. aircraft made during the late 1960s and early 1970s. Those failures were not caused by poor design detailing; indeed, the most recent adhesives failures known to the author that were due to mechanical overloading of bonded aircraft structures occurred over half a century ago on glued wooden aircraft. There were also some structural failures on some wooden aircraft in the tropics during World War II, due to a poor choice of glue, which was very sensitive to moisture. However, those joints were properly proportioned, and even the glue worked adequately in Europe.

Bonded joint failures in metal structures have occurred when the absorption of moisture by some adhesives on the surface of the adherends hydrolyzed and subsequently corroded the oxide surface of clad aluminum alloys. This subject was explored in depth during the U.S. Air Force Primary Adhesively Bonded Structure Technology (PABST) program (7, 8 9). It is now well known that aluminum alloys must be anodized, in phosphoric or chromic acid, to create a stable, durable oxide surface, and that the surface must be promptly coated with a corrosion-inhibiting primer, usually BR-127 or Redux liquid. Using clad 7075 aluminum alloys should be avoided. Similarly, titanium alloys and steels need appropriate surface preparations for reliable adhesive bonding, as do steels.

Somewhat surprisingly, the need for comparable attention to the preparation of fibrous composite surfaces for adhesive bonding has not received nearly as much publicity. The widespread use of inferior preparations, such as removing no more than a peel ply, or scuff sanding followed by solvent contamination, remains the norm. R.J. Schliekelmann, a pioneer of adhesive bonding of metal structures, has warned of the importance of this issue to composites (Ref 10). L.J. Hart- Smith et al. have strongly recommended light grit blasting as the best known treatment today (Ref 11). This view is shared by A.N. Pocius (Ref 12), who has also advocated mechanical abrasion with Scotch-Brite pads (3M Corporation). Promising work has also been done on composite surface preparation by so-called flash blasting, but no production applications are known yet.

Surprisingly, only the quality-control tests for adhesive bonding of *metallic* structures include both lap-shear tests to confirm the completeness of the cure process for the adhesive *and* wedge- crack (or other peel test) to confirm the *durability* of the joints, under a hostile (hot/wet) environment to accelerate the test. Specification for the manufacture of bonded *composite* structures includes only short-term strength tests and omits any requirements to confirm the durability of such bonds. The need for such additional tests is evident from service experience and is associated with two known phenomena. One is the transfer of release agents from peel plies (see Ref 13); the other is prebond moisture not removed by drying prior to bonding (see Ref 14 and 15). There is as great a need for a durability test as part of the quality-control program for bonded composite structures as

there is for bonded metallic structures. Unless this is implemented, no inroads will ever be made on the enormous cost of inspections that can tell *nothing* about how well the adhesive is stuck (only whether or not a gap has opened up between the adherends). These inspections would be rendered unnecessary by assurance that potential interfacial failures between adhesive and adherends had been precluded by proper processing at the time of manufacture.

The subsequent discussion in this article assumes that the durability of the surfaces to be bonded has been ensured by appropriate preparation. Otherwise, just as for metal bonding, no reliable life can be established for adhesively bonded composite structures.

The subject of environmental durability of the adhesive layer itself, rather than of the interface, is much more straightforward and can benefit from the massive amount of testing already done for metal bonding. The adhesive resin can be regarded as a well-behaved engineering material up to some service temperature, which depends on the amount of plasticizing additives as well as on the base resin. That temperature, called the glass transition temperature, can be reduced slightly by the absorption of moisture. Increasing the glass transition temperature for bonding on supersonic aircraft, or near engines, has meant sacrificing most of the adhesive strength at lower temperatures by omitting the modification of the basic epoxy or phenolic resin by rubber, nylon, or vinyl additives. The analysis of adhesively bonded joints requires a nonlinear shear stress- strain curve for all adhesives, ductile or not, because even the brittle adhesives exhibit substantial nonlinear behavior at temperatures approaching their upper service limits. The strongest structural additives are suitable for most of the structure of subsonic aircraft, having an upper limit of about 70 °C (160 °F).

Even a small amount of moisture can be very harmful to bonded composites (Ref 16). Absorbed water in cured laminates must be removed by careful, gentle drying before any bonded repairs are performed. If such moisture is driven off too rapidly, it will delaminate the composite. Conversely, if it is not driven off completely, it will later react adversely with any uncured material (adhesive or resin) in the patch. Likewise, any moisture absorbed by the uncured resin (in a prepreg) or adhesive will prevent the proper curing of the material. Many uncured resins are hygroscopic. It is therefore very important that such materials be properly stored and, subsequently, thoroughly thawed out, so that there is no opportunity for them to absorb the condensate formed when they are removed from the freezer.

Today, rational engineering design of bonded structures is based on the measured adhesive stress-strain relation in shear for a thin layer of adhesive between thick aluminum adherends. Given these stress-strain data for a range of operating temperatures, it is now possible to calculate the actual adhesive stress distributions within the bonded joints, at least in the short term. More work will be needed to characterize the time-dependent changes in internal load distribution under sustained loads. However, the lack of such information does not prevent the satisfactory completion of most designs.

After the surface preparation issue has been resolved, the real key to the durability of adhesively bonded joints is that the minimum adhesive shear stress in a joint needs to be restricted to prevent failure of the joint by creep rupture, every bit as much as the maximum stress needs to be restricted to prevent static failure. This issue is of tremendous importance in interpreting data from test coupons. The prime objective of designing bonded structural joints should be to ensure that the bond will *never* fail, while the objective of designing test coupons is to ensure that the adhesive will *always* fail, at as uniform a stress state as can be established. Unfortunately, therefore, bonded test coupons are, in many ways, totally unrepresentative of the behavior of real structural joints. In particular, a highly nonuniform stress distribution in the adhesive is necessary if a structural joint is to attain an adequate life.

Bolted and Bonded Joints

L.J. Hart-Smith, The Boeing Company

Nonuniformity of Load Transfer through Adhesive Bonds

The classical analysis by O. Volkersen (Ref 17) established in 1938 that the load transfer through adhesive bonds between uniformly thick adherends is not uniform, but peaks at each end of the overlap, as shown in Fig 5. This nonuniformity results from the compatibility of deformations associated with the variation of direct stress, within the adherends, from one end of the bonded overlap to the other.

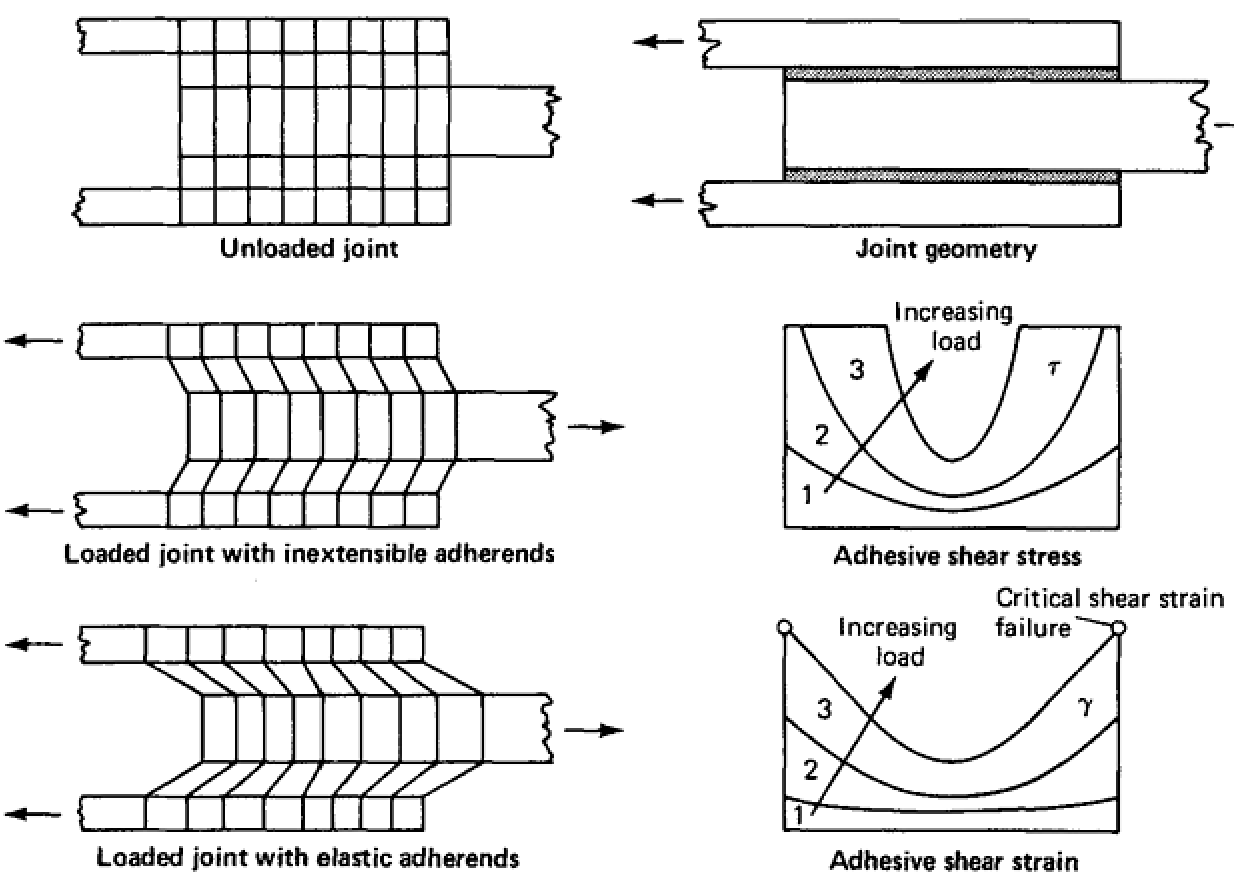

Fig. 5 Shearing of adhesive in balanced joints

A few years later, M. Goland and E. Reissner analyzed the distribution of the peel stresses induced in the adhesive layer by the eccentricity in load path associated with single-lap joints (Ref 18). Many investigators, including the author, have identified deficiencies in this work and derived "better" analyses. However, in a recent reassessment in which he corrected *both* the modeling errors by Goland and Reissner *and* the one he introduced in Ref 19 and 20 in correcting their mistake, L.J. Hart-Smith has shown in Ref 21 that their original analysis is numerically very close to perfection. Mention should also be made of the analyses published by N.A. de Bruyne (Ref 22) that have resulted from his work on Redux and its application in England during and after World War II.

L.J. Hart-Smith has built upon these pioneering investigations and added nonlinear adhesive behavior to the analysis and design of adhesively bonded joints in the form of an elastic-plastic adhesive model (23, 24 25). Also, the A4E series of digital computer programs was developed for joints of various geometries, under contract to National Aeronautics and Space Administration (NASA) Langley and the laboratories at Wright-Patterson Air Force Base. The origins of these programs are given in Ref 26 and 27.

The knowledge imparted by the precise analyses on which Fig. 5 is based makes it possible to understand the differences between the behavior of adhesive bonds in test coupons and structurally configured joints (see Fig. 6). The key difference is that for the short-overlap test coupon, the minimum adhesive shear stress and strain are nearly as high as the maximum values, while for the long-overlap structural joint, the minimum adhesive shear stress and strain can be made as low as desired by using a sufficiently long overlap. Consequently, the short-overlap test coupon is extremely sensitive to failure by creep rupture (which accumulates under both steady and cyclic loads), because there is no mechanism for restoring the adhesive to its original state when the load is removed. While there is creep in the adhesive at the ends of the long overlap, between points *F* and *G*, where the stress (at *J*) is high, there can be none in the middle, between points *D* and *E*, if the stress (at *A*) is low enough. Consequently, the creep that does occur cannot accumulate, because the stiff adherends push the adhesive back to its original position whenever the joint is unloaded. This memory, or anchor, in part of the adhesive is the key to a durable bonded structure. Without it, there can be no successfully bonded structure. Such recovery during unloading does not imply that the adhesive suffers no damage at all when loaded slightly beyond the knee in the stress- strain curve.

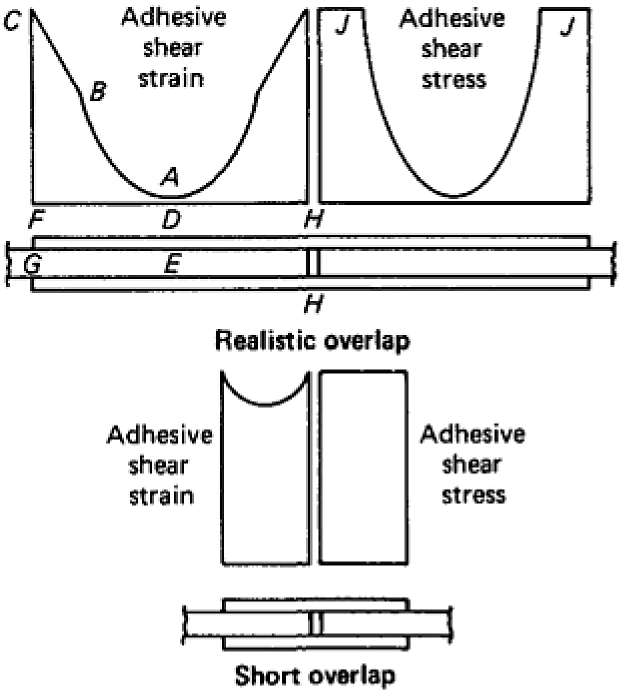

Fig. 6 Nonuniform stresses and strains in bonded joints. See text for discussion.

The question of just how low a minimum stress should be has yet to be resolved scientifically. However, during the PABST program, the minimum was set at 10% of the maximum, and environmental testing on both coupons and complete structures showed no adverse effects, even though premature failures were commonplace with the standard half-inch-overlap test coupons. The influence of minimum stress on the design overlap, for standard double-lap or double-strap bonded joints, is shown in Fig. 7. The width of the elastic trough is adjusted so that the minimum stress is 10% of the maximum. This value is reached when the elastic trough has a total length of $6/\lambda$, where λ is the exponent of the elastic adhesive shear stress distribution. To that elastic overlap, which transfers a fraction $1/\lambda$ of the total applied load, a sufficient plastic zone must be added at each end to bring the total shear strength of the bond up to a level at least equal to the entire strength of the adherends, with the adhesive stressed to its maximum shear strength (for a particular environment). The maximum design overlap is normally associated with the highest service temperature for the bonded joint. (The formula established for the overlap during the PABST program was equal to the sum of the plastic zones sufficient to transfer the *total* load and the length $6/\lambda$ of the elastic trough. This gave no credit for the elastic load transfer. When this is included, the overlap can be reduced slightly to the sum of the lengths of the plastic zones, calculated the same way, and $5/\lambda$.)

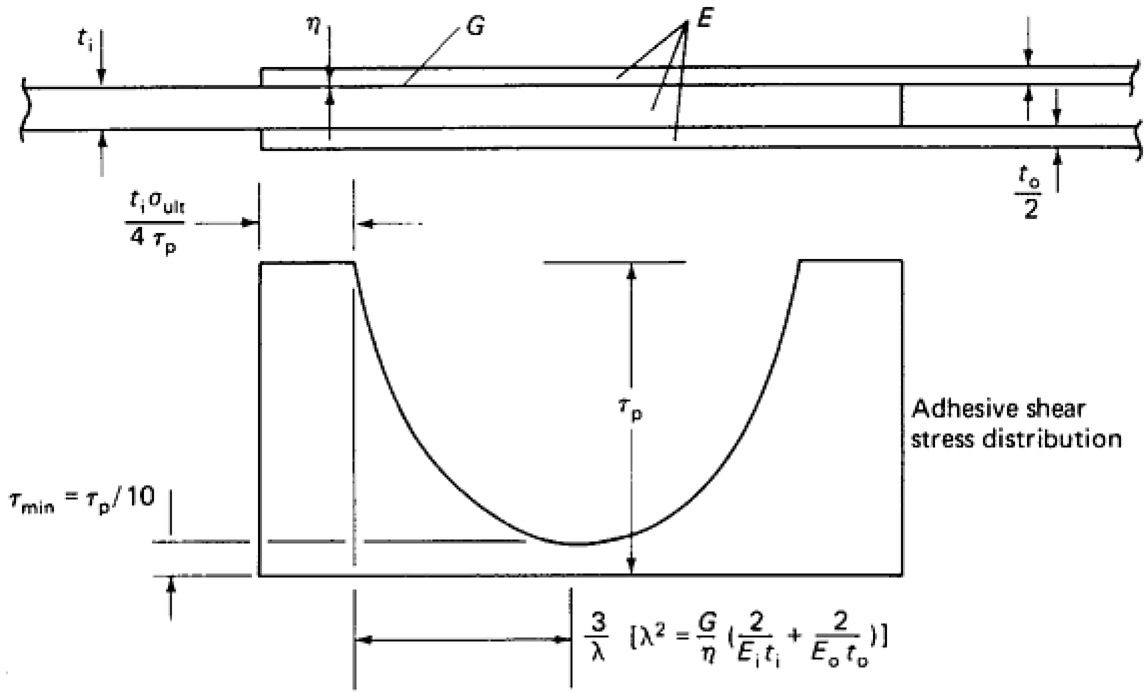

Fig. 7 Design of double-lap bonded joints. Plastic zones must be long enough for ultimate load. Elastic trough must be wide enough to prevent creep at middle. Adequate strength must be verified. *G*, shear modulus; E_i, elastic modulus of the center; E_o, elastic modulus of the outer pieces; η, adhesive thickness.

It was found during the PABST program that, for the thicknesses of aluminum alloy suitable for bonding on subsonic transport aircraft, the overlap could be calculated at approximately 30 times the central adherend thickness in a double- lap joint. In addition, because the modulus of cross-plied carbon/epoxy laminates within the shaded area in Fig. 1 is on the same order of magnitude as for aluminum alloys, a similar overlap-to-thickness ratio would also be satisfactory for such laminates.

Actually, the static strength of bonded joints between uniform adherends is quite insensitive to the precise (long) overlap, as shown in Fig. 8. Any longer overlap beyond point “C” would be superfluous. This insensitivity of the joint strength to the total bonded area is important in recognizing the folly of designing joints with the old notion that the bond strength is equal to the product of the bond area and some fictitious uniform “allowable” shear strength.

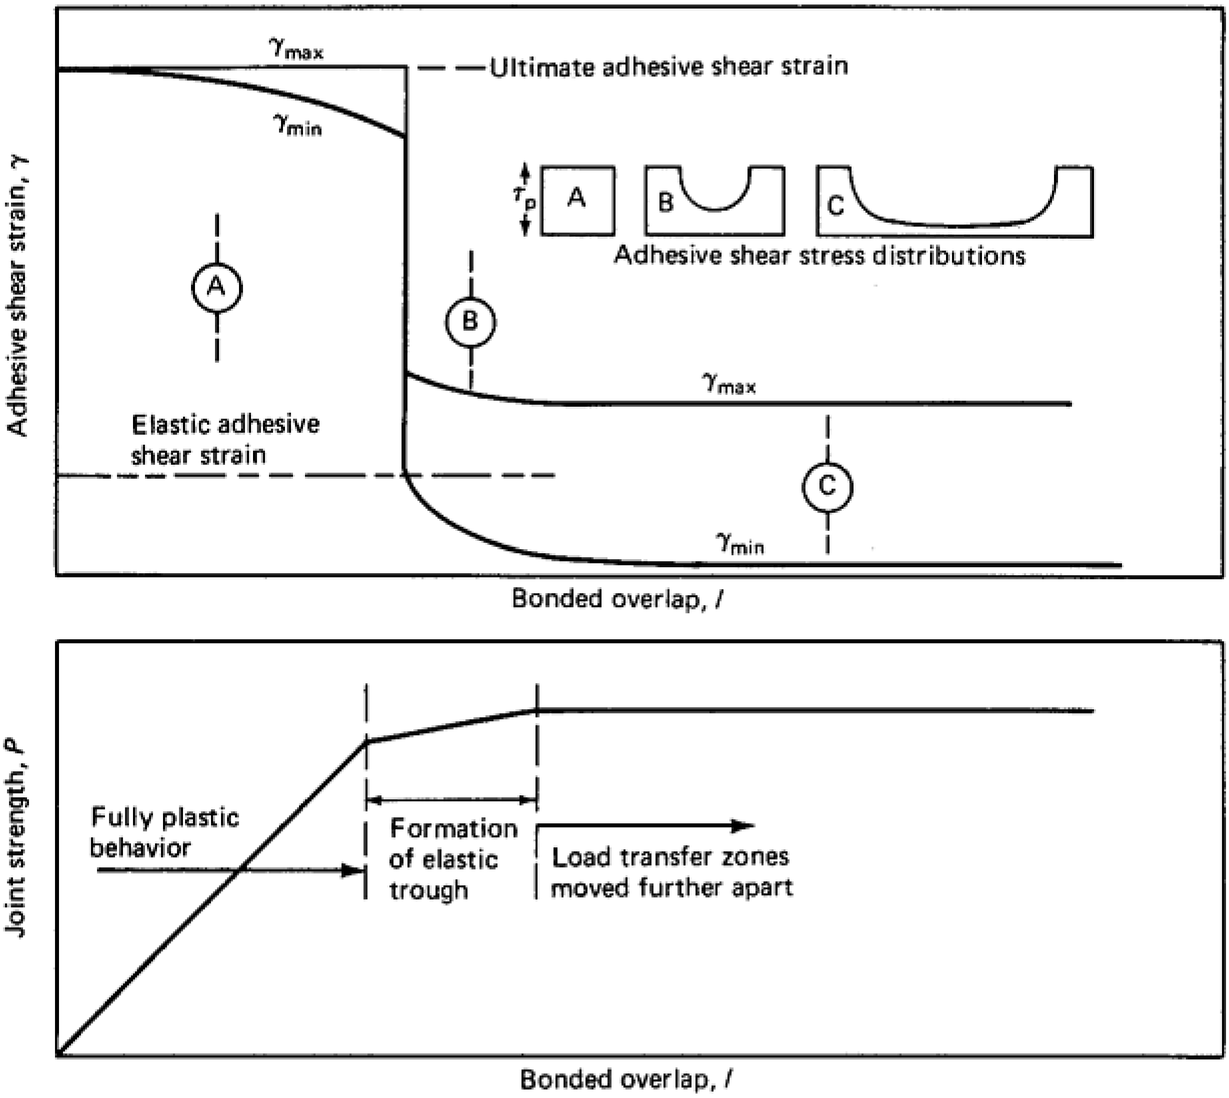

Fig. 8 Influence of overlap, *l*, on maximum and minimum adhesive shear strains in bonded joints

Another important point shown in Fig. 8 is that for all overlaps longer than the abrupt precipice in the upper diagram, the maximum strain in the adhesive is limited by the adherend strength to a value below that which would be needed to fail the adhesive. No such protection is afforded for short overlaps or thick adherends. This issue is explained more fully in Ref 28, where similar diagrams have been prepared for adherends of different thicknesses and adhesive properties appropriate for a range of thermal environments. It is shown there that if the adherends are too thick, the limit on the peak shear strain shown in Fig. 8 is removed. Therefore, a more complex stepped-lap joint is appropriate for adherends thicker than about 3.2 mm ($\frac{1}{8}$in.). Also, it is found that the limiting strength of the joint is usually set by the lowest service temperature, while the design overlap is set by the highest service temperature, at which the adhesive is the softest.

Another consideration in the design of bonded joints concerns the need to restrict the maximum shear strain developed in the adhesive at the ends of the bonded overlap. Once the knee in the stress-strain curve has been exceeded, progressively more fractures (hackles) develop at 45° to the bond surfaces, as the result of the tensile stress associated with the shear deformations. It is therefore appropriate to ensure that the design limit load does not strain the adhesive beyond the knee in the stress-strain curve. Because the shear strength of the bonded joint is proportional to the square root of the adhesive strain energy in shear, a design ultimate load 50% higher than limit load would be associated with an ultimate shear strain almost twice that at the knee, as explained in Fig. 9. The remainder of the stress- strain curve for ductile adhesives would be reserved for damage tolerance and the redistribution of loads around local damage. For brittle adhesives, the limits on joint strength would be established by equating design ultimate load to the end of the stress-strain curve, which would not contain any distinct knee.

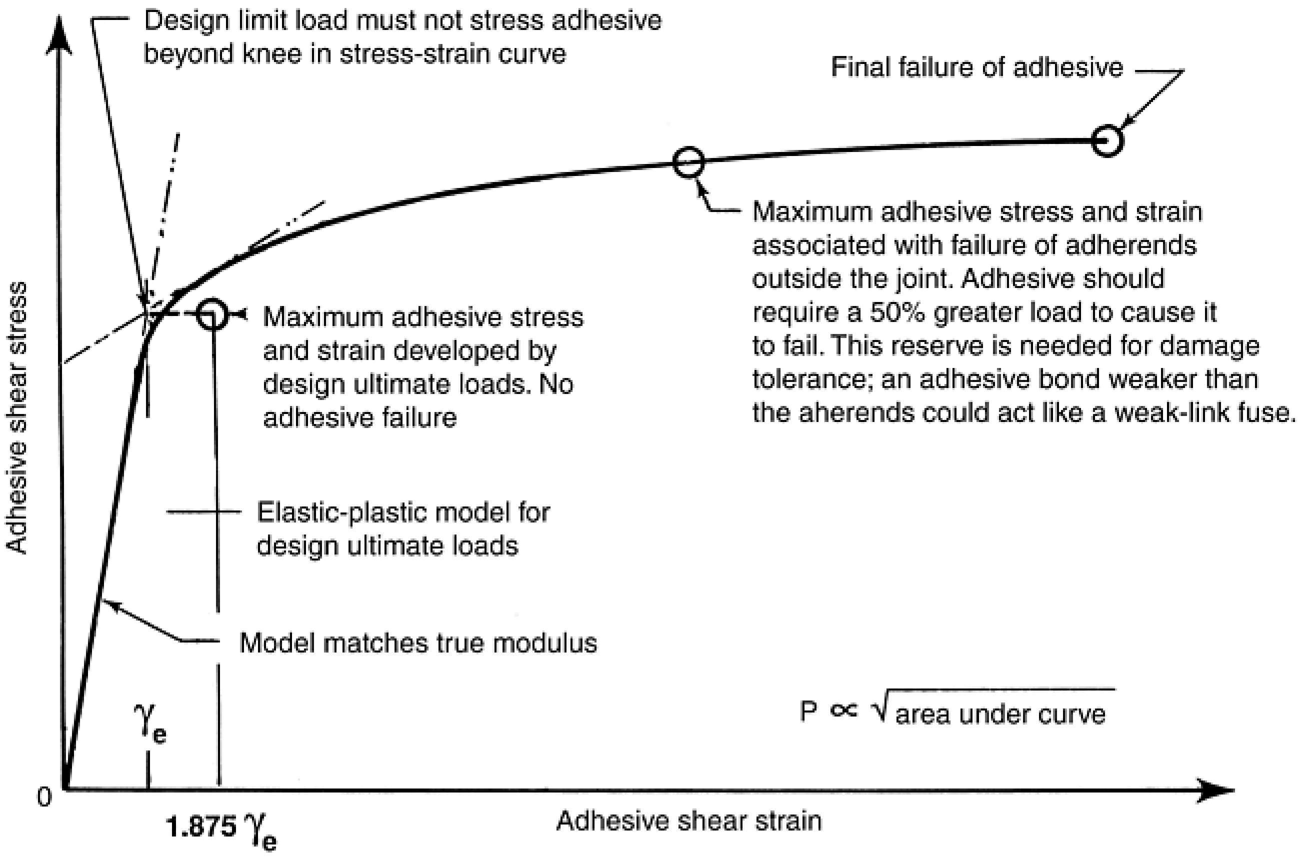

Fig. 9 Modeling of adhesives for design of shear joints. The design process must account for nonlinear adhesive behavior, but a precise stress-strain curve is not mandatory. An approximation, based on a similar adhesive, will usually suffice.

Having established the design overlap for simple bonded joints, the elimination of adverse peel stresses is addressed next. These peel stresses occur for single-lap and single-strap joints having a primary eccentricity in load path and for double-lap and double-strap joints, as shown in Fig. 10, even though there is no obvious eccentricity in the seemingly balanced joints. While some have argued that it is more appropriate to modify the adhesive failure criteria to account for an interaction between shear and peel stresses, the author contends that the presence of any significant peel stresses necessarily detracts from the shear strength of the joint. Therefore, to improve structural efficiency, those peel stresses should be removed from the structure by simple modifications in design detail rather than be included in a more complicated failure criterion. Such a philosophy also simplifies the analyses by separating the tasks of characterizing the adhesive stress components. Nevertheless, the importance of J.H. Gosse's new polymer failure criteria for quantifying the appreciable loss of shear strength inherent in designs in which adhesive layers *are* subject to intense peel stresses (explained in the article "Characterizing Strength from a Structural Design Perspective" in this Volume) cannot be overstated.

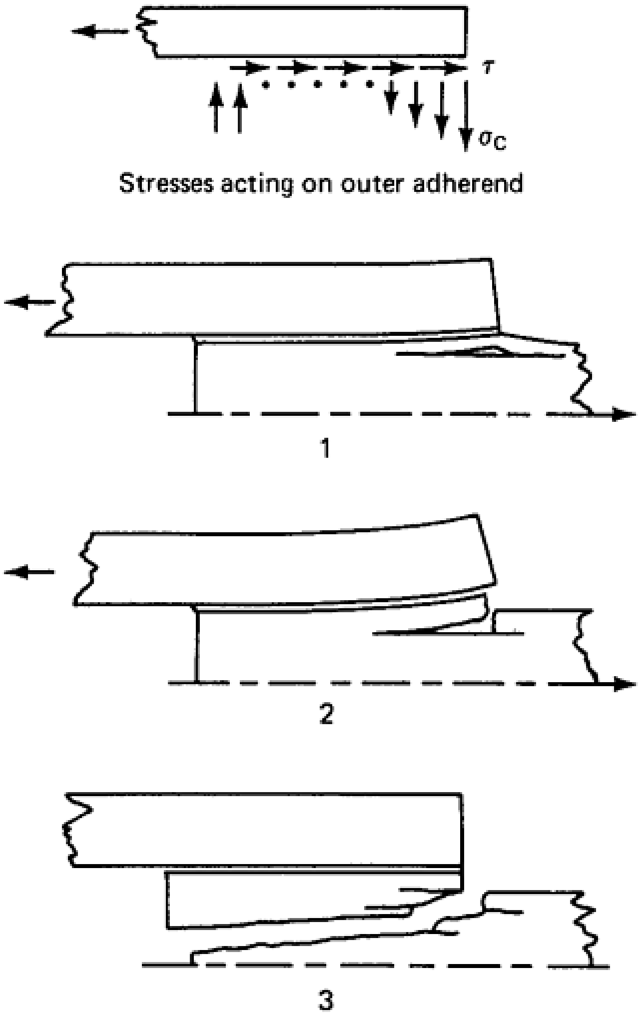

Fig. 10 Peel stress failure of thick composite joints, where 1, 2, and 3 indicate failure sequence

The simple design modifications that reduce the peel stresses to insignificance are shown in Fig. 11. The idea is to make the tips of the adherends thin and flexible so that only negligible peel stresses can develop. Reference 29 discusses the effects of variations in bondline thickness, such as those shown in Fig. 11. The local thickening shown is beneficial, and, as could be expected, any pinch-off would be detrimental. Such local thickening of the adhesive layer must be used with caution with high-flow heat-cured adhesives, lest voids be created by capillary action. Additional adhesive or scrim fillers can be used, if necessary, to avoid any such problems.

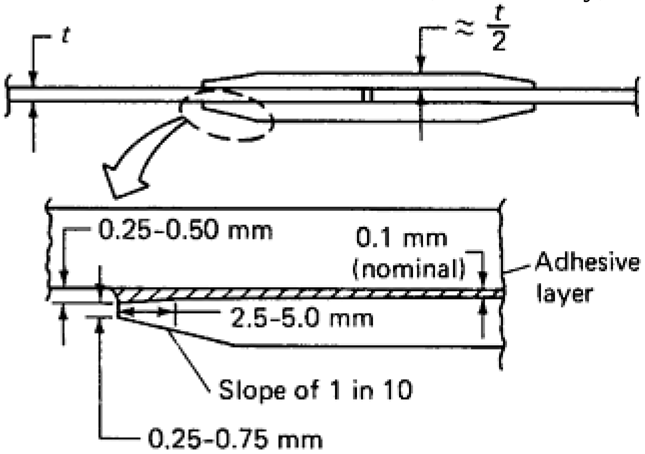

Fig. 11 Tapering of edges of splice plates to relieve adhesive peel stresses (slightly thicker tips permissible for aluminum)

The exact proportions in tapering the adherend or thickening the adhesive layer are not otherwise critical. If the overlap is long enough, it is impossible to overdo the peel-stress relief. This is demonstrated in Fig. 12, which

shows that the joint strength remains constant with varying amounts of tapering, because the *other* end of the joint, where no peel stresses develop, is unchanged. The precise distribution of the shear stress transfer at the tapered end is modified, but the integral of those shear stresses is not. This insensitivity can also be deduced from the comparison of bonded joints and bonded doublers in Fig. 13. Compatibility of deformations for long overlaps requires that there be uniform strain at the middle of the joint, and that consequently, for stiffness-balanced joints as shown, half the load must be transferred at each end of the joint, even if the ends are not identical. For long-overlap bonded joints, it is fair to say that the adhesive at one end of the joint is unaware of the presence or absence of the other end of the joint. In other words, the adhesive stresses around the edges of bonded splices are the same as those around the periphery of wide-area doublers.

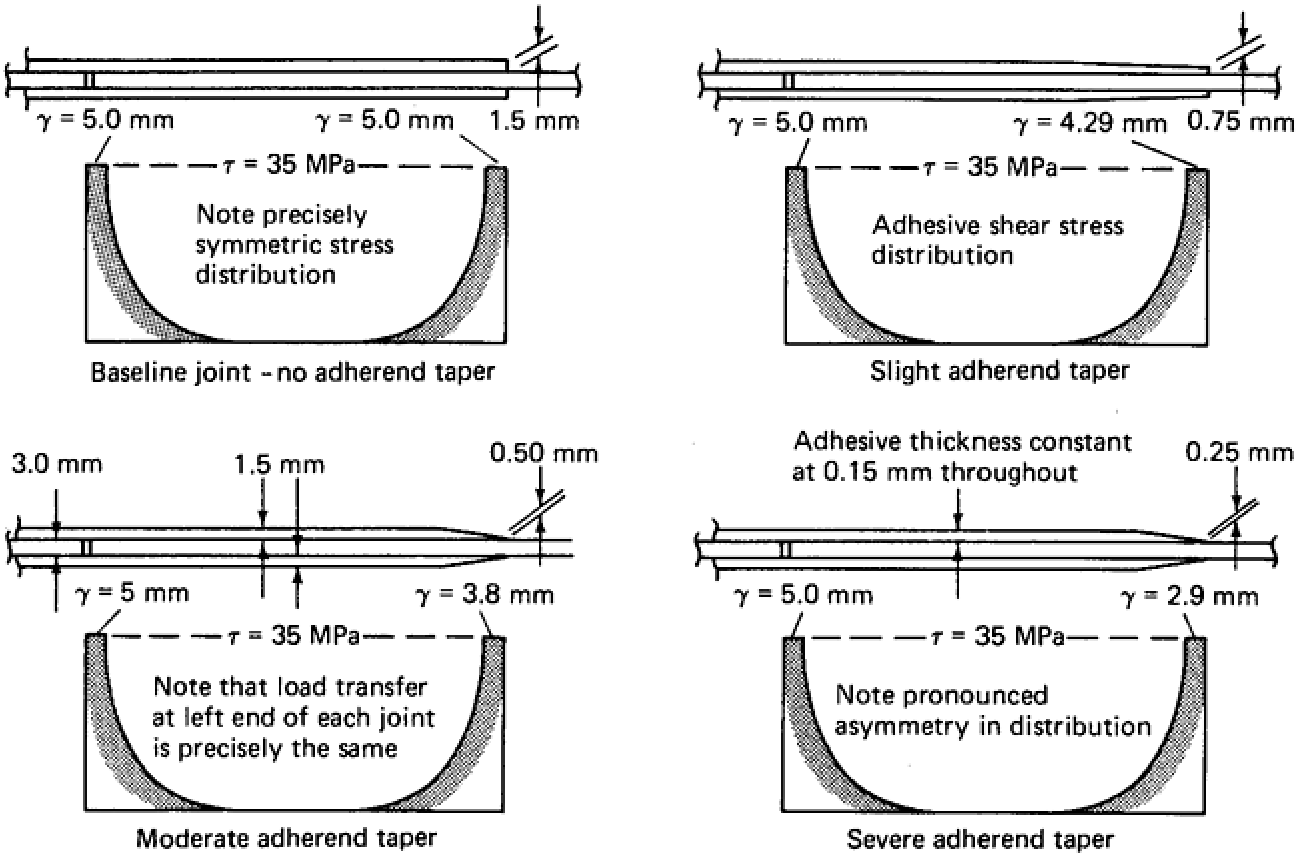

Fig. 12 Insensitivity of adhesively bonded joint strength to modifications at one end of joint only. Adhesive strain at right end of joint decreases with more taper.

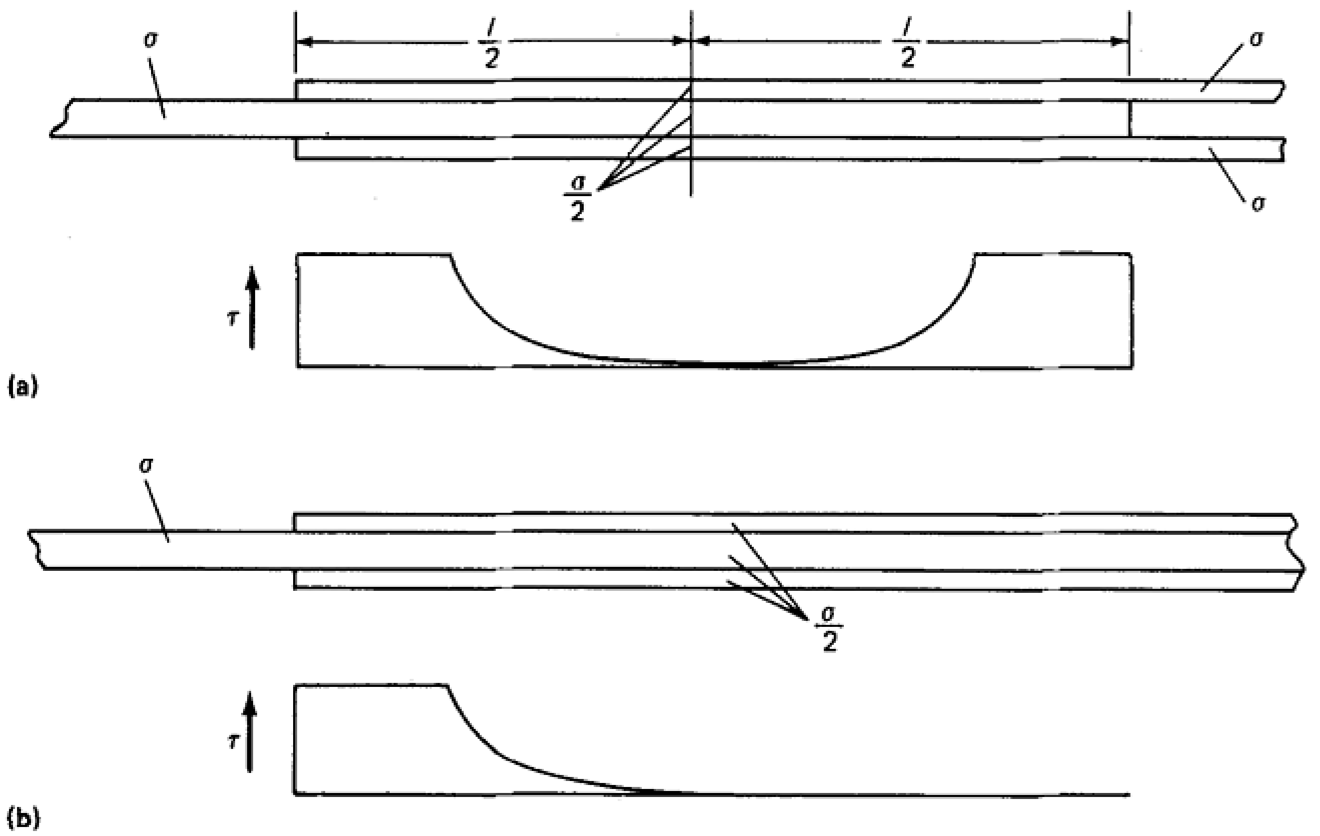

Fig. 13 Similarity of bonded stresses in joints and doublers. (a) Same adhesive stresses in each case. (b) Same maximum adhesive shear strain for same adherend and metal stresses

Elastic-Plastic Adhesive Shear Model

The linearly elastic analysis of bonded joints has been found to be far too conservative for the strong ductile adhesives used on subsonic transport aircraft. Of the possible nonlinear models that could have been proposed to characterize the actual adhesive behavior, only the simple elastic- plastic model has proved amenable to widespread application. This is because the mathematical simplicity permitted explicit closed-form solutions to be obtained for the simpler joints, and those results facilitated comprehensive parametric studies. In addition, those same closed- form solutions apply to each step of the more complex and stronger stepped-lap joints. The elastic-plastic model in Fig. 14 is shown in comparison with an actual stress-strain curve, which is now customarily measured on thick-adherend test specimens using a Krieger KGR-1 extensometer, shown in Fig. 15.

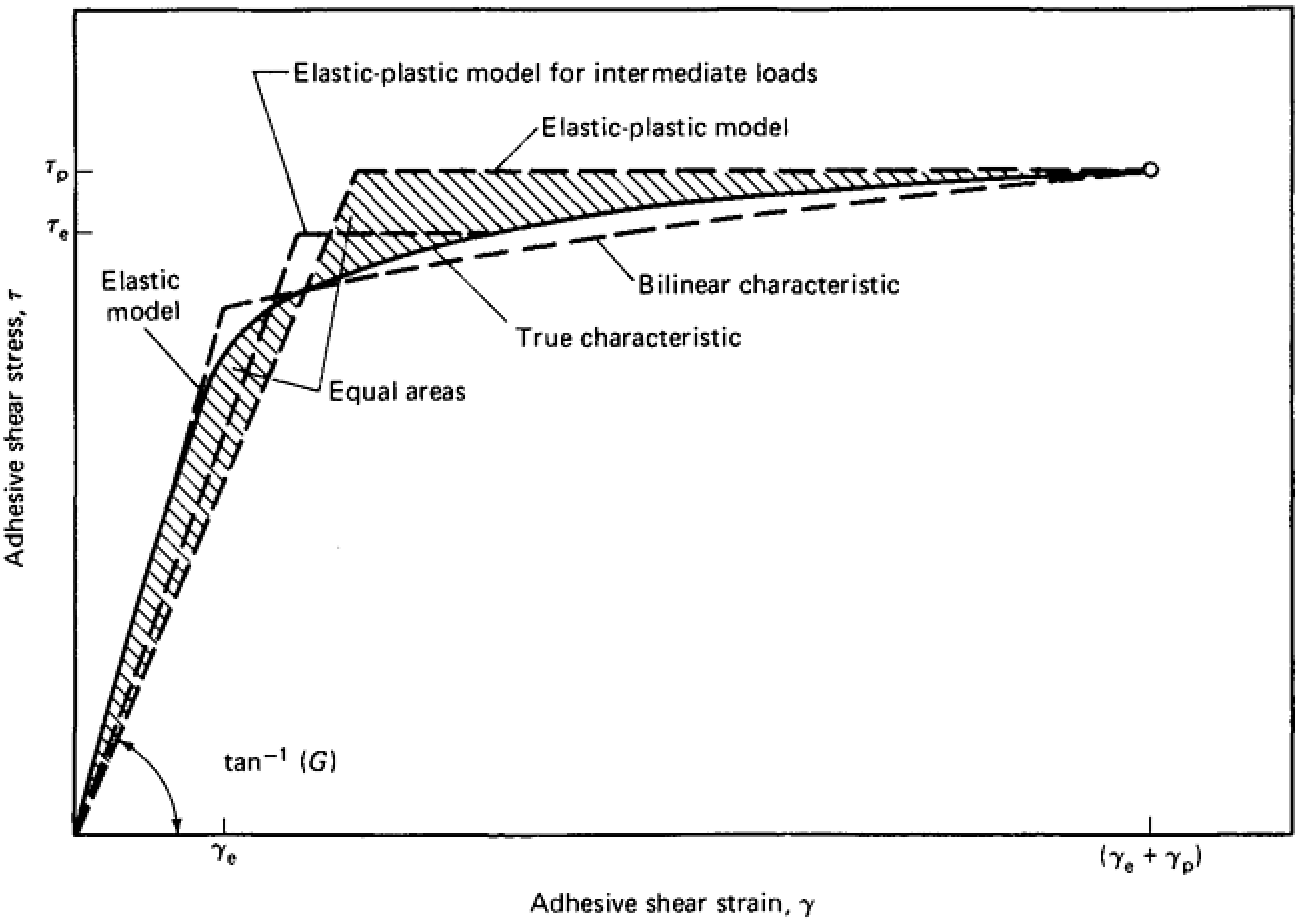

Fig. 14 Representations of adhesive nonlinear shear behavior

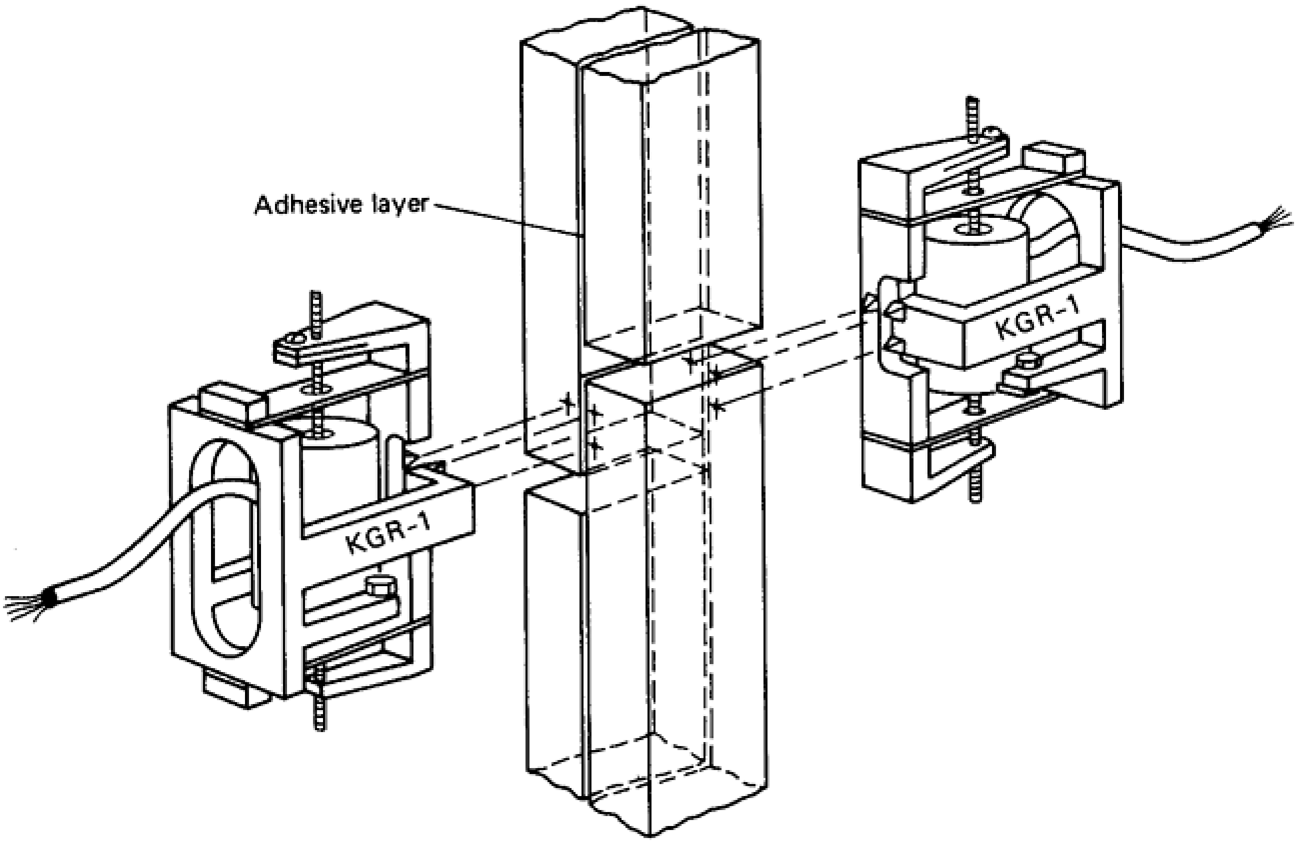

Fig. 15 KGR-1 extensometer and thick-adherend adhesive test specimen. Source: Ref 30

The mathematical model at ultimate load has the same peak shear stress and strain as the actual characteristic and the same strain energy (area under the curve). This was established as the appropriate model in Ref 31, in which the analysis for double-lap joints using the bilinear model shown in Fig. 14 reveals that the predicted joint strength would be the same for any two-straight-line adhesive model having the same strain energy. In other words, the only advantage of the bilinear model is that a single model would work for all load levels. The elastic-plastic model needs to be adjusted for less than ultimate loads, as shown in Fig. 14. Actually, it is usually sufficient to perform only two analyses: a linearly elastic one for limit load using the actual adhesive shear modulus, and an elastic-plastic model to predict the ultimate joint strength. The latter model is inappropriate for low load levels, because the initial shear modulus is too low then, and the elastic strain energy is too high. One must also pay attention to the effective limit imposed on *design* ultimate strength in Fig. 9.

It is important to understand that the simple elastic-plastic model in Fig. 14 is a mathematical *approximation*; it is far from the physical *reality* in which the softening is associated with the *linearly elastic* bending of the short ligaments of adhesive tying the adherends together between adjacent hackles, as shown in Fig. 16. On unloading, while there is some hysteresis, there is almost complete recovery of the strain; it is far from the straight-line load reduction with a large permanent offset that is associated with the classical ductile yielding of metal alloys.

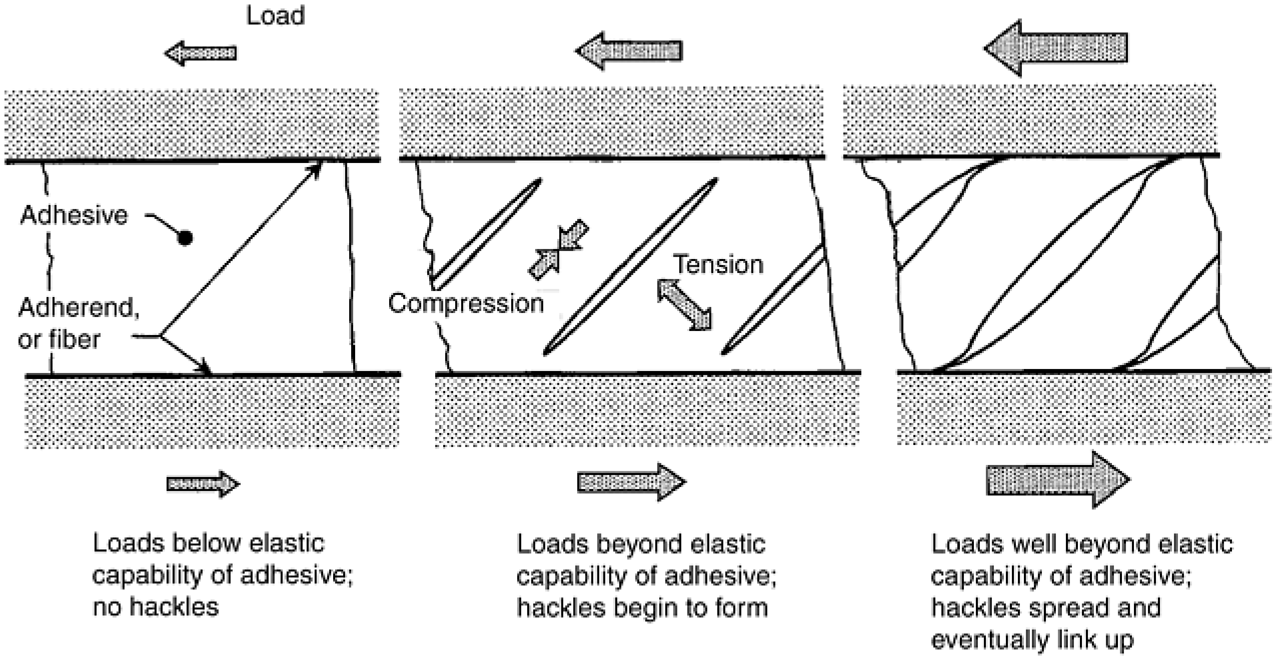

Fig. 16 Tensile hackle failures resulting from in-plane (or transverse) shear applied to constrained polymers in the form of thin films between fibers or adherends

The hackles shown in Fig. 16 apply for monotonic loading. In the case of reversed loading, it is possible to try to develop such hackles at both ±45°, culminating in a saw-tooth fracture surface. It really is important to respect the limits spelled out in Fig. 9. In practice, this means a willingness to use stepped-lap bonded joints for thicker adherends. Doing so adds the further benefit of automatically reducing the adhesive peel stresses induced at the end(s) of the joint.

The adhesive stress-strain curves in shear vary with the operating environment, as shown in Fig. 17 for a typical ductile adhesive. While the individual properties, such as peak shear strength and strain-to-failure, vary greatly with the operating temperature, the areas under all three curves in Fig. 17 are quite similar. The ultimate strength of a long-overlap bonded joint between uniform adherends is shown by analysis to be defined by the strain energy of the adhesive layer in shear, not by any individual properties, such as peak shear stress (Ref 31). The strain energy is proportional to the area under each of the curves in Fig. 17. Consequently, the strengths of realistically configured bonded joints are not very sensitive to the operating environment, provided that the temperature is kept below the glass transition temperature for each adhesive.

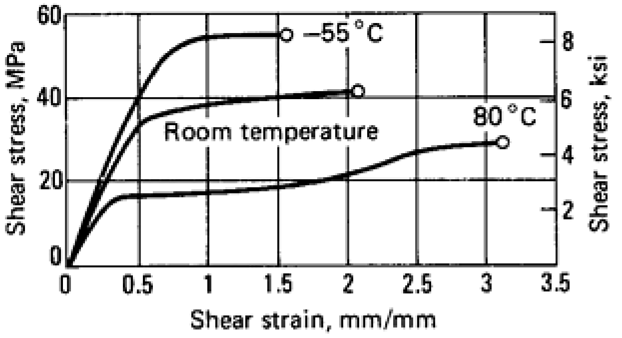

Fig. 17 Effect of temperature on adhesive stress-strain curves in shear. Nylon/epoxy adhesive (120 °C, or 250 °F, cure)

The difference between the behavior of ductile and brittle adhesives is characterized in Fig. 18. That difference is not as pronounced at the upper service temperatures, at which even the brittle adhesives are considerably ductile. It should also be noted that even at room temperature, the brittle adhesive characteristic is significantly nonlinear. The reasons that both ductile and brittle adhesives have been developed are that ductile adhesives are typically limited to service environments no greater than about 70 °C (160 °F), and that there are some applications (in proximity to engines or on supersonic aircraft) where brittle adhesive bonding is still viable, even if much of the strength has had to be sacrificed to attain much higher service temperatures.

Single-Lap Adhesively Bonded Joints

The eccentricity in load path inherent in unsupported single-lap joints decreases the joint strength below the level that could have been developed in the absence of the bending associated with that eccentricity. That loss of joint strength is quantified in Fig. 19, which shows, for example, that for the standard ASTM D 1002 lap-shear test coupon, for which the abscissa is about 2, the structural efficiency is limited to no more than one-third. (The structural efficiency is defined as the ratio of the direct membrane stress outside the joint to the sum of the stretching and bending stresses at the ends of the bonded overlap.) However, Fig. 19 also points the way to alleviating the problem, that is, by increasing the overlap from the 8 to 1 ratio used on the test coupon to about 80 to 1 for structural joints. The joint can never be as strong as the basic structure outside it. However, for long overlaps and thin adherends, the weakness is in the adherends rather than in the adhesive, and, in any case, the joint strength need only exceed the alternative, that is, riveting, which causes a significant loss of strength because of the holes.

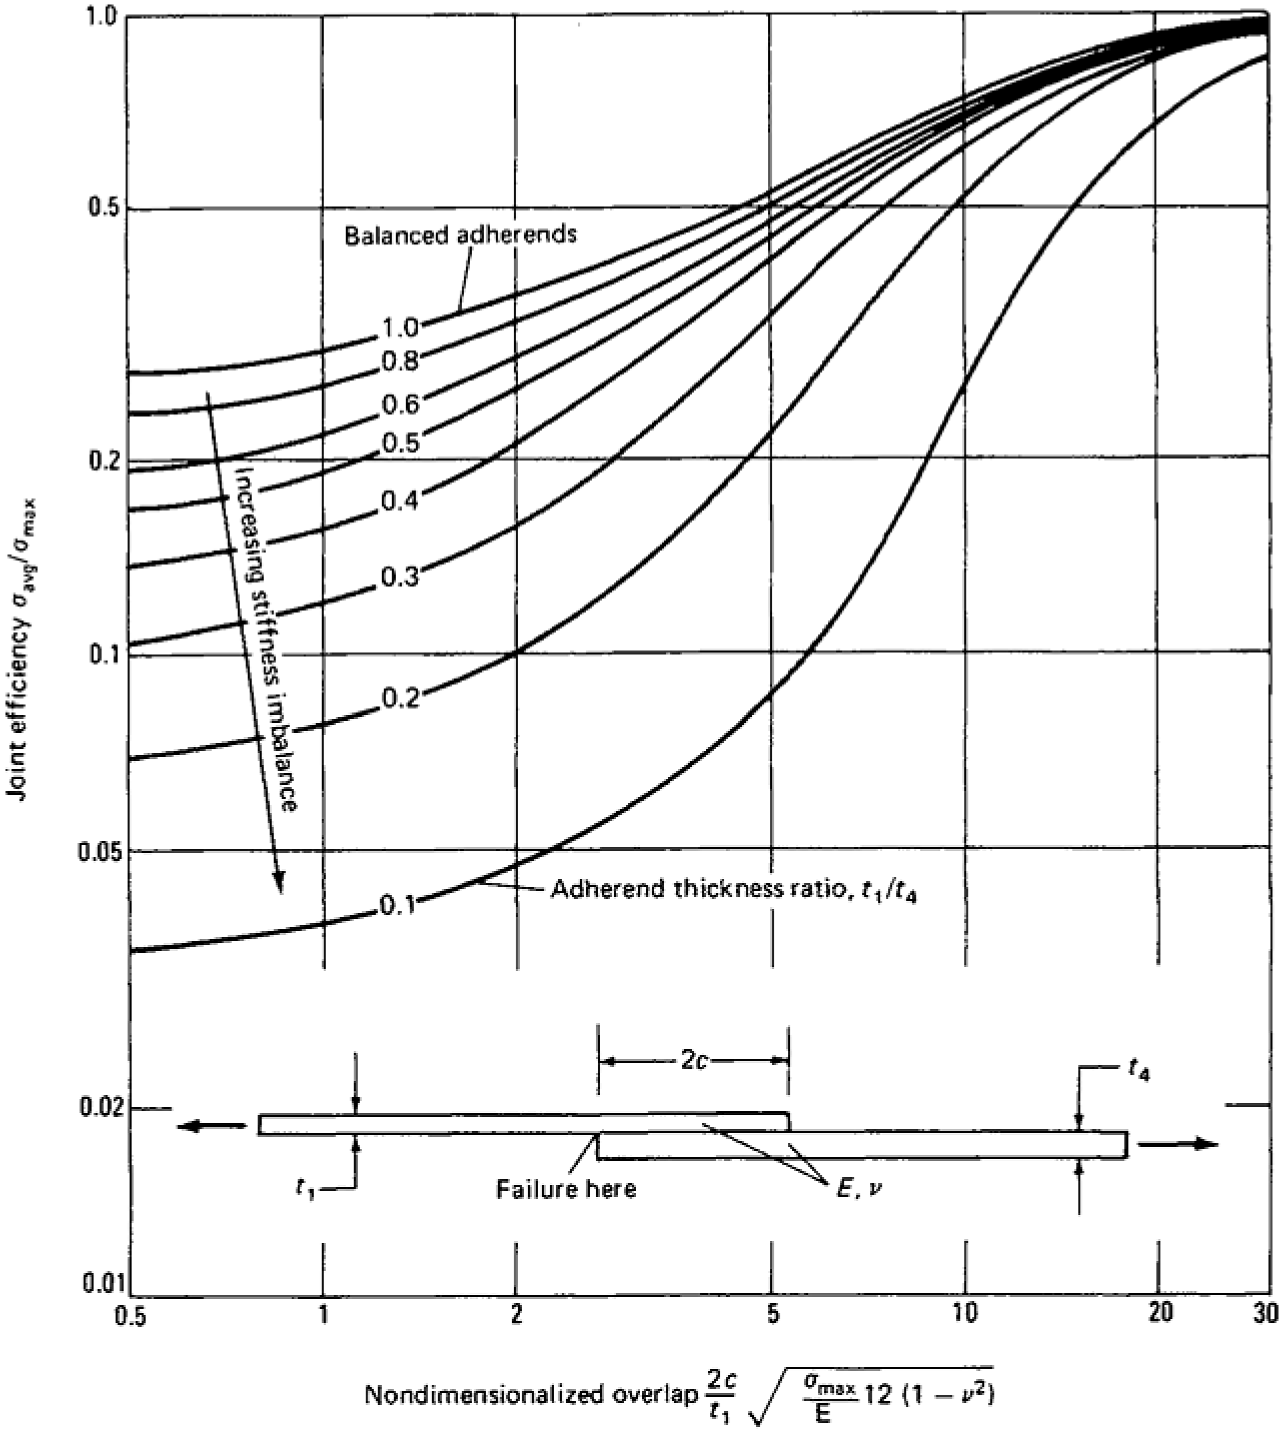

Fig. 19 Effect of adherend stiffness imbalance on adherend bending strength of single-lap bonded joints. Thinner adherend t_1 critical in combined bending and axial load at end of overlap

A detailed analysis of single-lap bonded joints can be found in Ref 15. Naturally, if the joint is supported against out-of-plane rotations, the appropriate method of analysis would be to consider the actual joint as one side of a double-lap joint that was twice as thick. Normally, single- lap joints should not be considered for joints thicker than about 1.8 mm (0. 07 in.) of aluminum alloy or its equivalent. The same peel-stress relief techniques shown in Fig. 11 are equally applicable to single-lap and single-strap joints, except that protection is needed at both ends of the bonded overlap instead of only at one.

Stepped-Lap Adhesively Bonded Joints

Composite laminates that are too thick and hence too strong to be joined by simple uniform lap-splice bonded joints can be bonded together successfully by stepped-lap joints of the type shown in Fig. 20. (Glued scarf joints, which work well for wood at a slope of about 1 in 20 at most, are not as attractive for advanced composites, because the slope needs to be much shallower, at no more than about 1 in 50, resulting in scarf joints for thick laminates that are very large.)

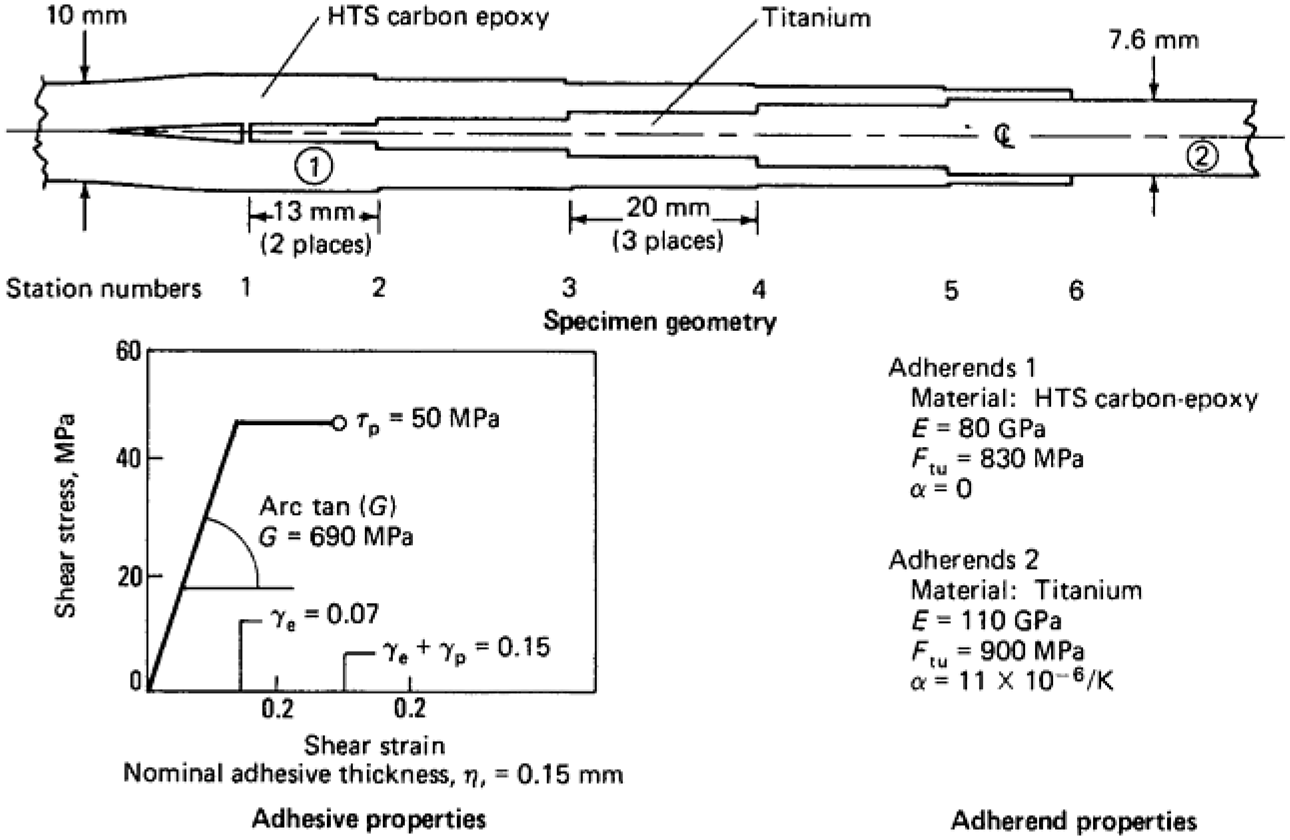

Fig. 20 Typical stepped-lap adhesively bonded joint

Each step of the stepped-lap bonded joint is governed by the same differential equation that applies to double-lap joints. Consequently, there is a highly nonuniform shear stress distribution in the adhesive, with the load transfer concentrated at the ends of each step, as shown in Fig. 21.

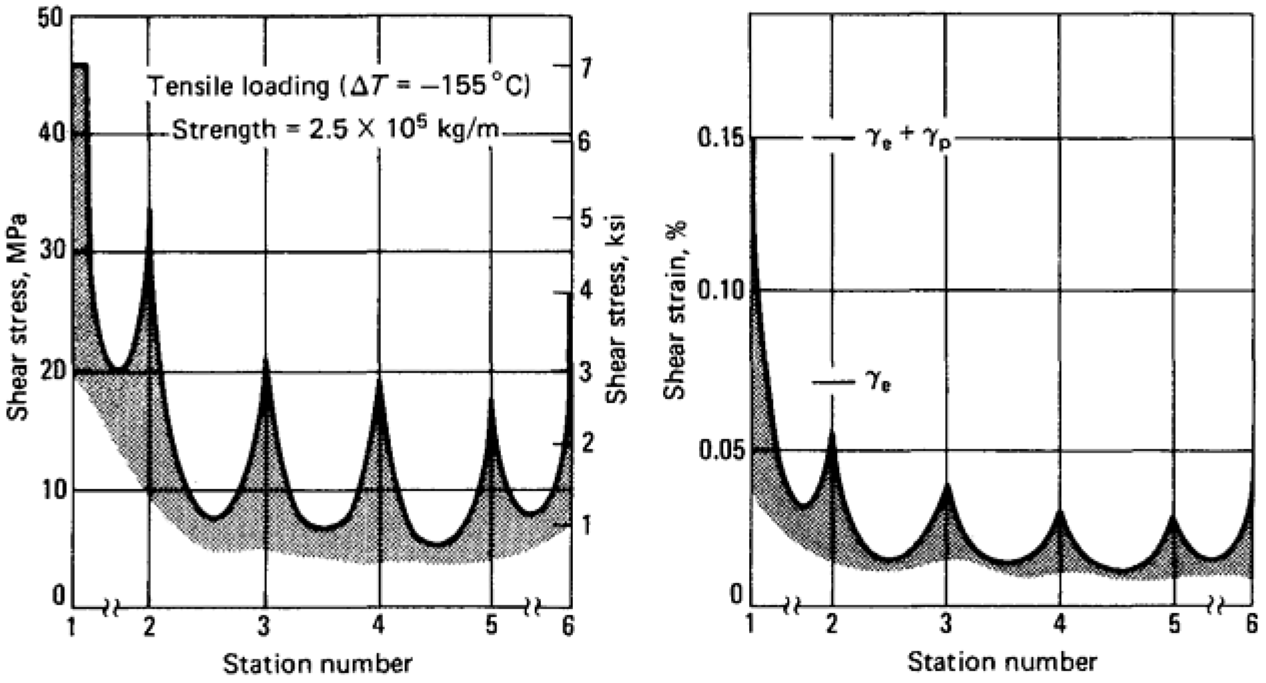

Fig. 21 Adhesive shear stresses and strains in unflawed bonded joint

The design and analysis of stepped-lap bonded joints have been made straightforward by the digital computer programs A4EG and A4EI, which are based on an elastic-plastic shear model (Ref 32, 33). The first program employs a uniform adhesive layer throughout the joint. The second program expanded on the first and incorporated variable adhesive properties, so that the effect of flaws and defects could be investigated (worked examples of joints analyzed by these programs are found in Ref 6, 26, 27, 29, and 34). It should be noted that the A4EG and A4EI programs do not merely predict the strength of joints of specified geometries, but also serve as valuable tools for improving the initial designs. Some rules of thumb for initial design are that the end steps must be neither too thick nor too long—0.76 mm (0.030 in.) thick titanium with a step length of 9.5 mm (0.375 in.) is typical, lest premature fatigue failures occur. Most of the other steps are usually 12.7 to 19.1 mm (0.50 to 0.75 in.) long, with step thicknesses no greater than 0.5 mm (0.02 in.) (and preferably much less) on each side of the joint, with one longer step near the middle of the overlap to provide creep resistance. The computer programs give enough detailed information about the internal stresses within the joint for the initial design to be improved upon by modifying design details. Any poorly proportioned step usually shows up rapidly. Once the proportions have been adjusted properly, the most powerful variable with which to increase the joint strength is the number of steps; merely increasing the bond area for the same number of steps is not effective. The strength continues to increase as the number of steps is increased to one per ply, and the number should always be sufficient to ensure that the bond strength (calculated by overriding the adherend strength limits while maintaining the same stiffnesses) exceeds the adherend strengths by at least 50%.

Load Redistributions with Flawed and Damaged Adhesively Bonded Joints

It is not sufficient to design bonded splices to a strength that is only adequate for the nominally applied loads, unless there is no need for damage tolerance. If a bonded splice is everywhere weaker than the local strength of the adherends just outside the joint, any load redistribution associated with local flaws in the bond or damage to it could cause the remaining bond to unzip catastrophically. This phenomenon is explained in Fig. 4; the uniform remote stress in the adherends must be kept lower for larger flaws or damage, lest the remaining bond become overloaded and fail just outside the ineffective bond area.

However, if the intact bond outside the weakened area was stronger than the adherends, no amount of load redistribution could ever fail the bond, as explained in Ref 6 and 26. Any subsequent failure would be transferred to the adherends, where it would become visible much sooner. The appropriate analysis for estimating the remaining life in the damaged bonded structure then pertains to the adherends and not to the adhesive. The same is true when structures so thick that they should not be bonded are bonded and then are protected by fail-safe mechanical fasteners. Any initial flaws or damage will unzip sufficiently to enable some of the fasteners to pick up the load through the defective area. From that point on, the basic load transfer is redistributed, as explained in Ref 26 and 33. The disbond will grow no further, and the subsequent life will be determined by the most severely loaded fastener through the area of defective bond.

A word of caution is in order about the current fashion of misapplying fracture mechanics theory (from cracked metal structures) to estimating the life of adhesively bonded structures. Such a malpractice is more likely to result in bonded structures inferior to those designed by classical nonlinear strength-of-materials approaches than it is to result in improvements. The key to designing bonded structures is that the nominally unflawed bond must never be weaker than the members being joined. If the bond is stronger, the adherends determine the structural life, whether there is a bond flaw or not. The notion that it is permissible to design weak-link fuse bonded joints and justify this practice by calculating a supposedly adequate finite fatigue life must be discouraged. The associated potential for instantaneous unzipping of the remaining bond area would place an intolerable burden on inspection. Finding cracks in metal structures has been difficult enough, and they are much easier to detect.

Further, the two situations (flawed bonds and cracked metal) are not at all comparable. The basis of the damage tolerance approach to cracked metal structures is that there will be a relatively long period of slow, stable crack growth before a critical crack length is reached. That usually allows sufficient opportunity to detect small cracks and repair them. In adhesive bonds, on the other hand, the measured disbond rates have either been so rapid that the bonds would need to be inspected several times on each flight to ensure that it was safe to continue, or so slow that no growth could be detected. There has been no in-between behavior that would lend itself to metallic damage tolerance techniques. This difference is explained in Fig. 22 (from Ref 35). Properly designed bonded joints, on the other hand, exhibit remarkable tolerance to quite large bond flaws. Fracture mechanics analyses can be valuable in this context when used to calculate thresholds below which initial damage will not propagate, rather than to calculate rates of damage growth.

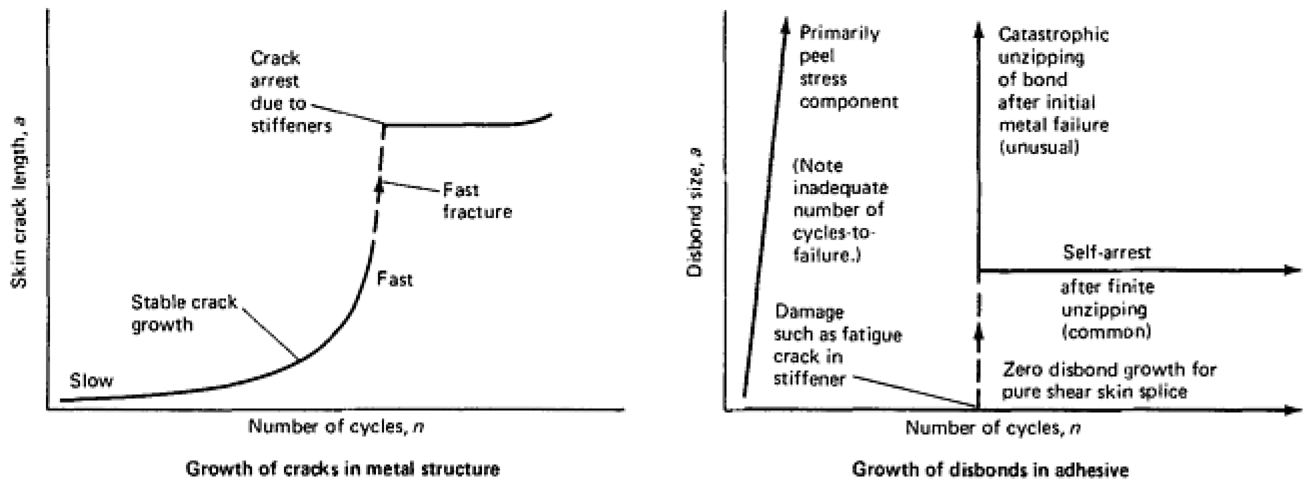

Fig. 22 Differences between growth of cracks in metal components and adhesive bonds. Source: Ref 35

Another beneficial use of fracture mechanics analysis of bonded and laminated composite structures is to identify design details and stacking sequences that should be avoided (see Ref 36). Special attention should be paid to the numerous publications on delaminations in composites by T.K. O'Brien at NASA Langley; one of these is included in Ref 36. The need for such an approach is accentuated by the current lack of capability in the standard composite laminate theories to account for residual thermal stresses in the resin, which is, after all, where the cracks and delaminations in fiber-reinforced composites occur. While a few of the published laminate theories (mechanistic rather than interactive) do an adequate job of predicting the fiber-dominated strengths of composite laminates under arbitrary in-plane loads, none of the published theories can do justice to resin-dominated strengths, and all are quite incapable of accounting for such things as stacking-sequence effects. Most laminate theories work only for uniaxial loading and are unacceptable for biaxial loads, although new and old cross-plied laminate theories that do work satisfactorily for biaxial in-plane loads are discussed in Ref 37 and 38. Such deficiencies in the laminate theories may be the reason that all bolted composite joint analyses have had to rely on substantial empirically determined correlation factors between theory and test.

Bolted and Bonded Joints

L.J. Hart-Smith, The Boeing Company

Fundamentals of Shear Load Transfer through Mechanical Fasteners

Perhaps the most important thing to understand about mechanically fastened joints in fibrous composite structures is that the eventual failure of the composite occurs long after the laminate has stopped behaving like the one- phase homogeneous engineering material on which it is usually modeled. While the fibers and the resin matrix are both essentially linear until failure, the microcracks and delaminations around bolt holes in composite laminates cause substantial internal load redistributions that are not accounted for in conventional mathematical models of bolted or riveted composite joints. Thus, there appears to be substantial nonlinear behavior associated with the normal rivet or bolt sizes used in composite structures. However, while there are indeed softened zones at the microlevel, as shown in Fig. 23, this softening is unlike the yielding associated with ductile metal alloys in similar circumstances.

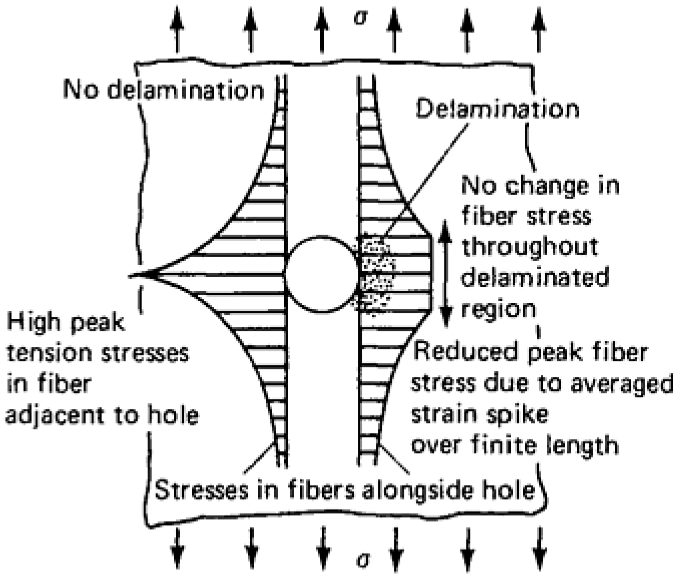

Fig. 23 Stress-concentration relief at small holes in fiber-reinforced composites

However, there are striking similarities in the behavior at the macrolevel. For example, the residual-stress zone around cold-worked holes in metal structures leads to very substantial increases in the fatigue life. Likewise, any increase in the albeit much smaller softened zone around fasteners in composites causes an increase in the static strength. Either the careful installation of interference-fit fasteners or the gentle fatiguing of bolted composite structures can increase the static tensile strength ever closer toward the unnotched net-section strength. The corresponding increase in compressive strength will not be as dramatic, because it is dominated more by bearing stresses than by net-section stresses. Indeed, with the more recent toughened resins that have been developed, a new failure mode has been detected—cracks right through the laminates that, if the nominal strain is high enough, grow under compressive cyclic loads in exactly the same manner as through cracks grow under tensile loads in metallic structures. The reason for this is that while the microdamage in the resin is benign under tensile loads, because it averages fiber strains in regions of high stress gradients, the same damage destabilizes axially compressed fibers. This phenomenon had never been noticed in the older, more brittle

resins, because the entire laminate would fail before the necessary strains for this mode of failure could be developed.

There is a very strong similarity between the effects of design details on the fatigue strength of bolted or riveted metal structures and on the static strength of composite structures. Perhaps the strongest analogy is associated with the desirability of restricting the bearing stress. As shown in Fig. 24, at the elastic level the peak tension stress alongside the loaded bolt hole in an isotropic panel is on the same order of magnitude as the average bearing stress, *P/dt*. Keeping the bearing stress low is the key to structurally efficient bolted composite joints, particularly for multirow joints, as explained in the section "Multirow Bolted Composite Joints" in this article.

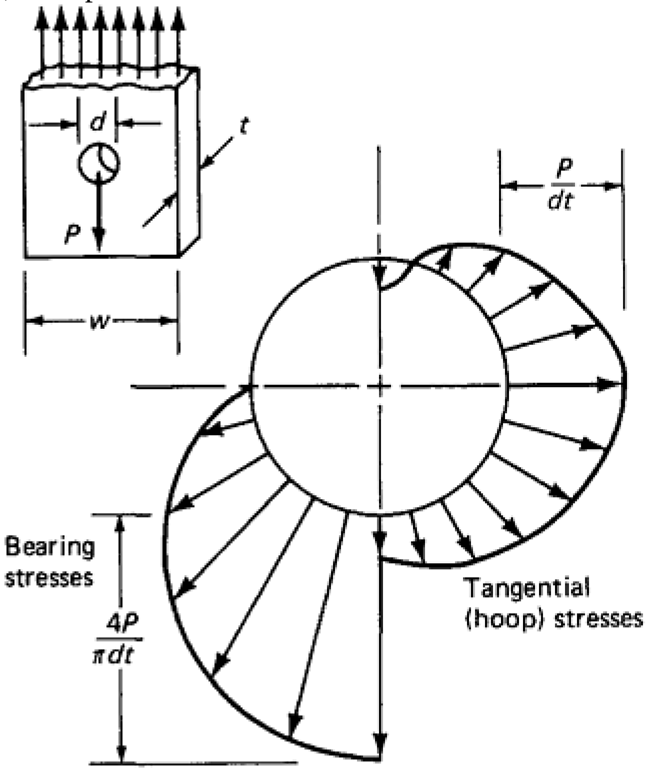

Fig. 24 Bearing and hoop stresses at bolt hole

There are also some curious juxtapositions of behavior between metallic and composite components. For example, in metal aircraft structures, a severe application of load early in the life of the aircraft will retard the subsequent growth of cracks by creating a larger plastic zone at the crack tips or likely crack sites. Conversely, if all bolted composite aircraft were subjected to five lifetimes of fatigue testing before delivery, their ultimate strength would be increased significantly, perhaps by as much as a factor of 2.

Because of the distinctly two-phase material behavior of fibrous composites around both loaded and unloaded holes (Fig. 23), there will be a continued need for a substantial empirically established correlation factor to reconcile test and theory for bolted composite joints. This can be done in a straightforward manner, as in the author's hypothesis (Ref 33, 39, 40 41), in which the amount of stress-concentration relief is assumed to be proportional to the intensity of the original elastic stress concentration. That hypothesis leads to an easily calculated residual stress concentration for other geometries that have not been tested. With a correlation factor determined from single-hole test specimens as a starting point, this method has been shown to be effective in predicting the strength of highly loaded multirow bolted composite joints (Ref 42). In Ref 43, this method has been extended to in-plane shear loads on multirow joints. Reference 43 also contains some improved stress-concentration formulas for loaded and unloaded bolt holes that are simpler than those developed earlier, with no loss of accuracy. This method of analysis is presented here.

The literature on bolted composite joints contains another basic approach to this nonlinearity problem, usually referred to as the characteristic- length or characteristic-offset approach. The origins of this approach are the point-stress and average-stress failure criteria (Ref 44). With that method, the linearly elastic analysis is presumed to be valid outside some empirically determined softened zone adjacent to the hole. The basic drawback to that approach, which can, of course, always be shown to be capable of explaining any test results one at a time, is that the so-called characteristic dimension varies considerably with bearing stress, and that

failure is being predicted at some place other than where it is known to occur. Nevertheless, both methods of analysis will continue to be used until it is possible to cover all joint geometries and bearing stress intensities with a single theory. At present, each approach covers some situations not covered by the other. Both have been used successfully in hardware applications, and both have led to increased understanding of stress concentrations around bolt holes in composite structures.

Bolted and Bonded Joints

L.J. Hart-Smith, The Boeing Company

Single-Hole Bolted Composite Joints

The methods developed in Ref 39, 40, and 43 for the analysis and design of bolted or riveted composite joints call for a major empirical correlation factor. Once that is accepted, it makes sense to use analyses for elastic isotropic materials as reference points, because they are simple and widely available. Corrections for both the nonlinear behavior described in Fig. 23 and for orthotropy can be combined into a single factor, provided that the mode and location of failure do not change. Separate analyses are needed for bearing failures and for the tension-through-the- hole failure modes. The various modes of failure are illustrated in Fig. 25. Compression strengths tend to be higher and not as sensitive to stress concentrations, because some of the load can be transmitted through the fastener instead of the entire load going around it.

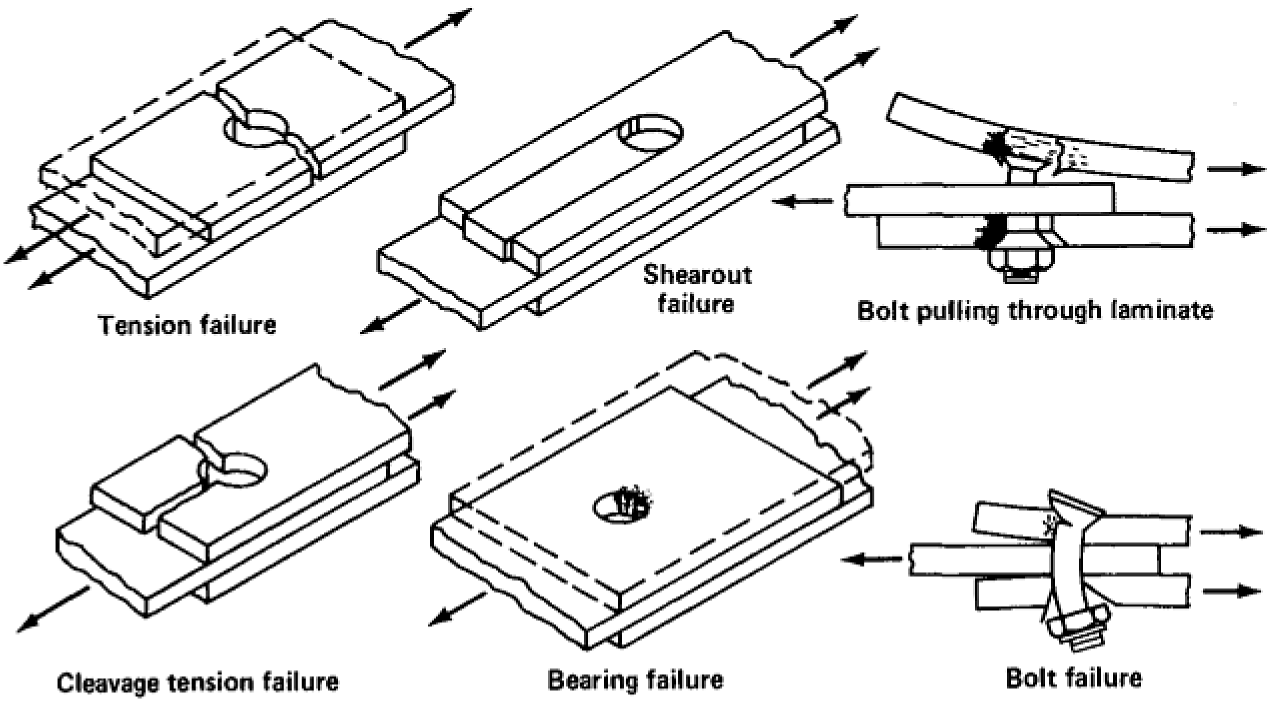

Fig. 25 Modes of failure for bolted joints in advanced composites

The other major failure mode, shear-out, does not occur within the shaded area of laminate patterns in Fig. 1. Outside that area, the wide-spread splitting accompanying shear-out and the low load level at which it occurs (see, for example, Ref 39 and 45) discourage the installation of fasteners in such highly orthotropic laminates. A weakness in shear-out cannot be corrected by adding more edge distance for the fasteners. Even an increase in thickness, without changing the troublesome fiber pattern, is not very effective. Any added thickness is better employed by changing to a more thoroughly interspersed, nearly quasi-isotropic pattern.

Reference 43 contains formulas for the elastic- isotropic stress concentration associated with a loaded bolt hole of diameter, *d,* in a finite strip of width, *w*. With respect to the average net-section tension stress, the peak stress-concentration factor on the net section immediately adjacent to the hole is:

$$K_{te} = \frac{w}{d} + \frac{d}{w} + 0.5\left(1 - \frac{d}{w}\right)\Theta \approx \frac{w}{d} + \frac{d}{w} \qquad \text{(Eq 1)}$$

where

$$\Theta = \left(\frac{w}{e} - 1\right) \text{ for } e/w \leq 1,\ \Theta = 0 \text{ for } e/w \geq 1$$

provided that the edge distance, *e*, is adequate (that is, $e \geq w$). The cited reference contains modifications for short edge distances. R.B. Heywood gives the corresponding expression for the stress-concentration factor at an unloaded hole in the middle of a strip (Ref 46):

$$K_{te} = 2 + (1 - d/w)^3 \qquad \text{(Eq 2)}$$

Reference 39 also contains formulas for stress conditions associated with holes in different geometries. A major benefit of having explicit expressions for these stress concentrations is that they facilitate parametric studies and identification of optimal joint geometries. The maximum strength of brittle, perfectly elastic strips loaded by a central bolt is 21% of the unnotched strength at an optimal *w/d* ratio of about 2.5. The bolts should be placed close together to minimize the peak hoop tension stress, which, as shown in Fig. 24, is on the same order as the average bearing stress.

Fortunately, at least for the small, typically 6.5 mm (0.25 in.) diameter, fasteners used in most aircraft structures, the pessimistic outlook for bolt holes in window glass materials does not occur in fiber-reinforced composites, because of the separate behavior of the two distinct constituents of such composites. There is then considerable relief of the stress-concentration factors, as shown in Fig. 26, which also includes the efficiency of bolted joints in highly ductile and perfectly brittle materials. It is evident that fibrous composite behavior cannot be predicted on the basis of a minor perturbation from either the elastic or plastic analyses shown. (It

should also be noted that the strength increase shown in Fig. 26 for roughly 6.5 mm, or 0.25 in., diameter bolts in carbon/epoxy composites decreases asymptotically as the fastener diameter increases, and, for very large bolt holes or cutouts, the linearly elastic predictions would be expected to apply.)

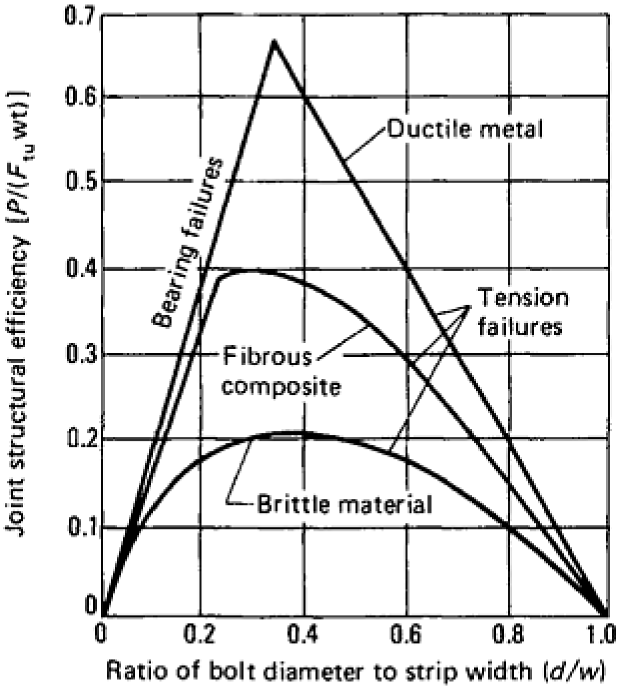

Fig. 26 Relationship between strengths of bolted joints in ductile metals, fiber-reinforced composites, and brittle materials

The origin of this substantial stress-concentration relief for typical fastener sizes is explained in Fig. 27, in which the theoretical stress-concentration factors, K_{te}, are calculated according to Eq 1. The observed stress concentration at failure, K_{tc}, is calculated as:

$$K_{tc} = F_{tu}(w-d)/P \quad \text{(Eq 3)}$$

where P is the load at which the specimen failed, F_{tu} is the ultimate tensile strength, and the numerator is the unnotched net-section strength.

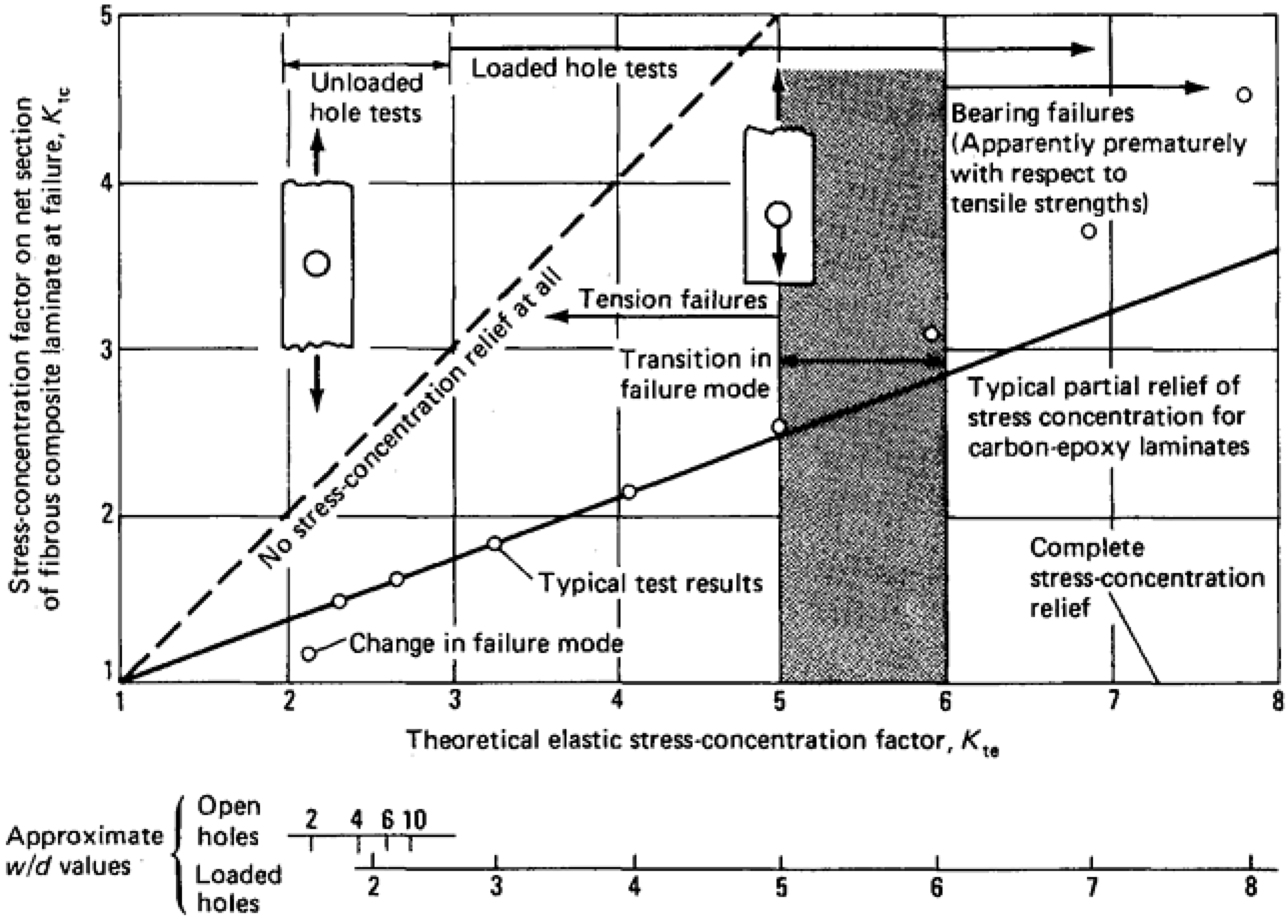

Fig. 27 Relation between stress-concentration factors observed at failure of fiber-reinforced composite laminates and predicted for perfectly elastic isotropic materials

It was postulated in Ref 39, 40, and 43 that the amount of (nonlinear) relief would be proportional to the intensity of the original (elastic) stress concentration. Thus, the effective stress- concentration factor experienced by the composite laminate at loaded and unloaded bolt holes is taken to be:

$$K_{tc} = 1 + C(K_{te} - 1) \quad \text{(Eq 4)}$$

in which the correlation factor, *C*, varies with both the fiber pattern and the hole size. A value of 0 for *C* would indicate complete stress-concentration relief, as with ductile metals, while a value of 1 (for quasi-isotropic materials) would indicate no relief at all. As a useful ***aide- memoire***, the value of the *C* factor has been found to be close to 0.25 for 0.25 in. bolts in three different carbon epoxy quasi-isotropic laminates, which fraction is the same as the percentage of 0° plies. Higher values have been deduced for orthotropic laminates. For 6.5 mm (0.25 in.) diameter fasteners in laminates within the shaded area in Fig. 1:

$$C \approx (\%\ 0° \text{ plies})/100 \quad \text{(Eq 5)}$$

as shown in Fig. 28.

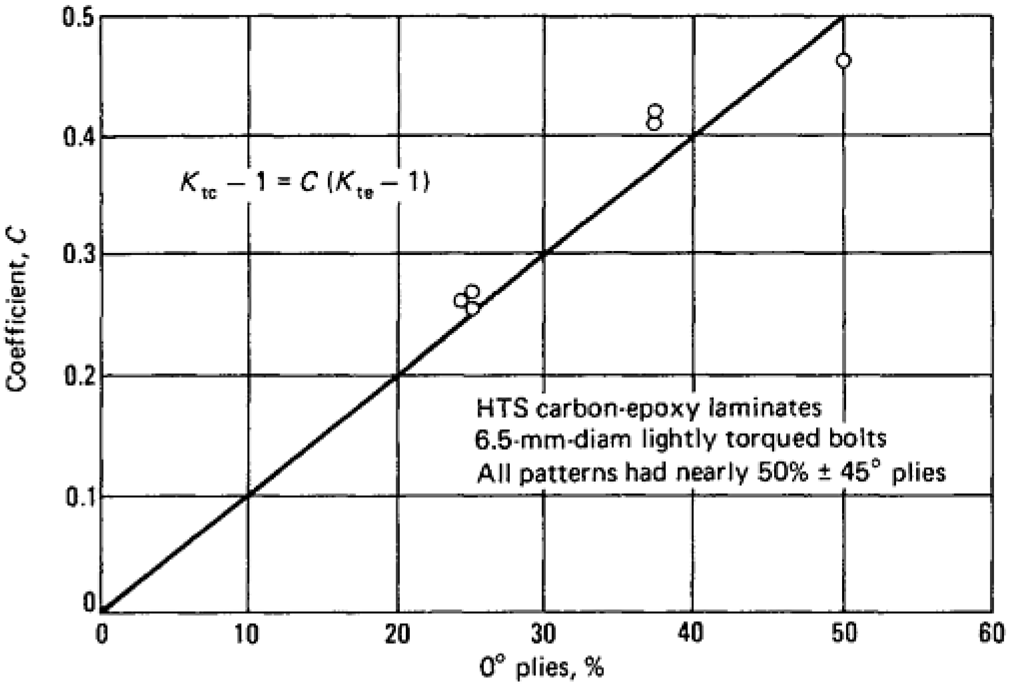

Fig. 28 Stress-concentration relief at bolt holes in composite laminates

Absorbing the orthotropy factor into the single coefficient *C* can be justified only when the mode of failure does not change. Whether this effect of orthotropy were incorporated into an expanded abscissa or into a steepened slope of the line in Fig. 27, the result would be the same. This combination would be expected to become invalid for most of the fiber patterns outside the shaded area shown in Fig. 1, because of a predominance of shear-out failures.

For small *d/w* (or large *w/d*) ratios, the laminates will fail at a lower load in bearing under the bolt rather than by tension through the hole. Therefore, a lower-bound cutoff is needed to cover this failure mode. This is shown on the left of the middle curve in Fig. 26. Such bearing failures also occur for ductile metal alloys, as shown to the left of the top curve in Fig. 26.

The optimal *w/d* ratio, when allowance is made for the nonlinear behavior of the composite around the bolt holes, is approximately 3 to 1 for 6.5 mm (0.25 in.) diameter bolts, being slightly higher for smaller bolts and lower for larger ones. These optimal ratios pertain to single-row joints in which all of the load is transferred through a single row of fasteners; different values are given in the section "Multirow Bolted Composite Joints" in this article. Also, whereas the maximum strength for ductile metals occurs at the intersection of the bearing and tension strengths, the maximum efficiency for single- row bolted composite joints is developed by tensile failures of the net section, at a bearing stress that is typically only about three-fourths of the bearing stress the composite material could withstand at wider bolt spacings. The philosophy of simultaneous failures is definitely not applicable here.

The bearing strength of composite laminates is strongly influenced by the presence or absence of any through-the-thickness clamp-up, as shown in Fig. 29. There is a nearly 2 to 1 difference between the pin-loaded case, in which there is no clamp-up at all, and the finger-tight case, for which the bolt head and nut prevent any initially damaged composite material from unloading itself by deflecting sideways. Because all the material is confined under these circumstances, the joint continues to carry on to higher loads, as shown. This improvement in strength is customarily accounted for in design. The even greater strengths achievable by torquing the bolts down tightly should not be relied upon for design purposes, because it would be very difficult to detect a single undertorqued fastener that would substantially reduce the static strength of the composite structure. In metal structures, on the other hand, the loss of such clamp-up would merely reduce the fatigue life, with no associated reduction in static strength. In any case, the improvement in bearing strength of composites due to additional bolt torque is often not realized, because tension-through-the- hole strength may govern the design, particularly for large fasteners.

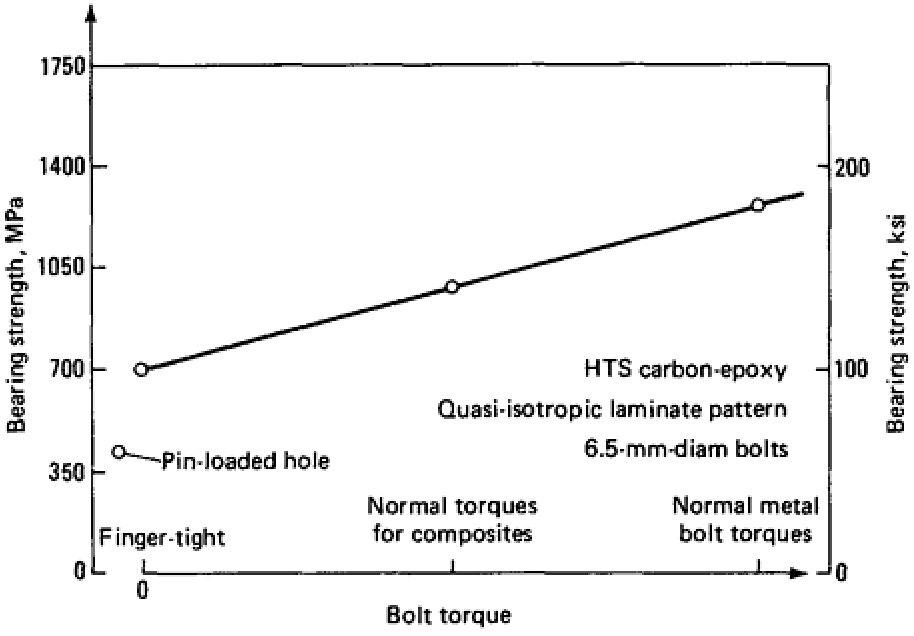

Fig. 29 Effect of bolt torque on bearing strength of fiber-reinforced composite laminates

Multirow Bolted Composite Joints

The limited structural efficiency of bolted composite laminates containing single-row splices is not sufficient for them to compete on a weight basis with well-designed aluminum alloy structures. This is indicated by Fig.

30, which points to the need for operating at higher strain levels. However, this need has sometimes been misinterpreted and has been responded to by changing to structurally inferior patterns to acquire the increase in strain, only to have that goal nullified by an associated reduction in modulus. Interestingly, diagrams similar to Fig. 30, but prepared for mildly orthotropic laminate patterns, have shown that the increase in strength associated with additional 0° plies (those in the primary direction of loading) are almost nullified by the associated reduction in strain-to-failure because of the higher stress-concentration factors, *K*. Likewise, the lower stress concentrations and higher strains-to-failure associated with softened laminates carry with them a balancing decrease in strength because of the lower modulus.

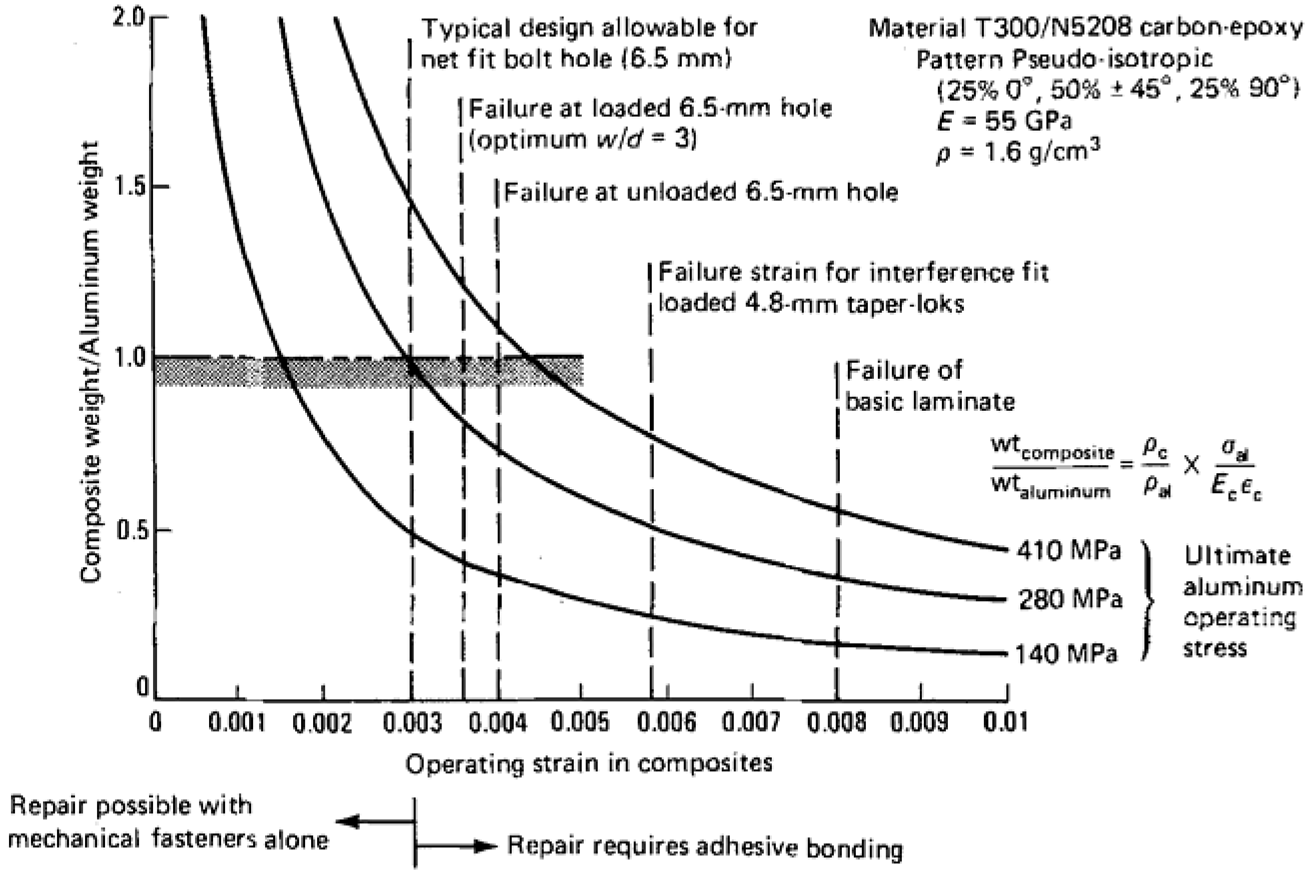

Fig. 30 Relative weights of aluminum and carbon/epoxy composite structures. Failure strains are less for loaded holes, for using statistical basis rather than average, and for larger holes. Reliance on benefit from interference-fit fasteners requires absolutely no net or loose-fit bolts. Otherwise, static strength will be reduced by a factor of 2. Multiple rows of bolts in uniformly thick members increase strength by only a few percent. Further strain limits for damage tolerance and impact resistance are not yet established.

Tinkering with a good fiber pattern usually cannot substantially enhance the strength of fibrous composite laminates. A well-known exception is the use of local softening strips and pad-ups, which can virtually eliminate the effect of stress concentrations with respect to the basic laminate. However, such an approach leaves the structure outside those locally protected areas with little, if any, damage tolerance (because of the higher operating strain permitted by the softening strips and pad-ups) and severely limits the opportunity to perform repairs, so the situations in which such an approach is practical are limited.

An alternative technique for improving the structural efficiency of bolted or riveted composite structures is to improve the joints themselves, by using more than one row of fasteners in conjunction with tapered splice plates. The analyses in Ref 39, 40 and 43 pointed the way to almost accomplishing this in the 1980s, and considerable progress has since been made in the design and analysis of such joints. The validity of the methods has been confirmed by extensive testing of large, highly loaded bolted composite joints (Ref 42). The key to the analysis of multirow bolted composite joints is a formula for the bearing-bypass interaction. Such an interaction, for tensile loads, is shown in Fig. 31, where the terms “bearing load” and “bypass load” are defined. The bearing load is reacted at the particular bolt under consideration, while the bypass load, interrupted by the bolt hole, passes by and is reacted elsewhere. Figure 32 also covers compressive loading, for which the bearing-bypass interaction is more complicated.

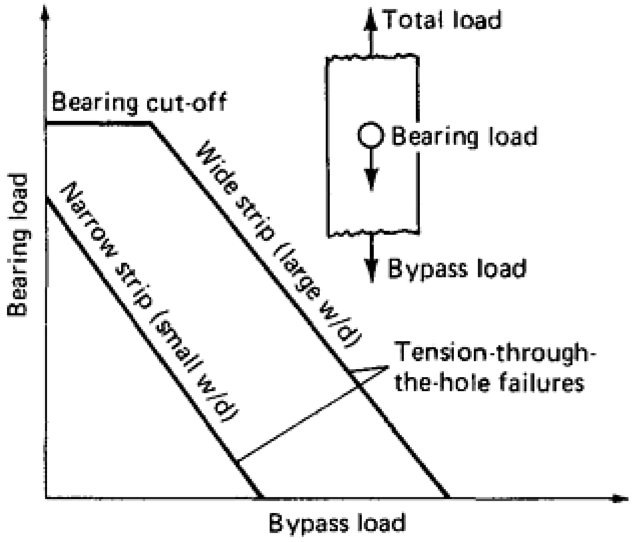

Fig. 31 Bearing-bypass load interaction for loaded bolts in advanced composites

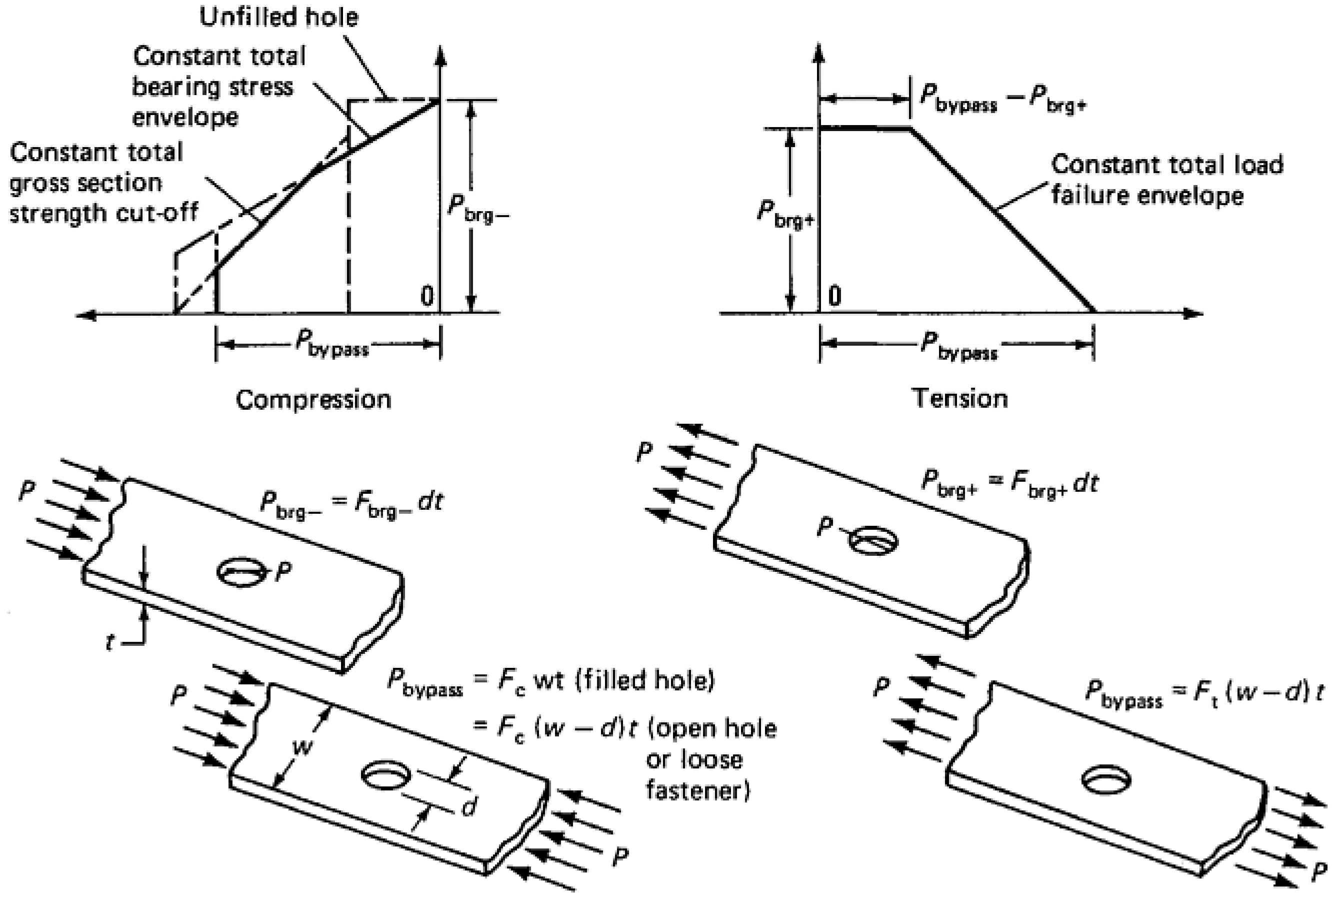

Fig. 32 Outer envelope of bearing-bypass load interactions. *F* symbols are all ultimate material strengths, *dt* is the bearing area.

When the bearing load is high enough, there is a bearing-stress cutoff for sufficiently wide fastener spacing, but for closer spacings, the failure will be in the net section whether the load is all taken out on that fastener (pure bearing) or all reacted at other fasteners in the joint (pure bypass). The extremities of the interactions could be established by test if a theory were not available. The real key to Fig. 31 is the linear interaction between bearing and bypass loads whenever the joint fails in tension through the hole; that is:

$$\sigma_{net} K_{tc} + \sigma_{brg} K_{tb} \le F_{tu} \text{ (and } \sigma_{brg} \le F_{brg}) \qquad \text{(Eq 6)}$$

where K_{tb} is the bearing stress concentration factor and F_{brg} is the ultimate bearing strength.

The existence of this linear interaction has been known since about 1970 and confirmed by other analysis methods. Many curves similar to Fig. 31 have been derived by the Bolted Joint Stress Field Model (BJSFM) computer program (such as Ref 47, 48) using the characteristic-offset analysis method, and the linearity has been confirmed by extensive testing reported in numerous documents. (The use of the BJSFM analysis method, with a fixed characteristic offset for all hole sizes, permits an assessment of the hole- size effect, which requires varying values of the coefficient *C* with the present method of analysis. The bearing-bypass interaction used with the BJSFM method is usually established for a fixed *w/d* ratio of 4 to 1, while the *C*-factor method can encompass such interactions that are permitted to vary with the *w/d* ratio, as demonstrated in Ref 43.)
Equations 1 to 5 permit the construction of joint efficiency charts of the type shown in Fig. 33, which covers all the intermediate cases for single-row joints between a pure bypass load along the upper envelope and a pure bearing load on the lowest curve. Figure 33 reveals that the only way to improve upon the efficiency of an optimized single-row joint is to move the fasteners in the most critical row further apart and simultaneously decrease the bearing stress on the same row of fasteners. The *last* row of a multirow joint in each member, where there is no bypass load left and a reduced total load, is best designed with the geometry for an optimized single-row joint.

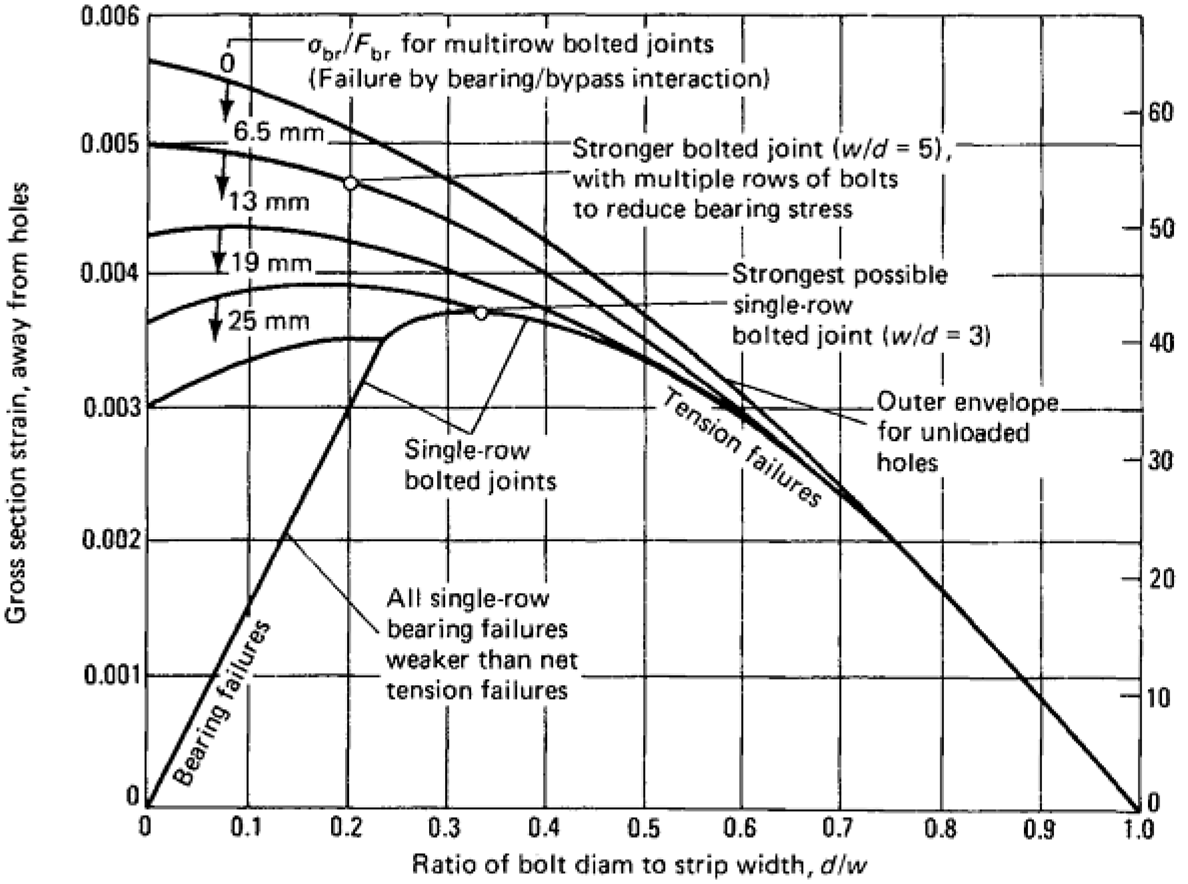

Fig. 33 Influence of bolted joint design on structural efficiency of carbon/epoxy composite structures

These seemingly mutually contradictory requirements can be met only with the assistance of an accurate load-sharing program. Only one has been developed that covers nonlinear behavior in the fastener load-deflection characteristic. That is the A4EJ program derived in Ref 33 and described in Ref 26.
This nonlinear analysis code requires nonlinear characteristics for the fastener load-deflection curves. This may seem to limit the utility of the method. However, Fig. 34 shows that the method will work quite well with approximate models. Standard design practice limits the increase in hole diameter that can be tolerated to a standard offset of 2% of the fastener diameter. At that limit, there is little difference between the actual load carried (when known) and that carried by a model in which the secondary slope is set at one-fifth of the primary slope and the knee at a height of 85% of the maximum. It is important to differentiate between the maximum fastener load, established only with far greater damage to the hole, and the design ultimate load at the 2% of diameter offset. However, once that is done, even a total neglect of any nonlinear increment in the fastener would not cause a significant error. What the nonlinear analysis accomplishes is that the critical fastener loads

are held constant, while additional load applied to the joint is able to increase (linearly) the lesser loads transferred through the more lightly loaded fasteners.

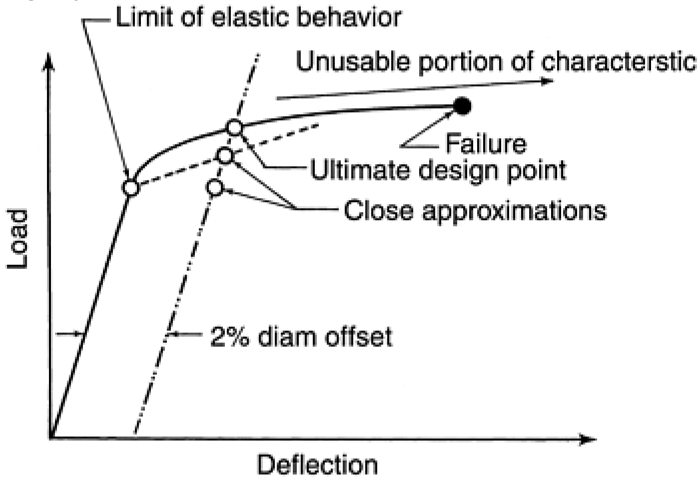

Fig. 34 Idealized fastener load-deflection characteristics

Comparative analyses of multirow bolted composite joints reported in Ref 42 have shown that if the basic structure is to be repairable, the optimal splices must contain uniformly thick skins with tapered splice plates, as shown in Fig. 35. Also, the diameter of the fasteners varies throughout the joint. The innermost bolts, adjacent to where the skins butt together, are largest, at about a *w/d* ratio of 3 to 1. There is no bypass load there in the skin, so that row is optimized as a single-row joint. Obviously, that is the worst possible thing to do to the splice plates, because the maximum bearing and bypass loads coincide there. Consequently, the splice plates must be suitably reinforced. The weight penalty associated with an off-optimal splice plate is trivial in comparison with the substantial weight savings associated with maximizing the structural efficiency of the entire basic skin. This highlights a commonly used, but totally inappropriate, metric for joints whereby it is the weight of the splice that is minimized instead of the total weight of the structure.

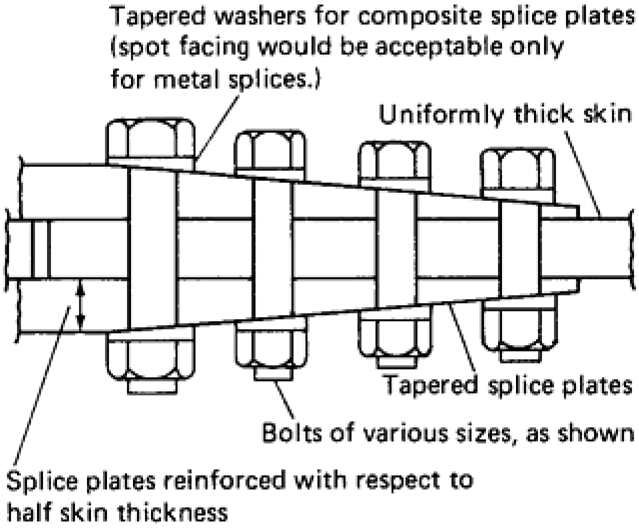

Fig. 35 Optimal proportions for multirow bolted composite joints

The next two rows of fasteners are sized at a *w/d* ratio of 4 to 1, because there is some bypass load there, in all members. The critical fastener row is the outermost one, near a tip of the splice plate. The smallest, most flexible fasteners are used there (*w/d*= 5), and the tip thickness of the splice plate is limited to prevent those bolts from picking up too much load. It was found that the bearing stress in the skin on that critical row of fasteners could be kept under 25% of the ultimate bearing strength. The resulting high structural efficiency, at a gross-section strain of 0.005, is shown by Fig. 33 to be much higher than can be obtained with optimized single-row bolted composite joints. It is also much higher than can be achieved by nonoptimized multirow bolted composite joints. For example, adding a second row of fasteners in tandem, while retaining the optimal

spacing for a single-row joint, would increase the joint strength by only about 10%, a rather small gain for having doubled the number, weight, and cost of the fasteners.

The strength increase is even greater with respect to off-optimal joints, with one or more rows of fasteners, proportioned in such a way as to enforce benign failures in bearing. While that is a noble goal, it must be recognized that there is an associated loss of about one-third of the ultimate strength to obtain that noncatastrophic indication of an overload.

Figure 36 shows how the strength of typical bolted composite structures varies with fiber pattern as well as with the efficiency of the joint design for mechanically fastened composite joints. It is apparent that the most efficient multirow joints are about 50% as strong as the unnotched parent laminate. Moreover, the joint strength is not very sensitive to the fiber pattern, even for a 6.5 mm (0.25 in.) diameter bolt, and becomes even less sensitive for much larger fasteners. The joint strength curves in Fig. 36 would tend to become much flatter and lower for larger bolt sizes for both joints, either with more than one row of fasteners or only one, if it were not that the critical fastener of a multirow joint has to be kept small to raise the structural efficiency by limiting the load it can accept.

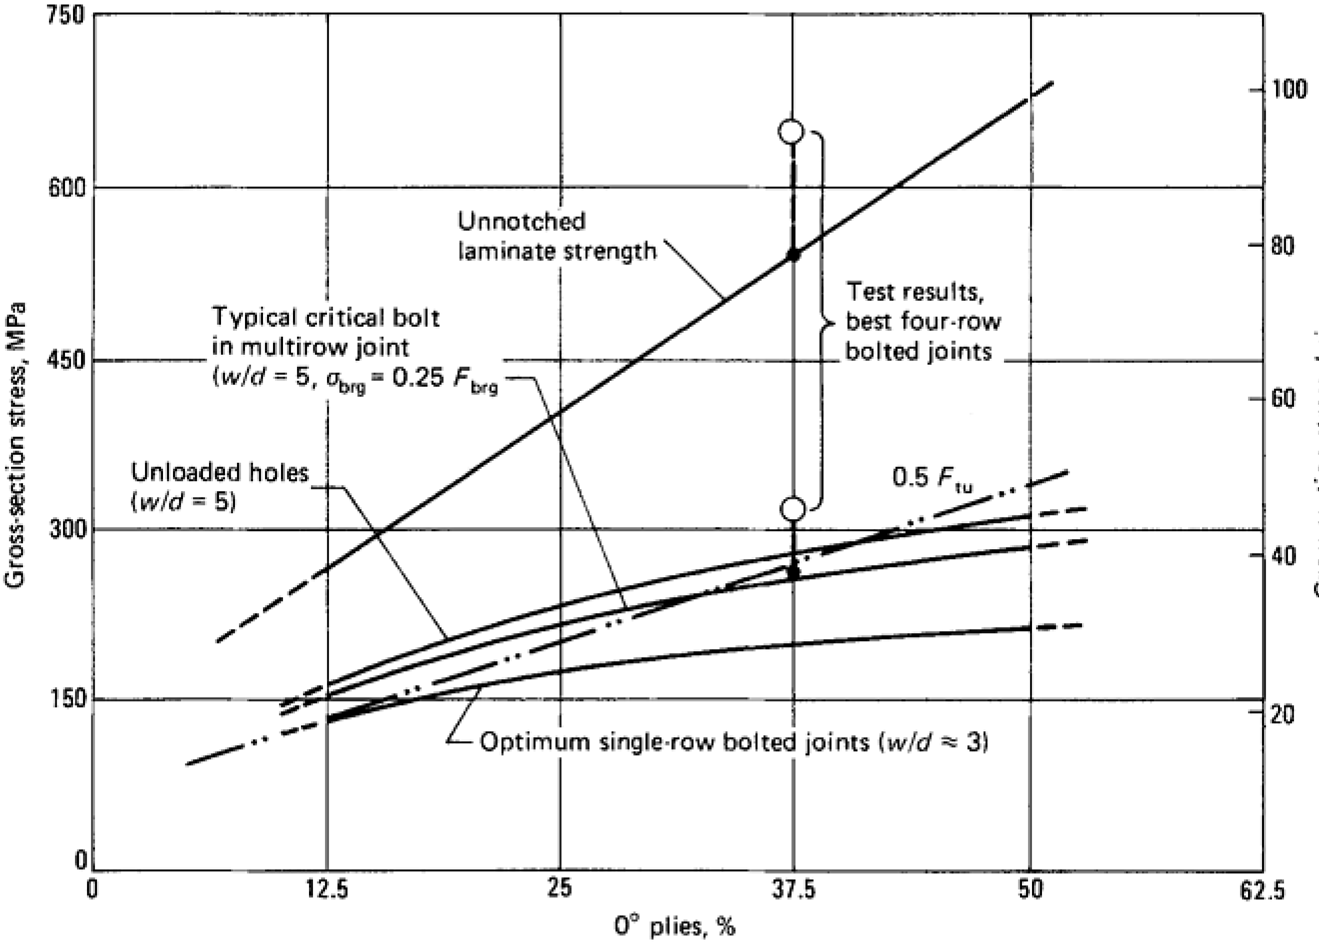

Fig. 36 Gross-section design stresses for bolted composite structures (carbon/epoxy laminates). Chart applicable for bolts up to 9.5 mm (37 in.) in diameter. Larger bolts are associated with progressively lower laminate stresses.

Practical Considerations

To attain the high structural efficiency of bolted composite joints, each fastener must accept its correct share of the load. Because composites fail at a very low strain level, such proper load sharing is incompatible with loose-fit holes. On the other hand, the testing of interference-fit fasteners, which were either hammered in or twisted in, also left something to be desired. The obvious solution to this dilemma is the use of a loose sleeve that subsequently is expanded to fit properly when the fastener (bolt or rivet) is installed. Much valuable work on this subject has been performed by E.R. Speakman (Ref 49). A sleeved rivet is illustrated in Fig. 37.

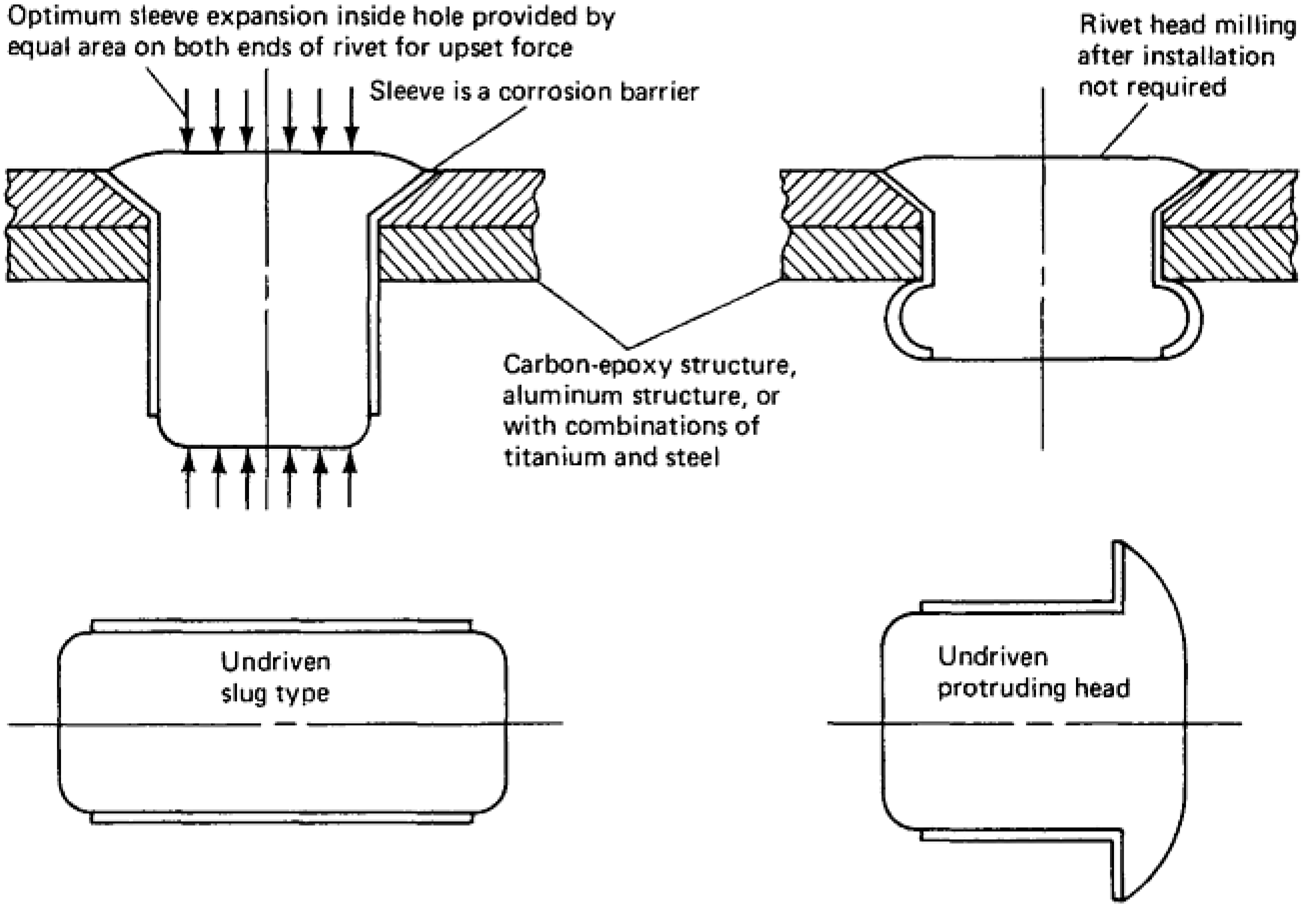

Fig. 37 Sleeved rivet

A similar problem exists in composite laminates in regard to the use of countersunk fasteners, particularly single-shear fasteners. As indicated in Fig. 38, as the fastener rotates under low loads, the head moves out of contact with the laminate, and all of the load is reacted by bearing on the (parallel) shank. For this reason, the author advocates that, in the analysis of countersunk fasteners, the head be totally discounted. Such a procedure means restricting the depth of the countersink to no more than one-half the thickness of the outer member. Only after the shank area has failed in bearing does the head make contact with the laminate again.

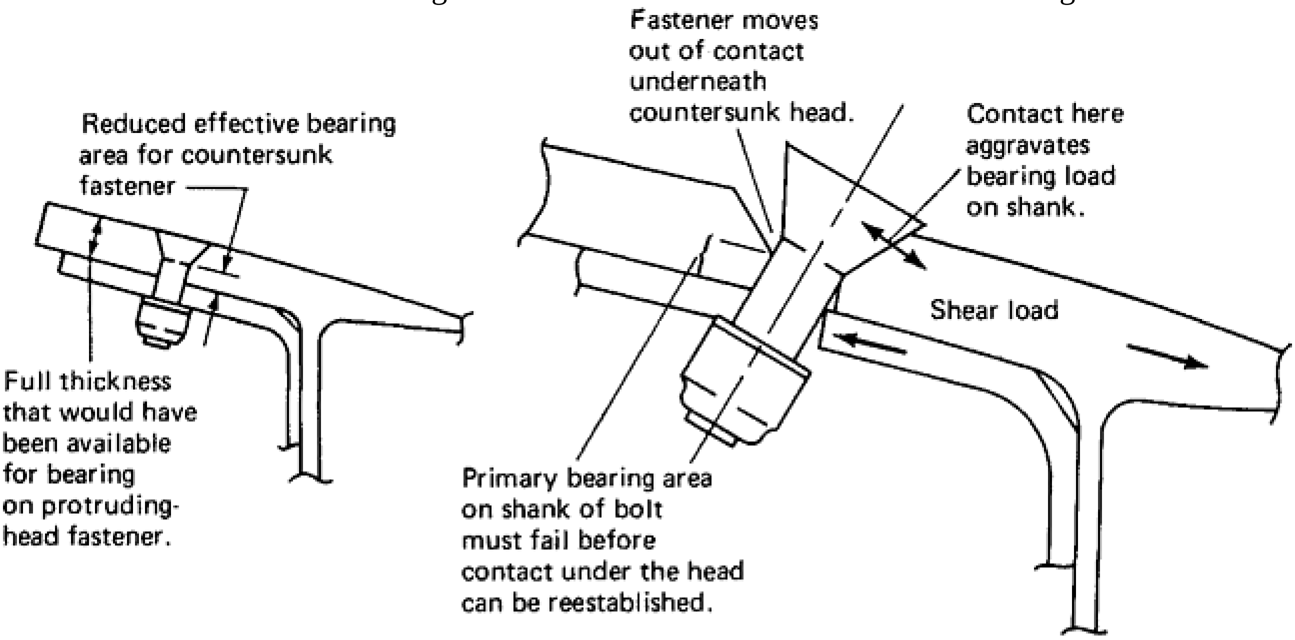

Fig. 38 Problems with using flush fasteners at fittings for composite structures

Such a design procedure would imply a minimum skin thickness of twice the size of the countersunk head on the fastener, even though it has become common practice to countersink deeper, in some cases knife-edging the outer composite member. There is no universal analysis method to cover the design of such questionable joints, and there have been failures associated with such concepts, even though some tests show such a practice to be tolerable, while others have not. It is necessary to confirm the adequacy or inadequacy of such designs by specific testing. Alternatively, because this problem can arise only for relatively thin structures, adhesive bonding might well be considered instead.
A related issue is the installation of fittings in composite control surfaces. Whenever such fittings occur behind cutouts in the leading edge of the surface, it is always permissible to use shallow protruding-head fasteners, as shown in Fig. 39. (The drag from the cutout masks that from the fastener heads.) Not only is there more effective bearing area on the shank than with countersunk fasteners, but the bolt-bearing allowable strength is also raised by about a factor of 2, because of the through-the-thickness clamp-up on the laminate. This substantial improvement on bearing strength is illustrated in Fig. 29.

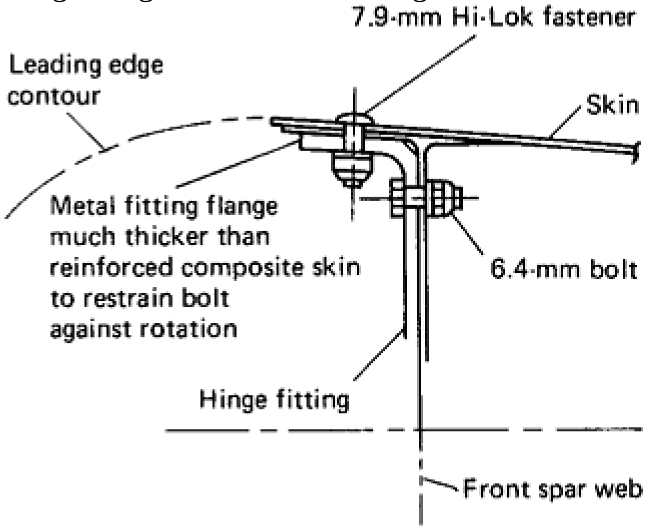

Fig. 39 Thickened hinge fitting flanges to minimize bolt bearing stresses. Hi-Lok (Hi-Shear Corp.)

A considerable simplification in the design process for mechanically fastened composite structures is afforded by the use of diagrams such as Fig. 40, which was prepared for older carbon fibers. Points A and B in the figure could probably be raised by a strain increment of 0.001 for the newer high-strain fibers. Such a simple chart, which can reasonably be applied when there are orthogonal load components also present, can safely cover all of the relatively lightly loaded fasteners, as at skin-to-spar and skin-to-rib seams on wings, leaving only the few major load-transfer splices requiring more detailed analysis of the kind discussed in the section “Multirow Bolted Composite Joints” in this article.

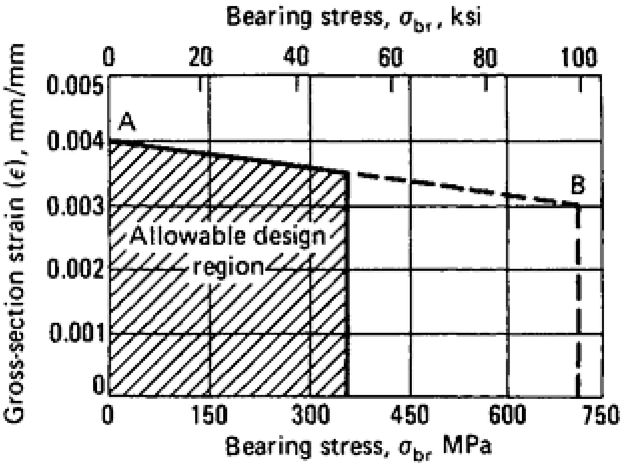

Fig. 40 Example of design guidelines for bolted carbon/epoxy structures

It is not possible to cover all that is known about joints in fibrous composite structures in a single article. Only some of the highlights have been addressed here, and the reader is referred to the references cited and the other copious literature on the subject for further information.

It has been explained here that adhesive bonding is more suitable than mechanical fastening for thin structures (both composite and metal), and that the strength of such joints can, and should, exceed the strength of the members being joined. The issue of the durability of bonded joints is just as important as the short-term static strength, and distinct, albeit simple, design features are needed to ensure that the adhesive bonds will not fail prematurely.

Either mechanical fastening or more complex, bonded stepped-lap joints are needed for thicker, more highly loaded structures; adhesive bonds would only act as weak-link fuses in thick structures. It is never acceptable to design an adhesively bonded joint that is weaker than the members being joined. On the other hand, bolted composite joints can never be as strong as the member being joined, either, unless one resorts to softening strips and local pad-ups, which leave the basic structure too highly stressed to be repaired. Indeed, designing to structural efficiencies of 50% is quite a challenge. Finally, it should be noted that the design of the joints should always precede the process of filling in the gaps (sizing the laminates), and that due consideration should always be given to designing structures that can be repaired.

Instability Considerations

Gerald Flanagan and Carol Meyers, Materials Sciences Corporation

Introduction

THE ANALYSIS OF STABILITY for laminated composite plates owes much to theoretical developments for isotropic plates and shells. Indeed, much of the progress in understanding stability of composites has occurred by rederiving the isotropic results while taking into account all of the additional stiffness terms that can be present for a composite. While the additional terms greatly increase the length and complexity of the equations, the fundamental mechanics largely remain the same. Considerable basic information on the buckling of composite plates and shells may be found in 1, 2 3, 4 5, 6. In addition, an extensive review of literature can be found in Ref 7. This article focuses on the unique characteristics of composites and laminated plates. It also focuses on stability issues associated with practical, structural laminates. The study of instability can also include postbuckling behavior. However, in a brief article, postbuckling phenomena cannot be addressed.

Background

Instability in laminated flat plates or shells is a state of critical loading, such that a small perpendicular static load would result in a large transverse displacement. The laminate is said to buckle. In dynamic situations, loading on the laminate is such that the response to transverse vibratory input is much greater than if it were unloaded.

This article assumes a familiarity with lamination theory. For laminated plates, the most general relationship between in-plane force intensities (N_i), moment intensities (M_i), strains (ϵ_i), and curvatures (κ_i) is given by the expression:

$$\begin{Bmatrix} N_x \\ N_y \\ N_{xy} \\ M_x \\ M_y \\ M_{xy} \end{Bmatrix} = \begin{bmatrix} A_{11} & A_{12} & A_{16} & B_{11} & B_{12} & B_{16} \\ A_{12} & A_{22} & A_{26} & B_{12} & B_{22} & B_{26} \\ A_{16} & A_{26} & A_{66} & B_{16} & B_{26} & B_{66} \\ B_{11} & B_{12} & B_{16} & D_{11} & D_{12} & D_{16} \\ B_{12} & B_{22} & B_{26} & D_{12} & D_{22} & D_{26} \\ B_{16} & B_{26} & B_{66} & D_{16} & D_{26} & D_{66} \end{bmatrix} \begin{Bmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \\ \kappa_x \\ \kappa_y \\ \kappa_{xy} \end{Bmatrix} \quad \text{(Eq 1)}$$

where A_{ij}, B_{ij}, and D_{ij} are computed using standard lamination theory. The A_{ij} coefficients are the stretching stiffness terms, the B_{ij} terms represent stretching-bending coupling, and the D_{ij} terms represent bending stiffness. N_i has the units of force/per unit length, and M_i has the units of force times length per unit length. For a symmetric plate, the B_{ij} terms are zero. In this case, the in-plane forces and midplane strains decouple from the moments and curvatures.

Under thin-plate assumptions (Kirchhoff theory), the vertical equilibrium in the presence of in-plane loads is given by:

$$D_{11}\frac{\partial^4 w}{\partial x^4} + 4D_{16}\frac{\partial^4 w}{\partial x^3 \partial y} + 2(D_{12} + 2D_{66})\frac{\partial^4 w}{\partial x^2 \partial y^2} + 4D_{26}\frac{\partial^4 w}{\partial x \partial y^3} + D_{22}\frac{\partial^4 w}{\partial y^4} = N_x \frac{\partial^2 w}{\partial x^2} + 2N_{xy}\frac{\partial^2 w}{\partial x \partial y} + N_y \frac{\partial^2 w}{\partial y^2} \quad \text{(Eq 2)}$$

where w is the out-of-plane deflection of the plate. Solutions of this equation form the basis of linear buckling theory for thin, symmetric, anisotropic plates.

Instability Considerations

Gerald Flanagan and Carol Meyers, Materials Sciences Corporation

Orthotropic Plates

In the full form of the plate equations, the terms D_{16} and D_{26} are bending-twisting coupling terms. If D_{16}=D_{26}= 0, then the plate is orthotropic in bending. Many composite laminates are not exactly orthotropic (see the subsequent anisotropic plate discussion). However, assuming orthotropic properties is often a reasonable assumption that leads to important simplifications to the governing equations. Simple-support (SS) boundary conditions will be satisfied by any term in the series:

$$w = C_{mn}\sin\left(\frac{m\pi x}{a}\right)\sin\left(\frac{n\pi y}{b}\right) \quad \text{(Eq 3)}$$

where a and b are the panel dimensions in the x and y directions, respectively, C_{mn} is a constant coefficient, and m and n are integers. For an orthotropic plate, and N_{xy}=0, Eq 1 will be satisfied by any term of the series (Eq 2) if N_x=N_{xcr}, where:

$$N_{xcr} = -\frac{\pi^2\sqrt{D_{11}D_{22}}}{b^2}k \quad \text{(Eq 4)}$$

and k is a buckling coefficient for a compressive load. Here, the convention is adopted where a negative load is compressive. For the SS boundary condition, k is given by:

$$k = \frac{D_{11}m^4 + 2c^2(D_{12} + 2D_{66})m^2n^2 + c^4 D_{22}n^4}{\sqrt{D_{11}D_{22}}\,(c^2m^2 + c^4n^2R)} \qquad \text{(Eq 5)}$$

where c is the aspect ratio, a/b, and R is the load ratio, N_y/N_x. The number of half-waves in the buckling mode shape are determined by the wave numbers m and n. One must find the values of m and n that yield the smallest value of k, and thus the smallest buckling load. If R= 0, then the minimum value of k_c occurs when n= 1. The value of m is a function of the plate aspect ratio and materials properties. This is illustrated in Fig. 1, in which the minimum buckling coefficient is plotted for the special case of $(D_{12}+ 2D_{66})/D_{22}$= 1, and different values of D_{11}/D_{22}. For D_{11}/D_{22}= 1, the plate is isotropic.

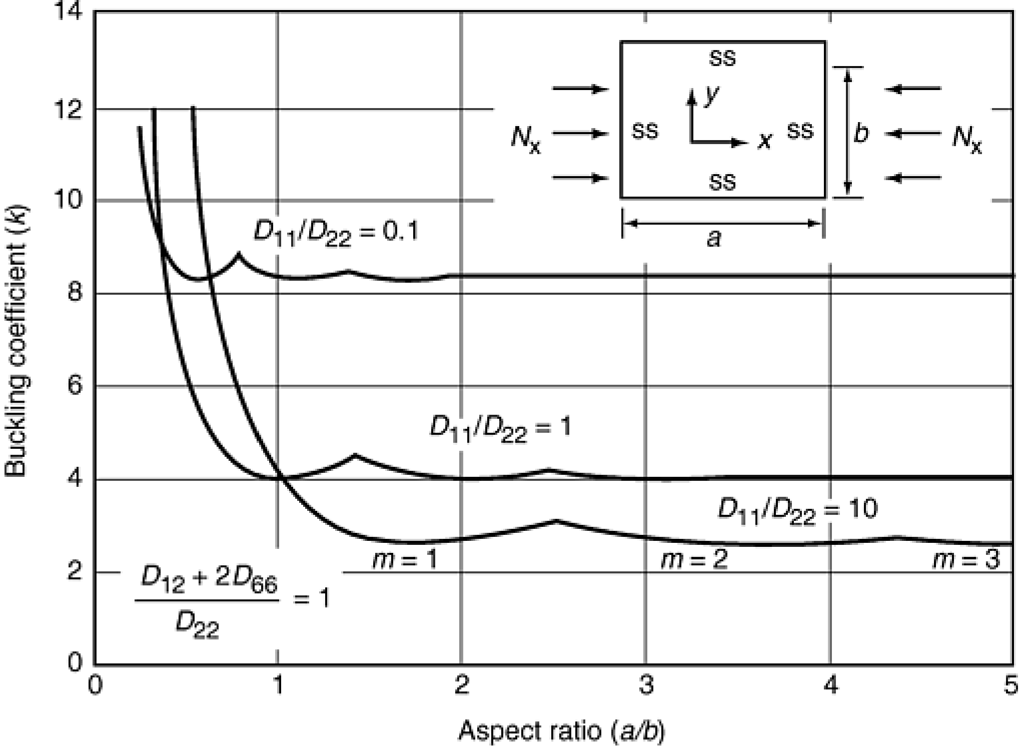

Fig. 1 Buckling coefficient for plate under uniaxial compression

For a given plate-aspect ratio, it is possible to plot the buckling coefficient as a function of the laminate stack. For a square plate (a/b= 1), the buckling coefficient as a function of the percentage of ±45° plies in a [±45/0/90] family laminate is shown in Fig. 2, where the 0° degree ply direction is parallel to the x-axis of the plate. In this plot, the buckling load is normalized by the layer fiber-direction modulus, (E_1). For a square panel, the optimal laminate for buckling uses all ±45° layers. The other counter-intuitive result is that the buckling load is independent of the relative percentage of 0° and 90° layers. The optimal laminate changes depend on the aspect ratio. Figure 3 shows a carpet plot of buckling coefficients for the same [±45/0/90] family of laminates, and a/b= 0.25. In this case, the optimal laminate contains all 0° plies. In the carpet plot format, the solid lines represent different percentage of 0° layers. The dashed line represents the limit of zero percentage of 90° layers.

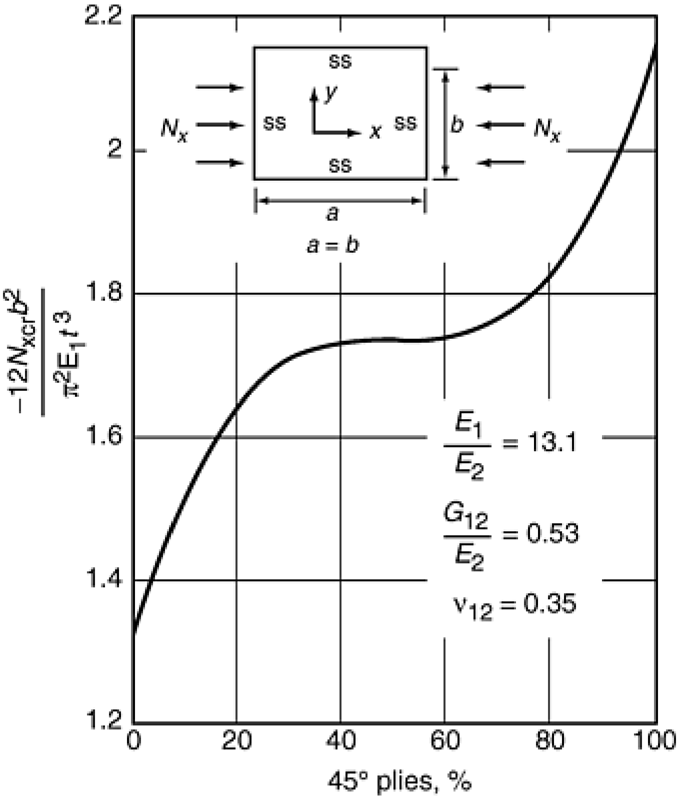

Fig. 2 Normalized buckling coefficient as function of percentage of ±45° plies. [±45/0/90] family laminate, square (*a/b*= 1). Uniaxial compressive load

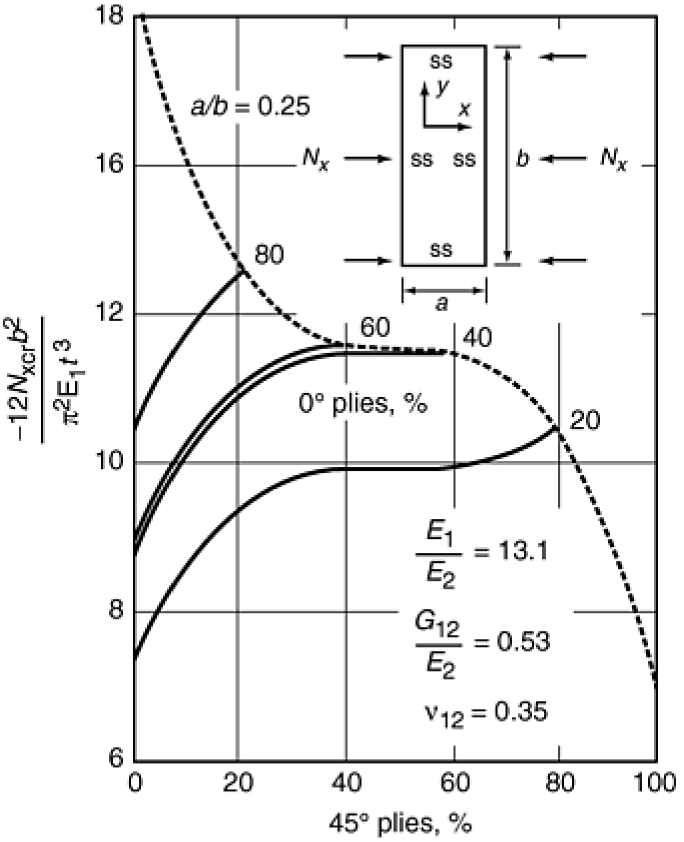

Fig. 3 Carpet plot of normalized buckling coefficient. [±45/0/90] family laminate with *a/b*= 0.25. Solid lines indicate different %0° plies. Dashed line is limit of 90° ply = 0%. (%90°= 100%–% 0°–%45°)

The shear load case does not have a closed- form solution. Equation 3 still applies for SS boundary conditions, but Eq 2 is not satisfied by a single term of the series. A typical approach is to use an energy method to obtain

an approximate solution using a finite series. The buckling coefficient plot for shear load (N_{xy}) given in Fig. 4 was created using such an approach. Using this coefficient, the buckling load for shear is given by:

$$N_{xycr} = \frac{\pi^2 \sqrt[4]{D_{11} D_{22}^3}}{b^2} k_s \quad \text{(Eq 6)}$$

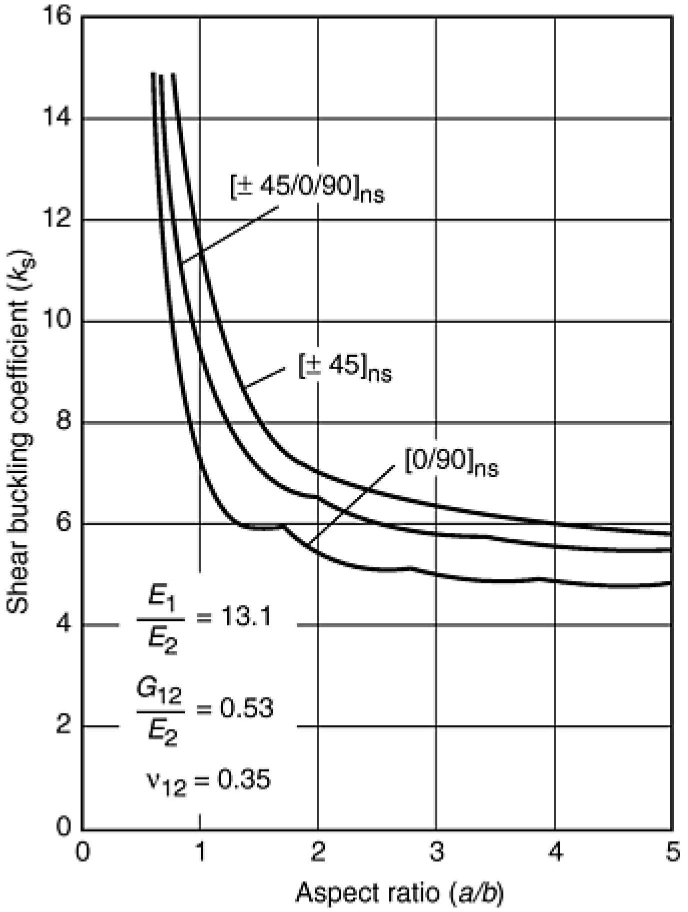

Fig. 4 Shear buckling coefficient for various graphite/ epoxy laminates

Materials properties for a typical intermediate modulus graphite/epoxy material (E_1= 21 × 10^6 psi, E_2= 1.6 × 10^6 psi, G_{12}= 0.85 × 10^6 psi, ν_{12}= 0.35) were used in the calculations for Fig. 4, and the curves are for specific stacking sequences. The plot assumes that the number of ply groups, *n*, is large, so that the laminate is effectively homogeneous through the thickness. For the shear case, there is a less distinct transition as the number of waves in the mode shape changes.

Approximate buckling coefficients for a variety of other boundary conditions and load cases can be found in the literature. One of the most complete collections available is contained in Ref 8.

Finite Stack Effects

Carpet plots can be generated assuming that the plate behaves as a homogeneous material. For example, one can compute the effective in- plane stiffness (the **A** matrix in Eq 1) using lamination theory. An approximation of the bending stiffness is:

$$D_{ij} = \frac{h^2}{12} A_{ij} \quad \text{(Eq 7)}$$

This equation assumes that the position of the ply in the stack is not important. In reality, the bending stiffness of a composite plate is a function of the stacking sequence. The importance of stacking sequence is particularly evident for thin laminates with a small number of layers. This effect is shown in Fig. 5 for a $[0/90]_{ns}$ laminate and a $[90/0]_{ns}$ laminate, where *n* is the number of times the basic ply pattern is repeated. In Fig. 5, the buckling load is normalized by the bending stiffness using a homogeneous assumption. As seen in the figure, for an infinite number of ply groups, the buckling coefficient for both patterns will approach 1. For a small number of ply groups, there can be a considerable error in the homogenous assumption.

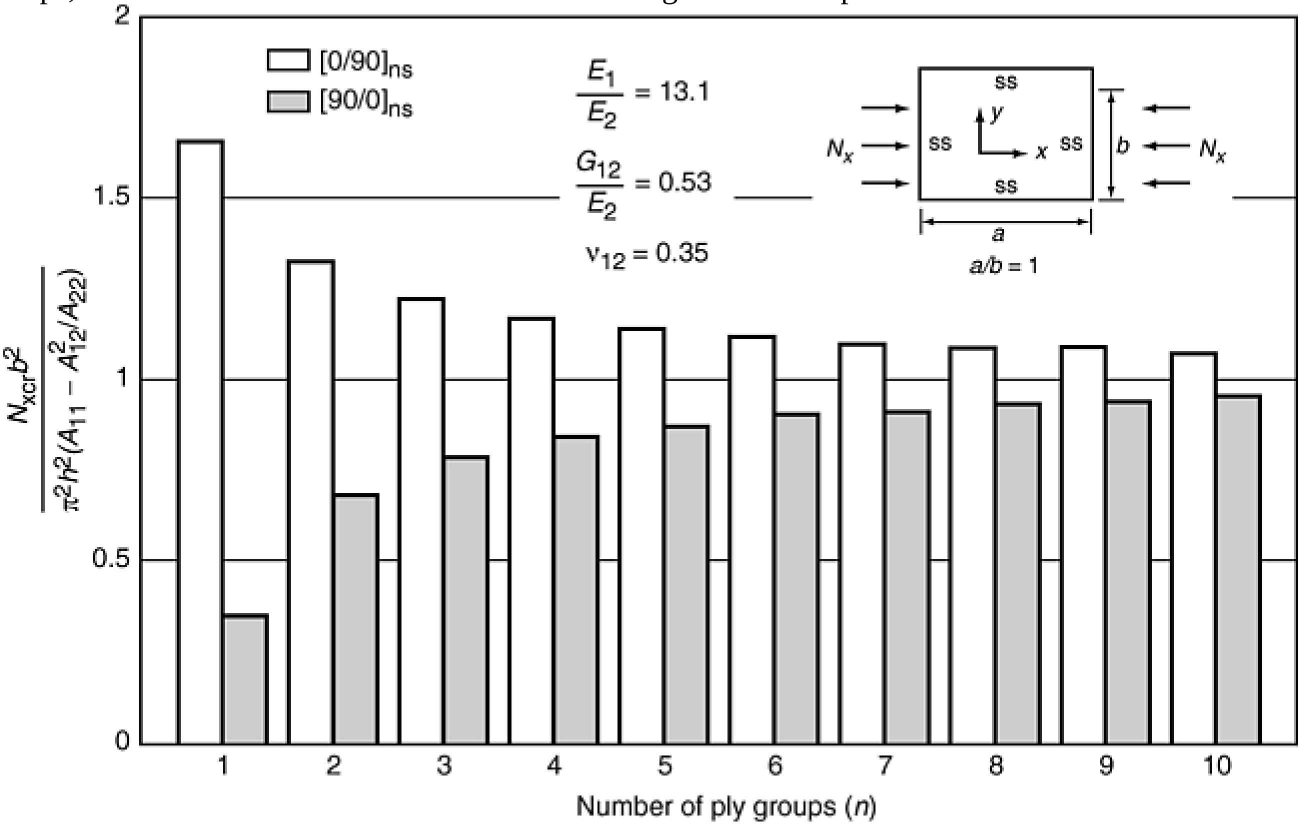

Fig. 5 Normalized buckling load for $[0/90]_{ns}$ and $[90/0]_{ns}$ laminates as a function of number of ply groups

Anisotropic Plates

Any composite laminate that uses angle plies (±θ) in the stacking sequence will have some degree of anisotropy in the bending stiffness. This means that the D_{16}, D_{26} bending-twisting coupling terms will not be exactly 0, even if there are an equal number of plus θ and minus θ plies. The effect is demonstrated in Fig. 6. Here, the ratio of D_{16} to D_{11} is plotted as a function of the number of repeated ply groups in a $[\pm 45]_{ns}$ laminate. The relative magnitude of D_{16} rapidly decreases with the number of ply groups, but will never exactly reach 0. The presence of D_{16} and D_{26} generally decreases the buckling for an axially loaded plate, as shown in Fig. 7.

Closed-form solutions can be obtained for the buckling of long (infinite) anisotropic plates. These solutions provide a lower bound for the anisotropic effect. Parametric studies of the influence of D_{16} are given in Ref 9.

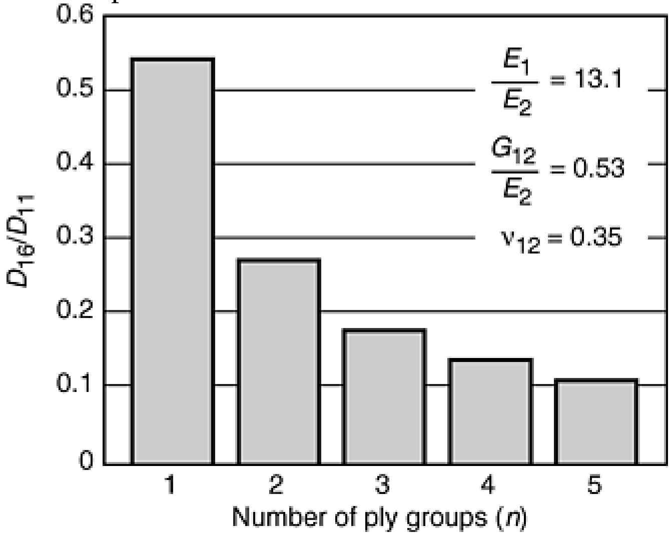

Fig. 6 Relative size of bending-twisting term as a function of number of ply groups for a $[\pm 45]_{ns}$ laminate

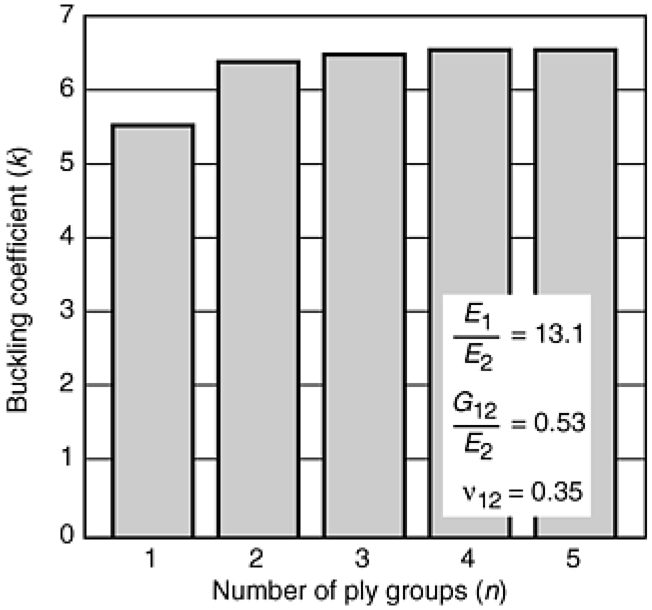

Fig. 7 Buckling load coefficient as a function of number of ply groups for a $[\pm 45]_{ns}$ laminate with *a/b*= 1

Another important difference between plates and shells with orthotropic or isotropic properties and those with anisotropic properties is the reflection symmetries of the mode shapes. While orthotropic plates exhibit reflection symmetry (or antisymmetry), allowing the use of quarter- plate models, anisotropic structures do not. Instead, anisotropic plates and shells exhibit inversion symmetry (or antisymmetry) with respect to the normal axis, resulting in a skewing of the mode shape, as shown in Fig. 8. This skewing of the mode shape results primarily from the presence of the twisting coupling terms, D_{16} and D_{26}, and is therefore a feature even in so-called quasi-isotropic laminates.

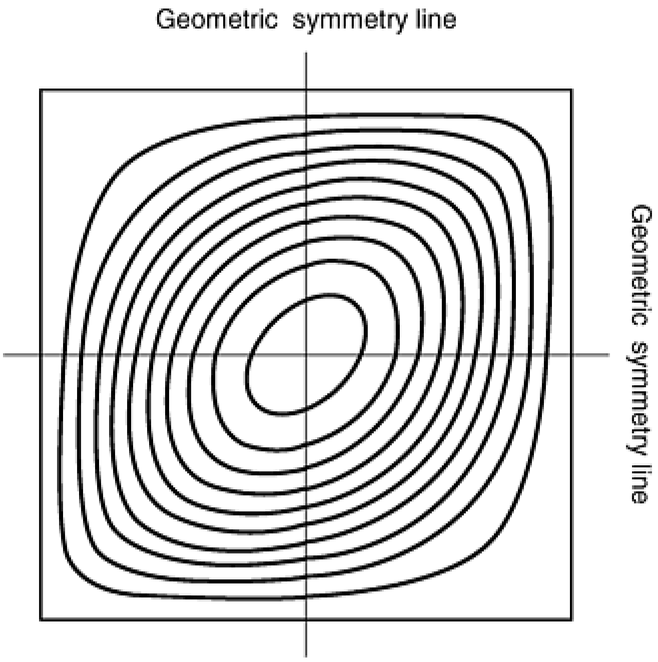

Fig. 8 Mode shape for $[\pm 45]_s$ laminate under axial load

Under shear loading, an anisotropic plate will have different buckling loads for positive and negative shear.

Instability Considerations

Gerald Flanagan and Carol Meyers, Materials Sciences Corporation

Unsymmetric Plates

Most structural laminates are constructed using a stacking sequence that is symmetric about the geometric midplane of the plate. Using a symmetric laminate eliminates the bending- stretching coupling that can exist for a general laminate. The bending-stretching coupling is reflected by nonzero **B** matrix terms in lamination theory. The presence of a nonzero **B** matrix will usually reduce the theoretical buckling load of a plate. One should use caution with the concept of linear buckling for a nonsymmetric plate, because out-of-plane deflections will occur when in-plane loads below the buckling value are applied.

Nonsymmetry also adds an additional degree of complexity to the solution of the plate buckling equations. However, if the edge boundary conditions are such that there are no in-plane forces as a result of bending deflections, that is, the edges are free to translate in the plane of the plate, then one can use reduced bending properties in the equations for a symmetric plate. The reduced bending stiffness matrix, $\tilde{D}$, is given by:

$$\tilde{\mathbf{D}} = \mathbf{D} - \mathbf{B}^T \mathbf{A}^{-1} \mathbf{B} \quad \text{(Eq 8)}$$

Gerald Flanagan and Carol Meyers, Materials Sciences Corporation

Transverse Shear Stiffness Effects

The interlaminar shear stiffness relative to the in-plane properties of a fiber reinforced composite is typically much smaller than for homogeneous materials. The reduced stiffness means that transverse shear effects are significant for much larger width-to-thickness ratios than for metal plates. Figure 9 shows the reduction in buckling coefficient as a function of *b/t* (width over thickness) for an axially loaded plate, and Fig. 10 shows a similar plot for a shear loaded plate. The materials properties used for these plots are typical of graphite/epoxy quasi-isotropic laminates, where E_1, E_2, G_{12}, G_{13}, G_{23}, and ν_{12} are effective laminate properties. Because of this reduction in buckling load, it is important to use a finite element formulation that allows for shear deformation. These are sometimes referred to as thick-plate elements.

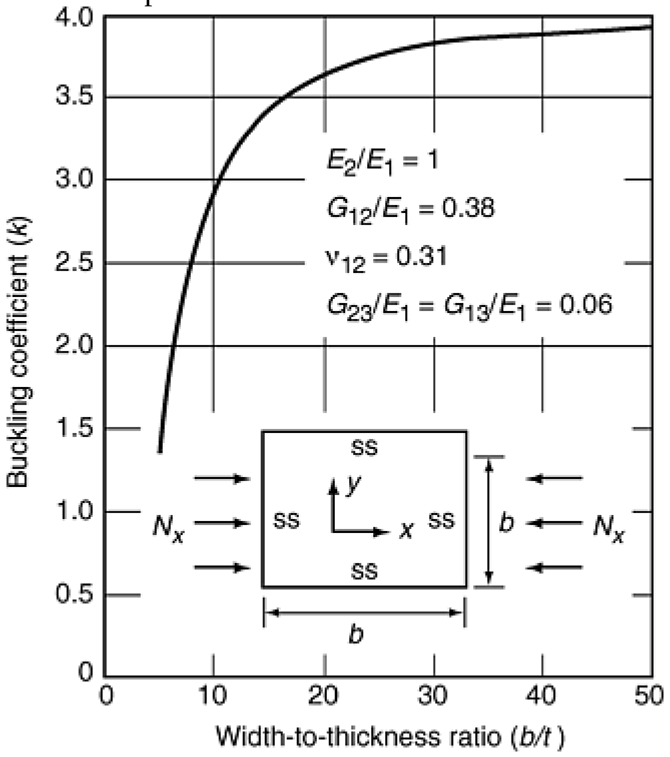

Fig. 9 Axial compression buckling coefficient as a function of width-to-thickness ratio (*b/t*) for a thick graphite/epoxy quasi-isotropic plate with *a/b*= 1

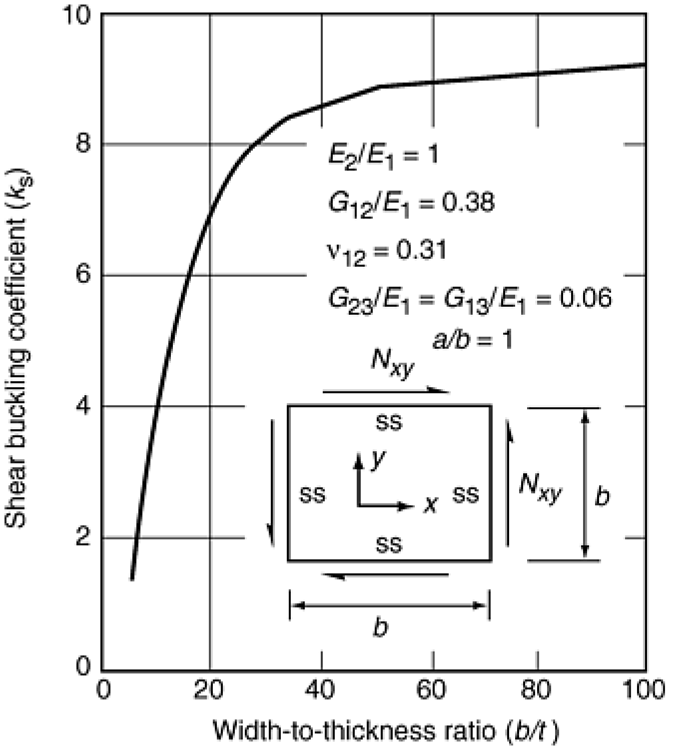

Fig. 10 Shear buckling coefficient as a function of width-to-thickness ratio (*b/t*) for a thick graphite/epoxy quasi-isotropic plate with *a/b*= 1

The most common thick-plate formulations allow for an additional rotation about the midplane of the plate in addition to the rotation related to the second derivative of *w*, as given by the Kirchhoff theory. Thus, there are additional degrees of freedom at a node in a finite element formulation.

The transverse shear stiffness of a laminated plate is also a function of stacking sequence. A commonly used method for determining the effective stiffness is given by Whitney (Ref 10). His approach involves determining the interlaminar shear stress distribution based in elasticity theory, and then finding the effective stiffness that yields the same strain energy for an assumed plate theory as for the exact stress distribution.

Edge boundary conditions require extra care when thick-plate formulations are used. For example, to specify a SS boundary condition along an edge parallel to the *x*-axis, one would normally only have to specify that *w*-displacement along the line is 0. In a thick plate, one can also specify whether rotation about the *y*-axis should be 0 or unconstrained along the same line.

Hygrothermal Buckling

Another consideration for composite structural stability is hygrothermal buckling. In this case, in-plane loads are induced at constrained edges by the expansion of the material due to thermal expansion and/or swelling of the matrix from moisture absorption. An interesting aspect of thermal buckling for graphite-fiber composites is that graphite fibers have a negative coefficient of thermal expansion, thus it is possible for plates with certain

angle-ply lay-ups to buckle due to a decrease in temperature. Moisture absorption is a consideration for polymer-matrix composites, with the amount of swelling depending on the degree of molecular cross-linking in the polymer. The article "Hygrothermal Behavior" in this Volume expands on this topic.

Gerald Flanagan and Carol Meyers, Materials Sciences Corporation

Composite Sandwich Panels

Sandwich panels can be treated as conventional laminated plates where the core is a layer of the laminate with low stiffness properties. An extended discussion of sandwich panel instability is given in Ref 11. For a sandwich panel, it is even more important to account for the transverse shear effects using a thick-plate theory or a finite element with transverse shear flexibility. Sandwich panels also exhibit additional failure modes associated with instability of the facesheet due to insufficient elastic support from the core. One form of instability is buckling between the cell walls of a honeycomb core. Facesheet instability can also occur on foam cores. A simple, approximate equation for the mode was developed by Hoff and Mautner (Ref 12), given by:

$$\sigma_{crit} = c(E_f E_c G_{cz})^{1/3} \quad \text{(Eq 9)}$$

where E_f is the facesheet in-plane modulus in the direction of the applied stress, E_c is the core through-thickness modulus, and G_{cz} is the core through-thickness shear modulus. The coefficient c is a constant and is usually assumed to be in the range of 0.5 to 0.65. More information on this topic can be found in the article "Analysis of Sandwich Structures" in this Volume.

Computer Codes

General-purpose finite element codes are typically used for the evaluation of stability for plates with more general shapes and boundary conditions. Modern finite element codes are usually acceptable for performing buckling calculations for composites if an appropriate thick- plate element is available. In addition to general-purpose codes, a number of specialized codes have been developed. The motivations for creating these codes are usually related to the ease of setting up problems, the solution speed, structural optimization, or more robust solutions for the post-buckling regime. Some of the more mature and easily obtainable codes are described.

There are several codes that start with the assumption that the structure is prismatic, that is, the geometry is uniform in one direction. This restriction allows one to assume that the deflections have a trigonometric dependence along the constant cross-section direction. The governing equations for the transverse direction

then can be solved as ordinary differential equations. These equations can be solved by either exact or numerical methods.

A general-solution approach was first described by Wittrick and Williams (Ref 13). Their code, called VISPASA, was later incorporated into a stiffened panel optimization code called PASCO (Ref 14). The exact solution scheme allows for rapid solutions, which in turn makes the optimization process more practical. PASCO is particularly useful for stiffened composite panels in which both the laminate and geometry of the stiffener are design variables. The basic approach has been enhanced by later developments (Ref 15).

Another efficient panel optimization code is PANDA2 (Ref 16). PANDA uses a combination of closed-form equations and numerical approximations to check a number of potential failure modes.

Structural Analysis of General Shells (STAGS) (Ref 17) is frequently used when a postbuckling solution is needed. STAGS uses the finite element method, and therefore can be used for general shapes and boundary conditions. The strength in STAGS is in its robust nonlinear algorithms. There is a large body of literature that demonstrates STAGS for a variety of stiffened plate and shell problems.

Shell Panel Instability

Many of the general observations made about the effects of anisotropy and shear deformation on composite plate stability also hold for shells. Buckling characteristics of shell panels may be different from those of plates even in the case of isotropic materials, however, because of the coupling of in-plane and out-of-plane responses due to the shell curvature. This may be further complicated in the case of composites by the presence of anisotropy. The complexity of the shell theory used to address these issues depends on the thickness, coupling, and geometry for a given shell configuration. A detailed discussion of the issues is beyond what can be accomplished within a short article. References 5 and 18, 19 20, 21 contain more detailed discussions of this topic.

Damage Tolerance

Mike R. Woodward and Rich Stover, Lockheed Martin Aeronautics Company

Introduction

THE DAMAGE TOLERANCE DESIGN PHILOSOPHY has been required on all U.S. Air Force aircraft as a result of a catastrophic in- flight failure in the 1960s. This philosophy requires a fracture-mechanics-based analytical demonstration of the ability of the airframe to operate safely for a specified period of time with periodic inspections of the airframe. The initial design goal is to have an inspection interval equal to the desired life of the aircraft. However, if this is not achievable due to an increase in the severity of usage or analytical errors, the aircraft can be operated safely for an extended period of time with the imposition of periodic inspections. The frequency of these inspections is based on the analytically predicted life of critical airframe components.

This article addresses the issue of the implementation of composite damage tolerance requirements as it relates to military aircraft. The issue of damage tolerance is applicable to other aircraft and applications in other industries as well. A Federal Aviation Administration (FAA) proposed policy for the certification of materials for other planes, including acrobatic and commuter aircraft, recognizes that key properties of structural laminates must include impact-damage element strengths. The FAA recognizes that complementary test data

and analysis are needed to account for the effects of damage as part of the material performance envelope for general aircraft (Ref 1).

This article includes a brief introduction of the concepts and definitions of damage tolerance and the closely related topic of durability. Also included is a discussion of the primary failure mode of interest, compression after impact (CAI). The methodology and issues associated with the development and analytical implementation of useful design allowables are also presented. Finally, since the damage tolerance criteria were developed for metallic structures, a discussion of certain shortcomings of current criteria, due to the unique growth and failure characteristics of composites, will be presented.

---

Definitions

Durability of a structure is its ability to maintain strength and stiffness throughout the service life of the structure (Ref 2). Durability also addresses such issues as corrosion resistance, fatigue, and thermal damage, which are discussed elsewhere in this Volume. The structure must have sufficient durability over its design life to meet its expected loads and environment without imposing an onerous maintenance or inspection burden upon the operator. The level of damage associated with the durability requirement is associated with typical impact events or manufacturing-induced flaws. Durability is primarily an economic issue and applies to all structures.

Damage tolerance is the ability of critical structures to withstand a level of service or manufacturing-induced damage or flaws while maintaining its function (Ref 2). However, the goal of this requirement is to allow operation of the aircraft over a specified period of time in order to assure continued safe operation. Safe operation must be possible until the defect is detected by routine scheduled maintenance or, if undetected, for the design life. The level of this damage tolerance and the initial flaw size for metals or required impact threat for composites is much greater than that required to meet durability requirements and represents worst-case type impact events or manufacturing-induced damage. Again, this requirement addresses a safety issue and applies only to *primary structures* necessary for safety of flight.

Durability and Damage Tolerance Criteria

Durability and damage tolerance are design philosophies in which the structure is designed to withstand a specified amount of damage or a specified damage threat. The amount of damage is a function of the structure of interest. While all procuring agencies impose damage tolerance criteria, the specifics of these criteria are tailored to the application. However, all criteria have the following in common.

Durability Impact Threat. This criterion requires that all composite structures have the capacity to withstand damage from a nuisance- type, low-velocity impact, typically 8 J (6 ft · lbf), without resulting in functional impairment. Functional impairment is defined as the presence of damage in a part that requires maintenance action. In addition, the diameter and shape of the impactor, typically 1.3 cm (0.5 in.) and hemispherical, are defined along with an impact velocity range, which assures that the impact is, indeed, low velocity. An example of the application of this criterion is the determination of the minimum thickness of a composite fuel boundary. This structure must be sized such that an 8 J (6 ft · lbf) impact does not result in a fuel leak.

Damage Tolerance Impact Threat. This criterion requires that critical, safety-of-flight structures are able to withstand damage from a worst- case, low-velocity impact without resulting in failure at a specified load level. The impact energy level is typically defined as one which results in barely visible damage up to an upper limit, typically 136 J (100 ft · lbf). Again, the diameter and shape of the impactor, typically 2.54 cm (1 in.) and hemispherical, are defined along with an impact velocity range, again assuring that the impact is, indeed, low velocity.

Other Damage Tolerance Damage Threats. Generally, other damage threats are defined. These include surface scratches of a certain length, depth, and orientation, and manufacturing defects, such as an inclusion in the laminate at the most critical location within the laminate. An inclusion could be a liner or paper backing that adheres to a prepreg. The relative criticality of the type of damage depends upon the type of structure, how it is loaded, and its location in the assembly.

Damage Tolerance

---

Specific Criteria

Specific criteria from a current military aircraft program have been summarized as follows:

Damage tolerance criteria

- *Damage tolerance impact:* Interlaminar delamination damage resulting from a low-velocity impact is assumed to represent a worst- case threat for damage tolerance analysis and verification testing. This damage shall be assumed to be representative of that caused by a 2.5 cm (1 in.) diameter hemispherical impactor dropped normal to the surface from a height of 0.6–1.2 m (2–4 ft). The kinetic energy of the impact shall be the lower of a specified upper energy limit of 136 J (100 ft · lbf) or the energy required to produce damage clearly visible from a distance of 7.5 m (5 ft). This impact threat is applicable to all fracture critical structure. *Fracture critical structure* is defined as a structure whose failure would result in the loss of the aircraft or injury to ground personnel.
- *Damage tolerance scratch:* 100 mm (4.0 in.) long by 0.5 mm (0.02 in.) deep. This tolerance limit is also applicable to all fracture critical structures.
- *Damage tolerance single circular delamination:* 50 mm (2 in.) in diameter. This tolerance limit is also applicable to all fracture critical structures.
- *Residual strength requirement:* The structure must carry maximum spectrum load after two lifetimes of fatigue loading under the critical environmental conditions.
- *Statistical basis:* Typical

Durability criteria

- *Durability impact:* Low-velocity impact 1.3 cm (0.5 in.) diameter impactor; drop height 0.6–1.2 m (2–4 ft). The kinetic energy of the impact shall be 3.4–8.1 J (2.5–6 ft · lbf) depending on availability of access and function of structure. This requirement is applicable to all structures.
- *Residual strength requirement:* Must carry maximum spectrum load after two lifetimes of fatigue loading at the critical environment.
- *Functional impairment requirement:* Impact must not result in functional impairment, such as a fuel leak, interference, or requirement for repair.
- *Statistical basis:* Typical

Damage Tolerance

Mike R. Woodward and Rich Stover, Lockheed Martin Aeronautics Company

Damage Tolerance Philosophy

The purpose of the damage tolerance design philosophy is to ensure that the aircraft can operate safely for a period of time with damage present within the airframe. Often, as the aircraft matures, internal loads are increased, or usage is determined to be more severe. In these cases, inspections may be imposed on the aircraft in order to assess the safety of continued operation of the aircraft. This usage tracking and management is a normal part of the flight test and the subsequent force management program. This philosophy is illustrated in Fig. 1 and 2 for a metallic structure and in Fig. 3 and 4 for a composite structure.

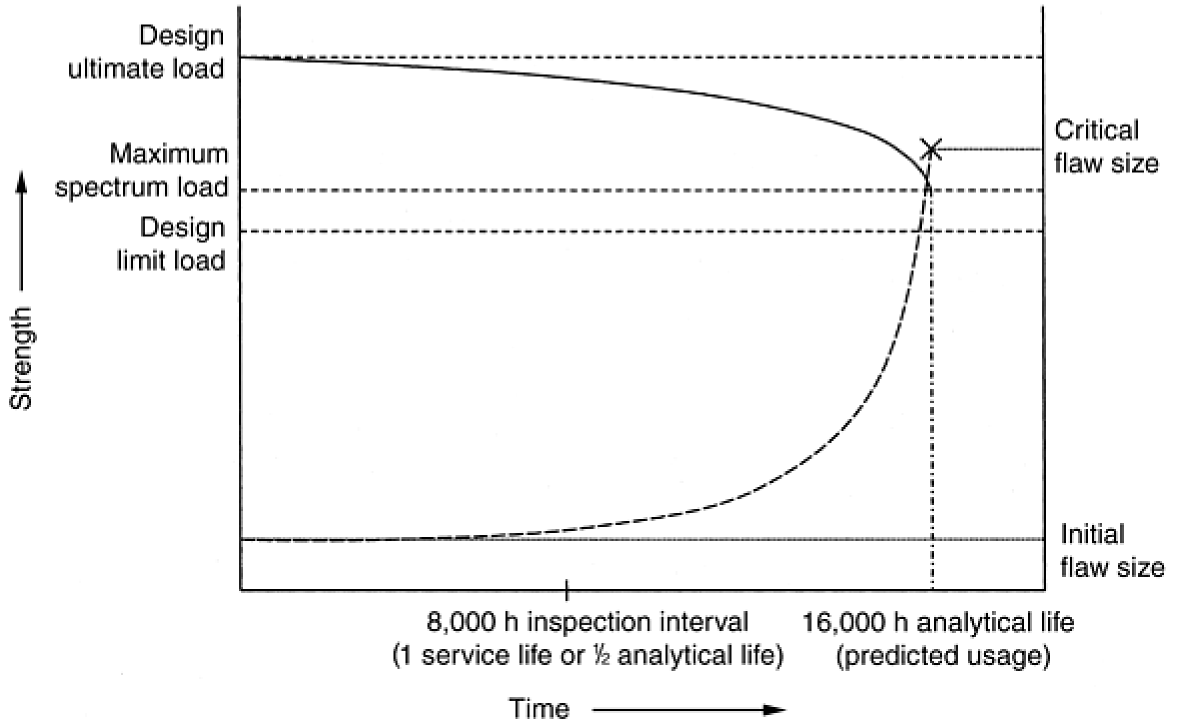

Fig. 1 Damage tolerance of a metallic structure based on initial design. Flaw size (broken line) and residual strength (solid line) are plotted versus time.

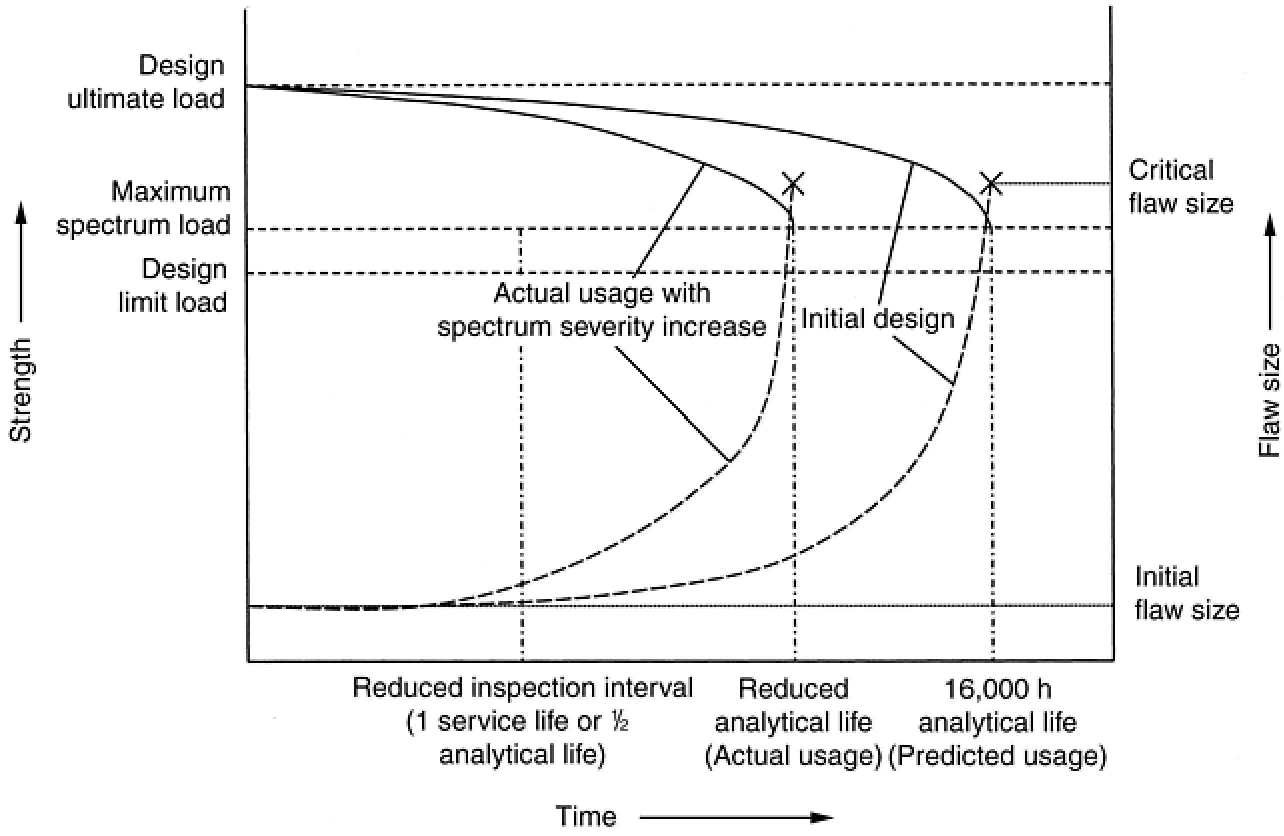

Fig. 2 Damage tolerance of a metallic structure based on actual usage. Flaw size (broken line) and residual strength (solid line) are plotted versus time. Analytical life is reduced due to increased loading, severity of usage, or the discovery of analytical errors in the original life prediction.

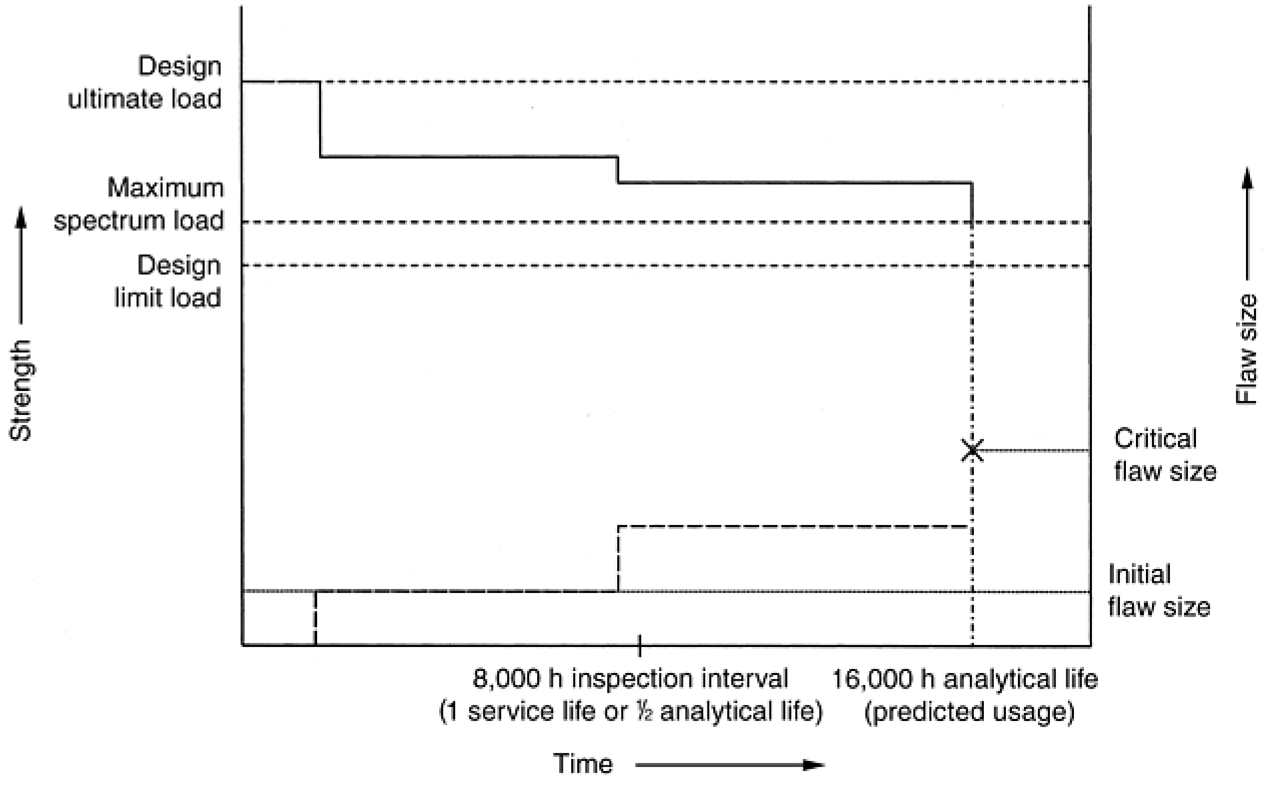

Fig. 3 Damage tolerance of a composite structure based on initial design. Flaw size (broken line) and residual strength (solid line) are plotted versus time. The step function nature of the curves represents large growths in the degradation associated with the

highest load cycles in each block of cyclic loading. The design ultimate load is 150% of the design load limit.

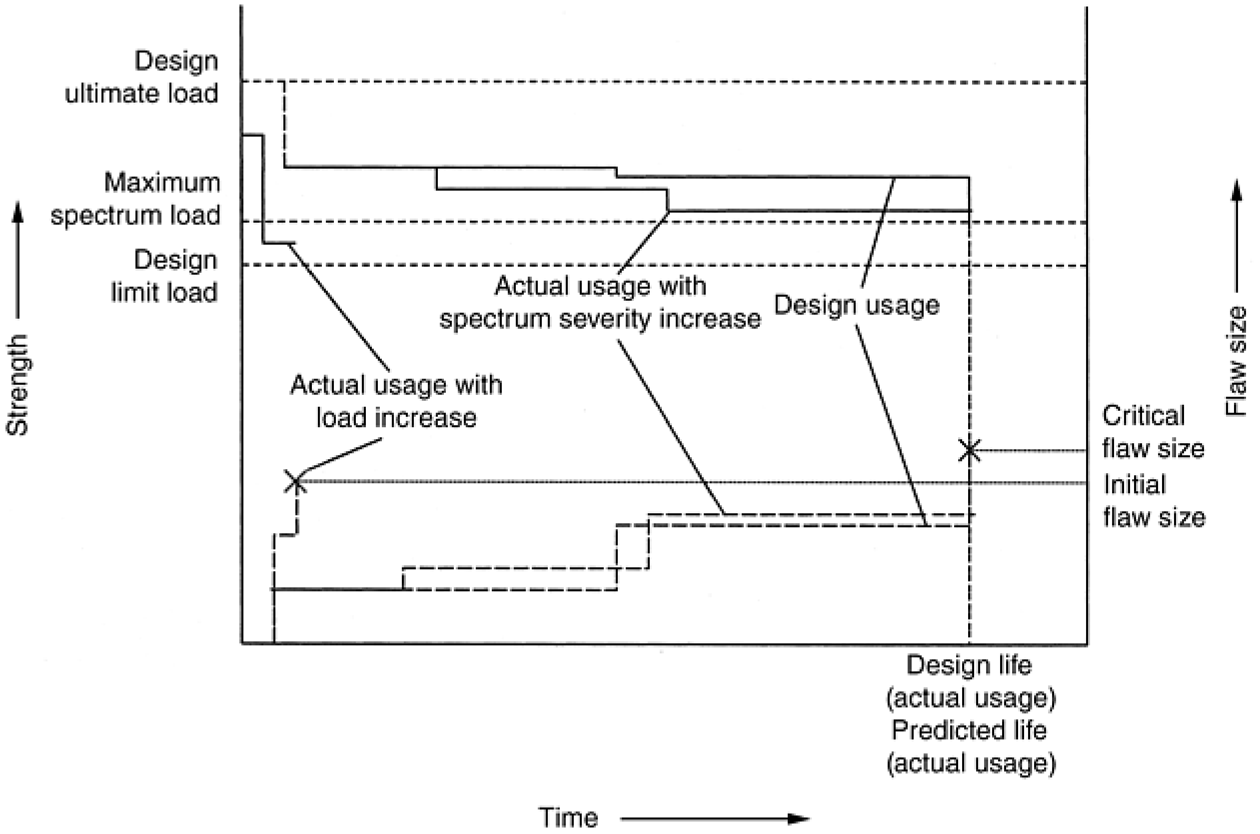

Fig. 4 Damage tolerance of a composite structure based on actual usage. Flaw size (broken line) and residual strength (solid line) are plotted versus time. Increased loading could lead to static failure. Increase in the spectrum severity does not affect the compression after impact failure mode.

Metallic Structures. The damage tolerance design philosophy for metallic structures is characterized by the following:

- The flaws are assumed to be cracks inherent in the material or induced during the manufacturing process. They are assumed to be in the most critical location for a given structure. The initial size is determined by specification (based on historical data) or by inspection technique.
- Crack growth is stable and self-similar.
- The assumed initial flaw does not appreciably affect static strength.
- The goal is to preclude fleet maintenance activity by demonstrating by analysis that a crack growth life of two times the expected usage life (an inspection interval of one usage life) exists.

Figure 1 illustrates implementation of the damage tolerance process for metallic structure at the time of initial design. Crack length as a function of time is shown for an aircraft with an 8000 h design life (i.e., an 8000 h inspection interval; the inspection interval is one-half the analytical life). The initial flaw size is determined by specification and is a function of material and inspection technique.

Figure 2 demonstrates what happens when usage severity increases or when analytical errors are discovered after the aircraft are fielded. As shown, if loads increase, there is an increase in usage severity; if an analysis error occurred, the aircraft can be operated safely for a period of time by the imposition of an inspection. This initial inspection interval is one half of the analytically-predicted life using current spectra and loads. Subsequent inspection intervals are a function of the field inspection capability. Once the structure is inspected and found to be crack free, no further maintenance needs to be performed until the re-inspection interval occurs. This process can be repeated until the aircraft is retired. Dealing with issues such as these is the function of the

force management programs implemented for all aircraft that are designed using the damage tolerance philosophy.

Composite Structures. The damage tolerance design philosophy for composite structures is concerned with the following flaw types:

- *A large, undetected manufacturing defect:* This defect is assumed to be an inclusion within the laminate, resulting in a delamination.
- *A surface scratch:* The length and depth is specified. The location and orientation is assumed to be that which is most critical for a given structure.
- *Undetected impact damage:* The damage area is consistent with an impact of an energy that caused barely visible surface damage. This damage is assumed to be in the critical location. Since this is the critical flaw for most structures, the rest of this article will focus on issues associated with this flaw type.

In addition, the damage tolerance design philosophy for composite structures is characterized by the following:

- Flaw growth is unstable and is not self-similar.
- The initial flaw (impact damage) does appreciably affect the static strength.
- The goal is to preclude fleet maintenance activity by demonstrating, by analysis and testing, that the damage described does not constitute a safety risk over the expected usage life.

Figure 3 illustrates some of these points. The growth of impact damage is characterized by periods of little to no growth at the lower load levels, followed by relatively large growth increments associated with the highest load cycles in each block of cyclic loading. Failure under cyclic loading is often quasi-static and the scatter in life is large. One detrimental aspect of impact damage is the immediate loss in static strength once the impact occurs. This phenomenon, coupled with the residual strength requirement, and the uncertainty associated with its growth characteristics are where the current criteria fail. The response of impact-damaged structures to cyclic loading will be discussed later. In summary, compression after impact does not lend itself to analytical life predictions and associated inspection intervals.

Figure 4 demonstrates the effect of an increase in usage load level. Compression strength after impact is relatively insensitive to spectrum severity. As seen, this situation could lead to a possible static failure situation. Since there is not necessarily a reliable stable flaw growth period, imposition of an inspection interval will not alleviate this situation. This growth characteristic and other issues associated with impact damage prevent the management of the presence of flaws in composite structure from being treated in a manner equivalent to metallic structure.

Damage Tolerance

Compression After Impact Failure Mode

Although, by specification, there are three types of damage tolerance flaws that are considered in the design of composite structure, the critical flaw is damage resulting from a low velocity impact.

Impact damage in a laminate is induced as a result of the contact force of the impactor and the deflection within the laminate. These contact forces result in localized crushing of the laminate resin and fiber (Fig. 5). The deflections, induced by the impact event, result in multiple delaminations resulting from interlaminar shear failures. The ply interfaces where these occur are a function of the stacking sequence of the laminate and tend to occur at interfaces at which there are large differences in the in-plane properties of the sublaminates. The size and location of the delaminations are a function of the material properties of the laminate, interlaminar shear strength, stiffness, mode II toughness, local panel stiffness, and impact energy. See the article "Fracture

Mechanics of Composite Delamination” in this Volume for more information on the modes of delamination. The deflection of the laminate may also result in the tensile failure of fibers. In most cases of low-velocity impact, the damage is confined to the matrix, and little fiber damage occurs. Therefore, the in-plane tension strength of the laminate may not be seriously degraded. However, even with impact levels that leave little indication of damage on the surface, the matrix damage may be significant, and, therefore, its ability to stabilize the fibers in compression may be seriously degraded. Because of this, tolerance to impact damage is often the critical design consideration and compression is the critical loading mode. Because this damage is insidious, the study of barely visible impact damage (BVID) is an important safety issue.

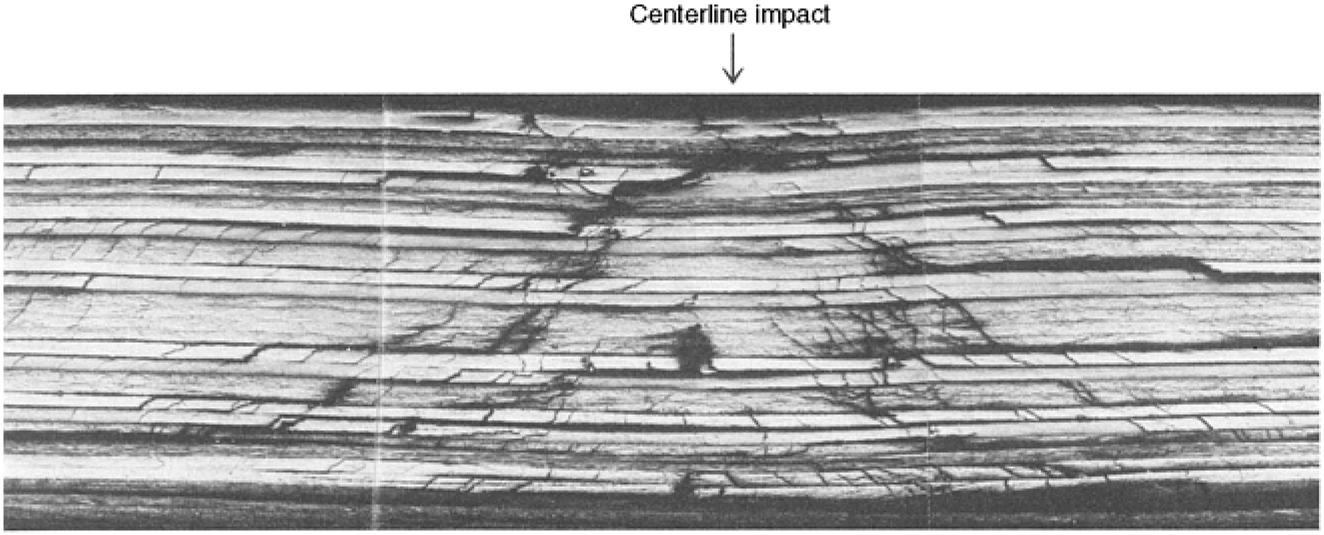

Fig. 5 Cross section of AS6/2220-3 graphite/epoxy laminate showing damage due to impact with energy of 40 J (30 ft · lbf). Diagonal shear cracks in matrix are seen and extensive delamination has occurred.

The critical failure mode for impact damage is CAI. It is a common misconception that this failure is a fiber failure, although there usually is fiber failure at final collapse. This failure has been shown, through testing, correlation, and observation of failures, to be able to be classified as an out-of-plane failure of the laminate due to buckling. In a postbuckled state, this compression results in out-of-plane loads around the perimeter of the delamination. These out-of-plane loads result in the sudden propagation of the delamination and subsequent collapse of the laminate. This CAI failure sequence is illustrated in Fig. 6.

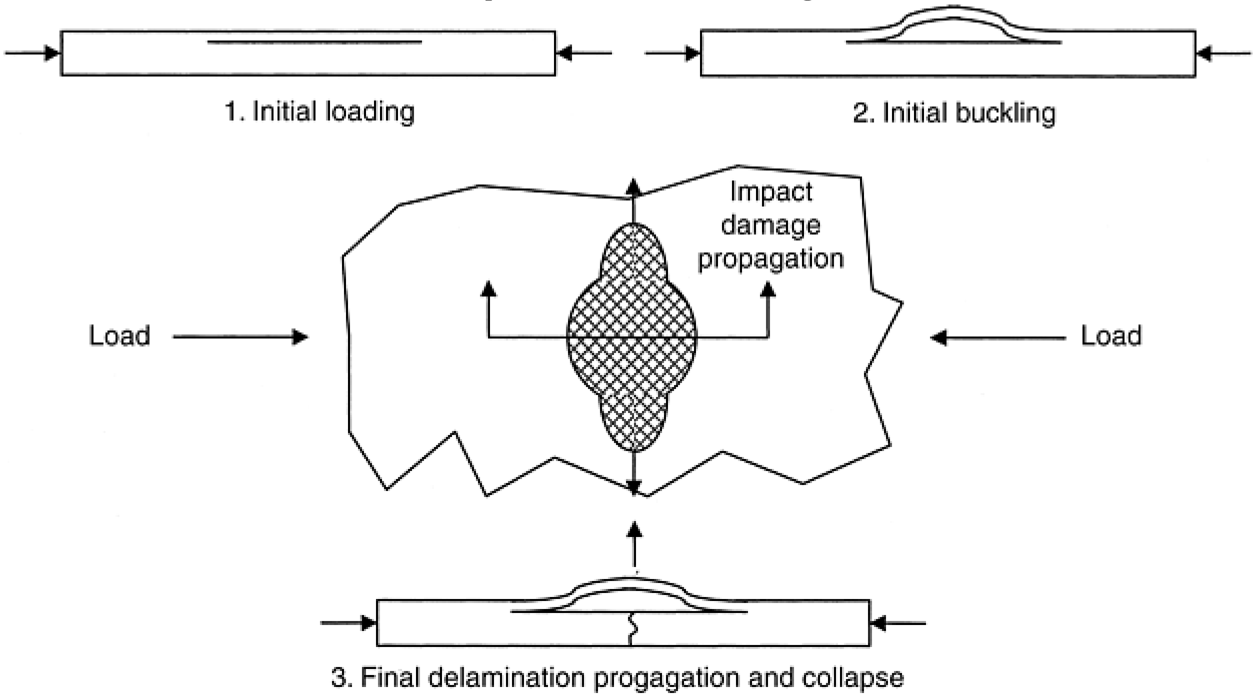

Fig. 6 The compression after impact (CAI) failure sequence. (1) At the beginning of the load cycle the damaged laminate remains stable. (2) The strain level becomes high enough to initiate buckling at one or more of the delamination interfaces, resulting in a thin, buckled sublaminate and a thicker, more stable sublaminate. (3) As the load increases, the thin sublaminate buckles and further out-of-plane loads result around the perimeter of the delamination. The postbuckling continues until the out-of-plane loads exceed the critical mode I strain energy release rate or the interlaminar tension allowable. The final failure occurs as the delamination propagates perpendicular to the principal strain direction and the laminate collapses.

It should be noted that, after initial buckling, it is possible to have additional sublaminates buckle. In addition, although Fig. 6 shows a relatively simple buckled mode shape, it is possible to have more complex buckling modes and contact between the top and bottom sublaminates. The complexity of the damage and failure mechanisms has increased the difficulty of the development and verification of adequate deterministic models of the compression after impact failure mode.

Impact Damage Growth Characteristics under Cyclic Loading. Composites respond differently to subcritical cyclic loads than metals. The fatigue curve for composites is relatively flat, compared to the curve for metals. For a constant-amplitude loading condition of R= 10 (that is, compression-compression) the 10^6 cycle endurance condition typically corresponds to a maximum cyclic stress (in compression) of 60 to 65% of the undamaged static ultimate (Fig. 7). The fatigue curve is much higher for spectrum-type loading, which is more representative of typical aircraft loading conditions. A typical transport loading sequence is also shown. The reason for the improvement in the spectrum load condition is that, for composites, only the high- level loads cause significant fatigue damage or damage growth. Consequently, typical aircraft loading is relatively benign compared to constant amplitude load cycling because of the few high-load or peak-load cycles encountered. This is in contrast to metals, for which the large number of low-stress cycles is the primary contributor to crack growth; the high-stress cycles may actually be beneficial. In metals, the higher compressive load levels may produce retardation of crack growth due to yielding at the crack tip. Because composites are only sensitive to the high-level loads, they have the advantage of being able to truncate spectrums drastically in simulating lifetimes of cyclic loading. Ironically, however, a large number of loading lifetimes may be required to obtain an *exceedance* confidence because of the characteristic flat cyclic loading curve of the material and the associated data scatter inherent in time-to-failure data. Exceedances are occurrences of loading in excess of the baseline loading used to determine the loading spectrum.

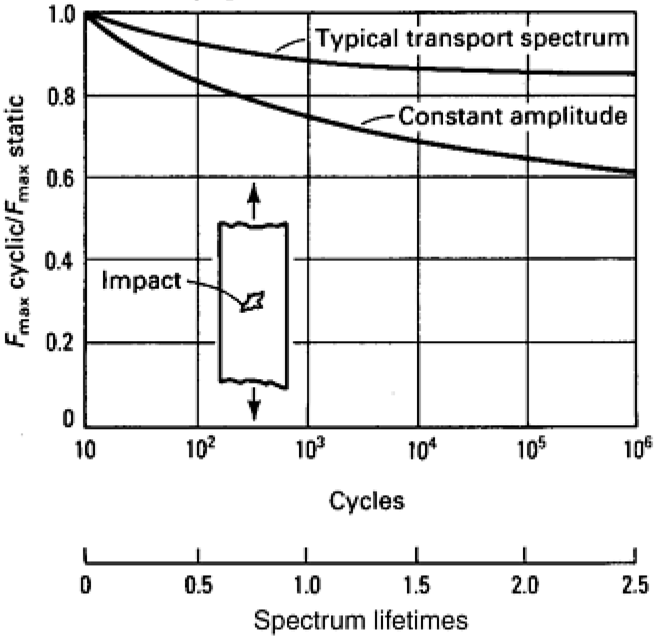

Fig. 7 Typical load cycle response for constant amplitude versus spectrum-loading fatigue testing. *R*= 10.0 (compression-compression).

The CAI failure mode is essentially a mode I failure. (Fig. 2 in the article "Fracture Mechanics of Composite Delamination" in this Volume illustrates the three modes of delamination fracture.) Even toughened composites exhibit very high mode I crack growth exponents; this results in very little difference between the threshold strain energy release rate (G_{Ith}) and the critical strain energy release rate (G_{Ic}). This manifests itself in tests by the following:

- No flaw growth (except for rounding out of the delamination) at strain levels of 75 to 85% of the static failure strain.
- The CAI failure does not exhibit a slow stable period of flaw growth. The failure typically occurs by sudden extension of the delamination at the higher load levels, as demonstrated in Fig. 3 and 4. For a given configuration and strain level, failure sometimes occurs during the first application of the highest cycles; it may also occur later in the life in a seeming random manner. This results in large amount of scatter in life for a given maximum spectrum strain level. As stated previously, this characteristic prevents force management in a manner similar to metals.

Damage Tolerance

Mike R. Woodward and Rich Stover, Lockheed Martin Aeronautics Company

Damage Tolerance Allowables Development

The general concept and development of design allowables is presented in the article "Design Allowables" in this Volume. The procedure for damage tolerance allowables development directly addresses the threats presented to the composite structure and the design criteria for the structure. Tool drops, rolling equipment strikes, and runway debris all act as possible threats to the integrity of a composite structural member. These threats fall into the category of low-velocity impacts (LVI). When they possess sufficient energy, they will develop into low-velocity impact damage (LVID). Since impacts are a way of life for any real-world large airplane, the following questions must be answered: "When does impact severity go from trivial to functional impairment?" and "Can defects causing structural impairment be detected during a non-mission-interrupting inspection?" For many other applications, impacts are likewise numerous. Tests must be developed that provide the analyst with design guidelines to assure safe, reliable structures.

As discussed previously, the two philosophies of damage tolerance and durability each result in unique levels of testing and differing guidelines. The damage tolerance tests incorporate the criteria of functional capability with damage level. Exactly how much damage is tolerable and how an inspection is performed to find such damage will drive the allowables tests. As mentioned previously, delamination damage can often be quite sizeable before it reaches the point of visibility, and the inspection of a large composite structural member such as a wing or vertical tail is complicated by the relative inaccessibility presented by the item. While it may be advisable to do an ultrasonic inspection when any known accidental LVI has occurred, it would be impractical and should not be necessary as a part of a routine preflight inspection. Most criteria employed today involve the concept of defining undesirable damage as that which is clearly visible by a trained observer at a set distance, for example 1.5 m (5 ft). This allows composite surfaces to be visually inspected in a time-efficient manner. Since damage areas can be sizeable without being clearly visible, the part must be designed to perform its function with the damage present. Usually, damage tolerance test impacts are performed with 12.7 mm (0.5 in.) diameter impactors, which tend to limit fiber breakage and maximize delamination damage. Other sizes may be used. To simulate large hail stone damage in composite sandwich airframe structures, a 63.4 mm (2.5 in.) impactor can be used (Ref 3).

Durability tests incorporate lower energy impacts and the concept of functional impairment. Besides strength, these test criteria include other impairments, such as moisture intrusion into honeycomb panels, or fuel leakage from a fuel tank. Usually, durability tests are performed with smaller impact heads, usually 12.7 mm (0.5 in.) diameter.

Defining the Range and Scope of Coupon Tests and Trial Impact Coupons. While the combinations of materials, laminate stacking sequences, and thickness are infinite, an allowables developer can perform only a limited number of expensive coupon tests in order to establish a reliable set of composite damage tolerance allowables. Varying parameters of thickness and stacking sequence are necessary, as is the establishment of maximum impact energy before damage is visible. If, for example, a criterion of visibility at 1.5 m (5 ft) is desired, a number of trial impact tests should be performed prior to any other mechanical testing. These trial impact tests will establish the impact energy level needed to be applied to mechanically tested coupons for BVID evaluation. A full range of laminate thickness and stacking sequences should be tested at various impact energies to correctly establish the relationship between panel attributes, impact energy, dent depth, and visibility. Visibility can be subjective, based on the viewing conditions and panel surface treatments. Often, a dent depth criteria can be established and matched to a visibility requirement. An upper limit on impact energy is usually established based on an analysis of threats found in the aircraft environment (Fig. 8).

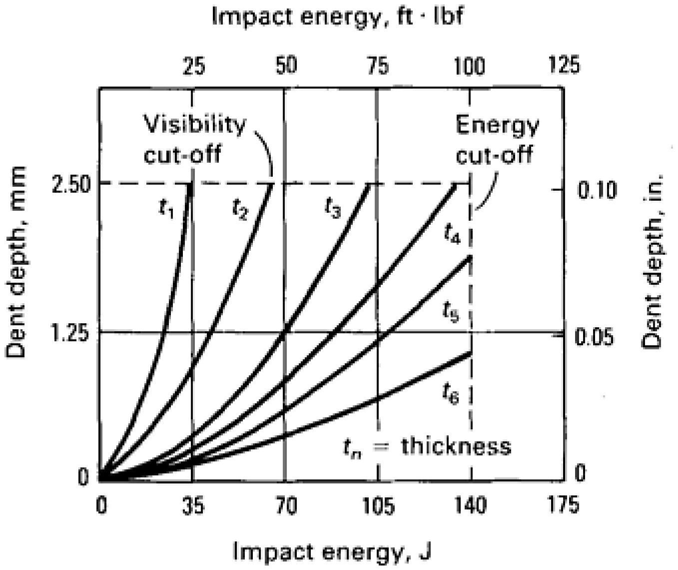

Fig. 8 Impact energy versus dent depth with energy and visibility cut-off limits. Source: Ref 4

There is usually a design range of laminate families available to the composite laminate designer. These range from hard laminates with a high percentage of 0° fibers, to laminates stiff in shear with a high percentage of cross-plies. Test programs should endeavor to sample a variety of laminates throughout the design space.

Impact Boundary Conditions. Care must be taken when applying boundary conditions to coupons being impacted. The effects of edge translational and rotational stiffness can drastically affect the resultant damage area and the residual strength. Standard test methods specify a specific size impact window, with the coupon being clamped at the periphery. The size of the window may depend on the level of impact energy and thickness of the panel being impacted. The ideal fixity is the actual adjacent structure, which may be difficult to reproduce. When defining tests are performed for damage resistance only (no moisture intrusion) thinner laminates can be tested. For damage tolerance, thicker laminates should be used.

Environmental and Cyclic Tests. Like most allowables development programs, a building block approach should be used. Once a set of criteria has been established, coupons are constructed and tested. These coupons should be conditioned to represent the extreme cases of exposure to environment effects: cold temperature dry (CTD), room temperature dry (RTD), elevated temperature dry (ETD), and elevated temperature wet (ETW). These are specified in the Advanced General Aviation Transport Experiments Consortium (AGATE) program (Ref 1). Next, cyclic fatigue effects should be established. When performing cyclic fatigue tests, test coupons normally are subjected to two lives of fatigue. Then, residual compression strength is determined at the end of the life with the coupon at elevated temperature and saturated moisture. Strain gages are applied to the compression panel in a judicious way (Fig. 9). Far field strains should be measured, as well as the strains over the delaminated portion of the coupon. Cyclic tests will usually be conducted at strain levels that result in postbuckling of the delaminated coupon. Strain gages monitor this activity. Rounding out the ragged damage area usually occurs during cycling. At some point, delamination growth becomes unrestrained and the panel

fails. When enough tests are performed to quantify a fatigue reduction factor, the static failure loads are reduced by this factor to calculate allowables.

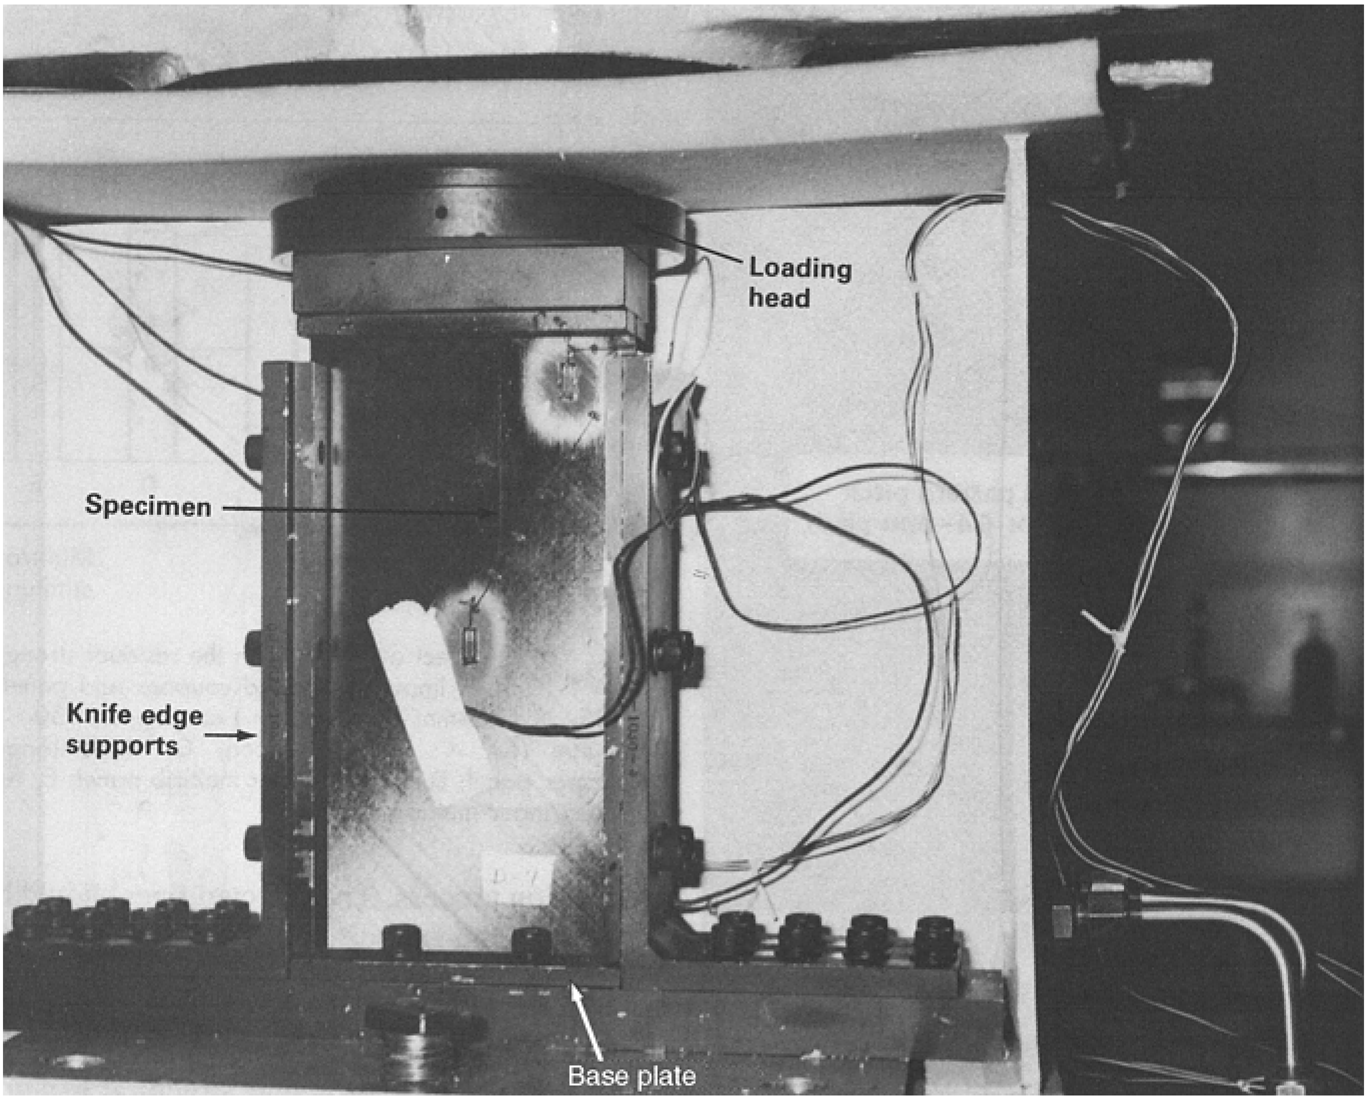

Fig. 9 Test set-up for compression testing of 125 × 250 mm (5 × 10 in.) laminate panels

The Building Block Approach and Scale- Up Effects. In any good allowables program, a building block approach to allowables development may be used. The building block approach is explained in the article “Overview of Testing and Certification” in this Volume. At the beginning, trial impact tests assess the material damage areas. Next, compression-after-impact tests are performed to quantify basic coupon strength. Scale-up effects, such as the effects of adjacent fasteners, stitching, or other through-the-thickness binding methods, should be quantified with the use of multi-bay stiffened test panels. Normally, for airframe structures, a three-bay panel is tested with the damage applied at the center of the panel or over a stiffener. Often, application of impacts over stiffeners do not create large delaminations, because the substructure supports the impact forces. Off the supports, impact loads are carried by interlaminar stresses which may result in delaminations. Delamination growth at binding points may be restrained, but most often panel widths are greater than damage runout widths. Box beams are normally used to verify a design with combined shear-compression-pressure loads once a design concept has been chosen.

Designing a damage-tolerant composite structure that incorporates postbuckling during cyclic loading should be avoided. The bending moments and internal loads generated in a postbuckled structure make an accurate damage tolerance analysis extremely difficult.

Damage Tolerance

Mike R. Woodward and Rich Stover, Lockheed Martin Aeronautics Company

Implementation of a Damage Tolerance Analysis Methodology

Compression after impact failure does not lend itself to prediction by a purely deterministic model. A semiempirical analysis methodology that has been successfully implemented is presented in the following paragraphs. This methodology combines a complex regression algorithm with a simplified analytical model of the failure.

Mechanics Based Model. Initial attempts at predicting CAI strength were accomplished purely analytically. The model (Ref 4) is a one- term Raleigh-Ritz approximation of a clamped elliptical plate under general biaxial loading in an infinite parent laminate. The model consists of an initial buckling solution and a postbuckled solution. The derivative of the total strain energy is taken with respect to delamination growth in the axial and transverse directions. A Newton- Raphson technique is then used to determine the strain level required to produce a strain energy release rate equal to the critical mode I strain energy release rate (G_{Ic}). This is the predicted static failure strain. This model was developed in a closed form in order to speed computation.

However, after an in-depth comparison with an extensive set of test data, it was determined that a purely analytical approach to the prediction of CAI strength was inadequate for the range of laminates being considered. Possible reasons for this include the following:

- *Delamination characteristics:* The impact damage was modeled as a geometrically exact single delamination. Examination of impact damage shows that the actual damage consists of multiple irregularly-shaped delaminations.
- *Shape function:* The assumed shape function was a one-term elliptical function. Although it was never confirmed experimentally, it is possible that this was inadequate in describing the postbuckled shape of the delamination.

As a result, it was determined that an empirical approach was needed.

The regression algorithm requires a set of CAI test data that adequately represents the range of laminate stacking sequences and thickness combinations that will be used for the design. The CAI strength of a given laminate is highly dependent on stacking sequence. Therefore, it is important that, during the design process, consistency must be maintained between the laminates used in the allowables development effort and those used in the actual design.

The regression variables include various laminate stiffness terms representing in-plane stiffness E_x E_y, bending stiffness G_{xy}, and the degree of stiffness stratification through the thickness of the laminate. The basic regression is of the form:

$$\sigma_c = a_0 \cdot a_1 \cdot a_2 \cdot a_3$$

where σ_c is the uniaxial CAI strength, a_0 is the open hole compression seed, a_1 is the CAI adjustment, a_2 is the impact energy term, and a_3 is the D matrix stratification term.

Further,

$$a_0 = (C_1 / a_{kt})(E_x^{C2} \cdot E_y^{C3} \cdot G_{xy}^{C4})$$

$$a_1 = (C5 \cdot E_x + C6 \cdot E_y + C7 \cdot G_{xy})(t^{C8})$$

$$a_2 = C9 \cdot E^{-C10t^{-C11}}$$

$$a_3 = (d_{11} / d_{11s}) \cdot (d_{33} / d_{33s})^{C13} \cdot (d_{22} / d_{22s})^{0.4675}$$

where $C1$–$C13$ are regression constants; E_x, E_y, G_{xy} are the effective axial, transverse, and shear moduli; t is thickness; E is impact energy; a_{kt} is the orthotropic stress concentration factor; d_{11}, d_{22}, and d_{33}, are laminate bending stiffness terms; d_{11s}, d_{22s}, and d_{33s} are smeared laminate bending stiffness terms.

Linear regression factors are applied to E_x, E_y, and G_{xy} moduli and to bending stiffness terms. Thickness and impact energy terms require exponents. As thickness is increased, failure stress is reduced. As impact energy is increased, failure stress is reduced.

When dealing with a visibility or dent depth criteria, additional relationships are established which define the impact energy necessary to produce detectable damage for a given laminate type and thickness. The assumed conditions for nondetectable damage or flaws are given in Table 1. The combination of these two relationships will yield failure predictions.

Table 1 Assumed nondetectable flaw/ damage

Type	Size
Scratches	A surface scratch that is 100 mm (4.0 in.) long and 0.50 mm (0.02 in.) deep
Delamination	An interply delamination that has an area equivalent to a 50 mm (2.0 in.) diameter circle with dimensions most critical to its location
Impact damage	Damage caused by the impact of a 25 mm (1.0 in.) diameter hemispherical impactor with 135 J (100 ft · lbf) of kinetic energy, or with that kinetic energy required to cause a dent 2.5 mm (0.10 in.) deep, whichever is least

Adapted from JSSG-2006 (Ref 5)

Semi-Empirical Analysis Methodology. The final analysis methodology combines the analytical model and the regression algorithm. An initial uniaxial compression strain is calculated using the regression algorithm. This is then used to determine a calibrated critical strain energy release rate for the analytical model. This analysis is the run using the calibrated strain energy release rate, G_c, under the actual strain state (biaxial principal strains) to generate an initial static allowable. This allowable is then modified by an environmental and fatigue knockdown factor and a bending factor, resulting in the final CAI design allowable.

This process is automated to allow direct integration of loads and stacking sequences from a finite element model or it can be run on a case- by-case basis. Both the regression algorithm and the analytical model were developed with computational efficiency in mind.

Out-of-Plane Analysis

Jonathan Goering, Albany International Techniweave, Inc.

Introduction

THE STRENGTH AND STIFFNESS of laminated composite materials is most often anisotropic. The methods of analyzing the directional dependence of the mechanical properties of composites, especially those perpendicular to the major plane of the laminate, are discussed in this article.

Out-of-Plane Analysis

Jonathan Goering, Albany International Techniweave, Inc.

The Challenge

Laminated composite materials are often fabricated from stacks of plies (lamina) consisting of strong, stiff, reinforcing fibers, such as carbon, surrounded by a relatively weak, soft matrix, such as epoxy. The mechanical properties of these plies in the direction parallel to the reinforcement are controlled by the longitudinal properties of the fiber. The mechanical properties perpendicular to the fiber are controlled by the properties of the matrix. This results in unidirectionally reinforced plies that have substantially different properties in the

directions parallel and perpendicular to the fiber (the longitudinal and transverse directions, respectively). The ratio of the longitudinal to transverse stiffness of an intermediate modulus carbon/epoxy ply, for example, can be on the order of 30 or 40 to 1. Differences in strength can be even more profound, and it is not uncommon to use plies with transverse strengths that are nearly two orders of magnitude less than the longitudinal strength.

Designers minimize the effects of these differences by employing stacking sequences that orient plies in several different directions in the plane of the laminate. In very simplistic terms, the directions of these plies will correspond to the directions of the primary loads, and the amount of reinforcing fiber in a given direction will be proportional to the magnitude of the load in that direction. While this technique can be used to optimize a laminate's ability to carry in- plane loads, it does very little to influence the strength or stiffness in the direction through the thickness of the laminate (the *z*-direction in Fig. 1).

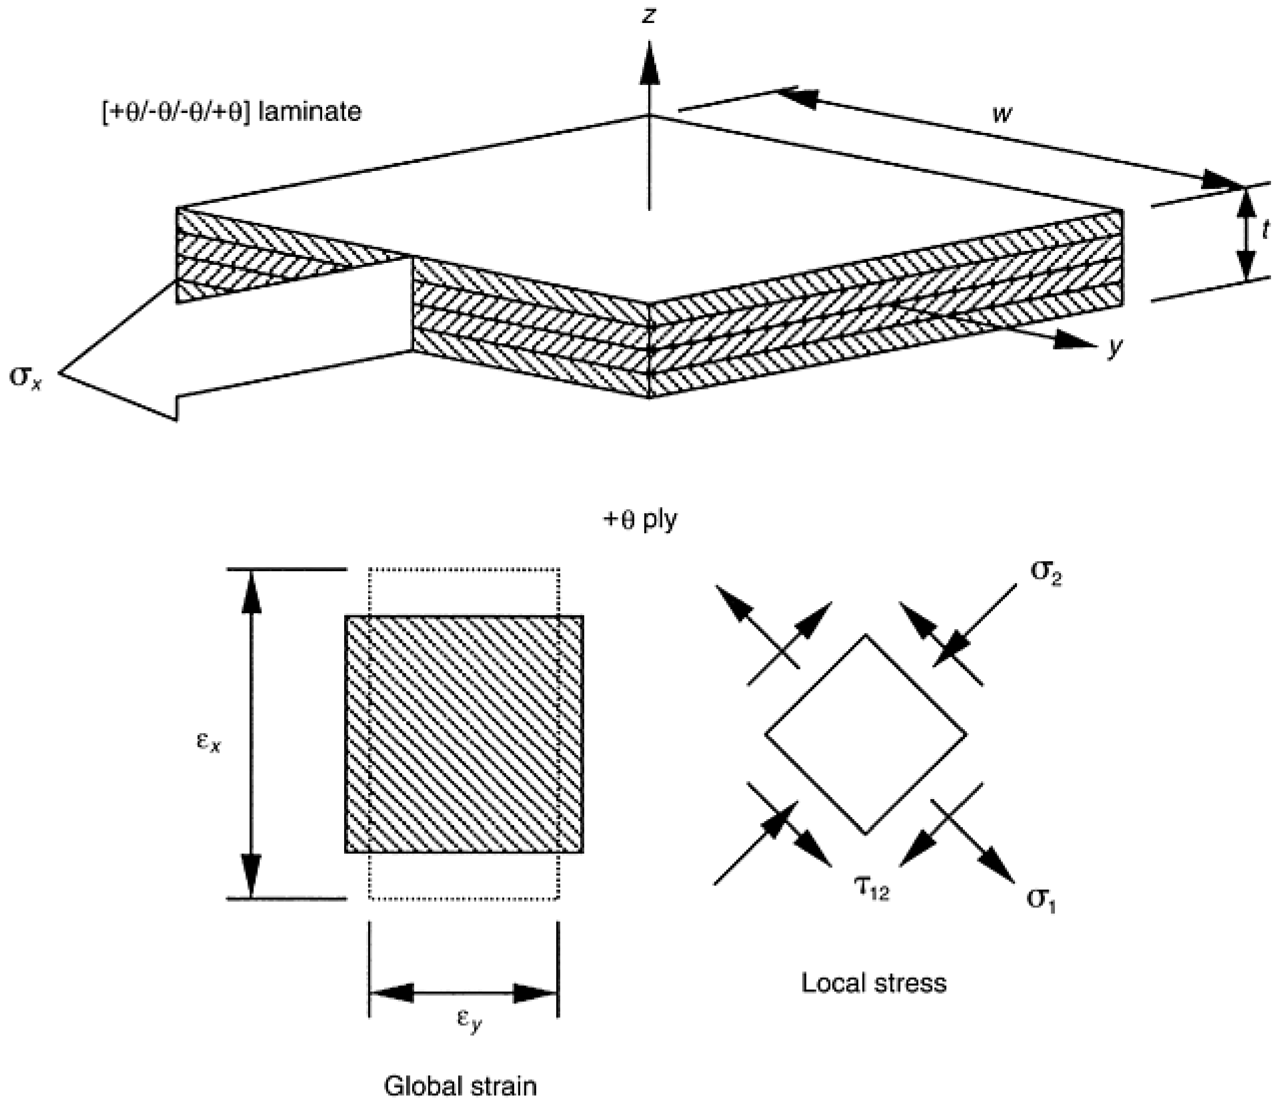

Fig. 1 Local shear stress in a symmetric laminate subject to a uniform axial stress in the *x*-direction (σ_x). The global strain is shown, but there is no in-plane shear strain (γ_{xy}). Local shear stress (τ_{xy}) is developed in each ply.

In the through-thickness direction, a laminate can be characterized as a number of relatively weak, soft layers separated by layers of equally weak, soft matrix. This combination of weak layers coupled through weak layers leads to laminate out-of-plane strengths that are comparable to the transverse strength of a ply.

Relatively low laminate out-of-plane strengths can result in structures that fail in through-thickness modes, even though the primary loads are in-plane. In addition to direct out-of-plane loads, such as beams in three- or four-point bending and stiffener pulloff, the strength analyst must be cognizant of cases where primary loads in the plane of the laminate induce secondary loads that act in the through-thickness direction. Such cases include free-edge stresses in cross-plied laminates under axial loads, radial stresses in curved laminates subject to tangential loads and bending moments, and curling of axially loaded curved flanges.

Analytical models for calculating out-of-plane stresses due to direct and indirect loads have been developed for most cases of practical interest to structural engineers. The approaches used in these models have included simple mechanics of materials formulations, complex closed-form elasticity solutions, and computationally intensive numerical solutions. Each approach has its strengths and weaknesses, and the correct model for a given application depends on many factors. For example, a simple model based on beam theory may be adequate for predicting trends, while a more detailed finite element model may be required to accurately predict interlaminar stresses.

Regardless of the approach taken, the analyst must weigh the fidelity of the selected analytical model against the fidelity of the available materials properties data. Coupon tests that are used to measure out-of-plane strengths are generally characterized by significant scatter, resulting in reduced “B-basis” statistical allowables. Out-of- plane tensile tests, in particular, are notoriously inaccurate and unreliable (see the article “Lamina and Laminate Mechanical Testing” in this Volume). It is therefore unreasonable to expect extremely accurate interlaminar strength predictions from any analytical model, regardless of its fidelity, if there is a high degree of uncertainty in the materials properties that are used. It is therefore recommended that a good degree of caution accompany any stress analysis intended to quantify out-of-plane failure modes.

Out-of-Plane Analysis

Jonathan Goering, Albany International Techniweave, Inc.

Out-of-Plane Analysis Techniques

The following sections discuss some of the more common out-of-plane analysis techniques. These sections begin with some common indirect load cases, followed by direct out-of-plane load cases, and conclude with a brief discussion of composite materials that are reinforced in the *z*-direction (also known as three-dimensional, or 3-D composites). The intent of this article is to introduce some (but certainly not all) of the models available, to summarize the relevant concepts involved, and to discuss applicability. It is not intended to provide rigorous derivations of the theories behind the models considered. In most cases, references that include details of the derivation have been cited.

Free-edge stresses refer to interlaminar stress components that can develop at free edges of a laminate subject to in-plane loads. Classical laminated plate theory provides a good method for determining the states of stress and strain away from the edges of a laminate, but tends to break down near free edges. The basic problem is that the classical theory includes in-plane shear and extensional stresses that cannot exist on the free surfaces of edges parallel to the applied load. The classic example is a $[+\theta/-\theta]_s$ laminate subject to a uniform axial stress in the *x*-direction (σ_x). Since the laminate is balanced and symmetric, this strain will cause an extension in the *x*-direction (ϵ_x) and a contraction in the *y*-direction (ϵ_y), but there will be no in-plane shear strain (γ_{xy}) or bending (Fig. 1).

The problem becomes evident when a ply-by- ply analysis is performed to determine the local stress state for each ply. This process will predict a uniform shear stress (τ_{xy}) in each ply that exists even at the free edge. Since this condition is physically impossible, another stress component must develop to satisfy the imbalance in the moments due to the in-plane shear. For this particular case, a shear stress in the *x*-*z*-plane (τ_{xz}) develops in the vicinity of the free edge. The actual distributions of the shear stresses across the width of the laminate will be similar to those shown in Fig. 2.

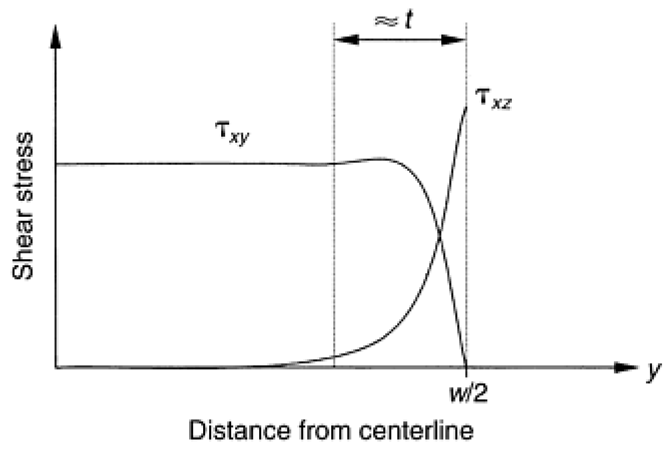

Fig. 2 Distribution of shear stresses across the width of a laminate. Free-edge stress distribution is limited to a region approximately one laminate thickness wide.

A similar phenomenon occurs in cross-ply laminates (i.e. $[0/90]_s$). In this case, it is the mismatch in Poisson's ratios between plies, rather than shear coupling, that leads to transverse extensional stresses (σ_y) that cannot exist at the free edge. For this case, shear in the *y*-*z*-plane (τ_{yz}) and normal stresses (σ_z) develop to keep the moments in balance. Since laminates often possess a combination of shear coupling and mismatches in Poisson's ratios ($[0/90/\pm\theta]_s$ laminates, for example), the full compliment of interlaminar stresses can usually be expected. In all cases, these interlaminar stresses are restricted to a region that extends approximately a laminate thickness away from the free edge. Beyond that boundary, the classical laminated plate theory solution is valid.

A substantial number of researchers have investigated the free-edge stress problem, and a wide variety of models have been developed. This work was pioneered by Pipes and Pagano (Ref 1), who used finite difference solutions to calculate free-edge stress distributions. More recent models, such as that presented by Flanagan in Ref 2, use series solutions based on stress functions. Both approaches have benefits and drawbacks.

The finite difference (or finite element) approach can be applied to any geometry, but requires a new model for each new laminate. This drawback can easily be overcome by developing a preprocessor that automatically generates the finite difference grid or finite element mesh, and a postprocessor for interpreting the results. A more difficult problem is that this approach can require highly refined grids to characterize the very steep gradients of interlaminar stress distributions that may be singular. Convergence can therefore be very slow. See the article "Finite Element Analysis

Solutions based on stress functions avoid this problem, but are more difficult to formulate. This approach generally requires the solution of an eigenproblem with several dozen degrees of freedom. Problems of this size present no real computational difficulties for even modest personal computers. When selecting a method of this type, care should be used to ensure that the model has not made restrictive assumptions regarding the distribution of various stress components.

A very simple alternative approach has also been developed for generating quick estimates of the interlaminar stresses. This approach is based on assuming simple shapes for the distributions of the interlaminar stress components and calculating the magnitudes required to keep all forces and moments in balance. This approach was suggested by Pagano in Ref 3, and the assumed shapes of the interlaminar stress distributions were guided by finite difference results. The assumed shape of the normal stress (σ_z) is shown in Fig. 3. The magnitudes of these distributions are chosen such that the resultant of σ_z is 0, and the moment due to σ_z balances the moment due to σ_y. This approach obviously provides a very rough approximation to the magnitude of the peak interlaminar stress, but it can be very useful for quickly determining trends when comparing various laminate families. This type of solution has been extended to other interlaminar stress components with different shapes assumed for their distribution. Reference 4 is a typical example.

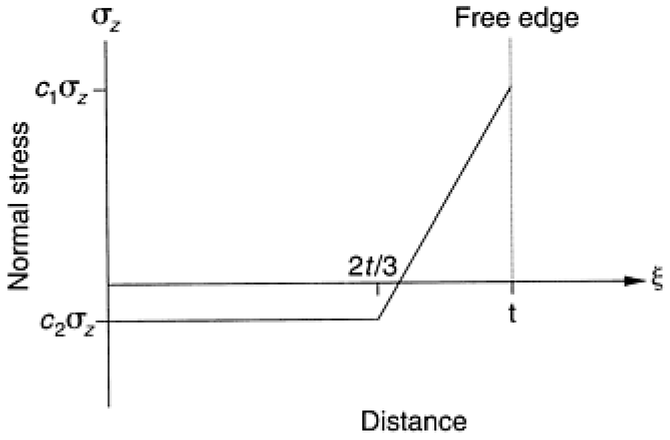

Fig. 3 Approximation of free-edge normal stresses

Several authors have reviewed the existing body of work that has focused on modeling the free-edge stress problem. Details of the various approaches that have been taken to this modeling can be found in sources such as Ref 2 and 5. It should be noted that while free-edge failure is a real phenomenon, the free-edge stress analysis often becomes an academic exercise for real structures that are usually bonded or mechanically fastened to other structural members. This type of failure is, however, a practical concern in the test lab because it can preclude the desired failure modes for some types of coupon test (tensile tests of ±45° laminates, for example).

Curved Laminates. Laminated composite structures often include corner details that can be treated as curved laminates. Web plies wrapping around a radius to form the flanges of a C-channel or I-beam are typical examples. When this type of structure is loaded, the applied loads can act to "open" or "close" the corner radii, depending on their direction (Fig. 4). This results in the development of interlaminar stresses in the radial direction, through the thickness of the composite. When the corner is being closed, the radial stress is compressive and typically not a concern, but when the corner is opened, the radial stress is tensile and can lead to delamination.

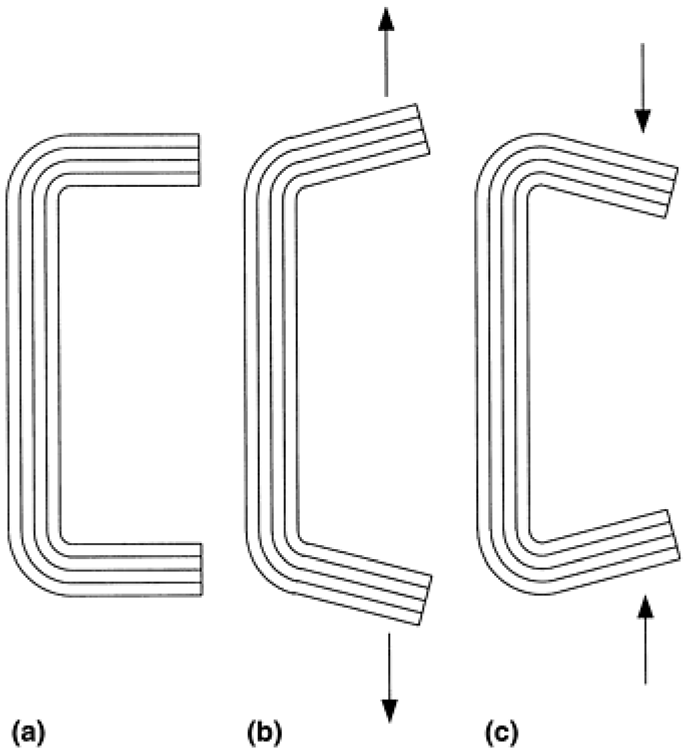

Fig. 4 A curved laminate "C" channel in various loading conditions. (a) Unloaded. (b) Radii open under tensile load. (c) Radii close under compressive load

The development of this radial stress can be demonstrated by considering a two-ply curved laminate subject to a couple acting on either end (Fig. 5a). The free-body diagram of each ply reveals the need for radial stresses to balance the vertical components of the tangential loads applied to the edges (Fig. 5b). For this simple case, the

magnitude of the radial stress can be calculated by assuming some distribution (uniform, for example), integrating the vertical component of the radial stress over the surface of the interface, and setting the result equal to the vertical component of the applied load.

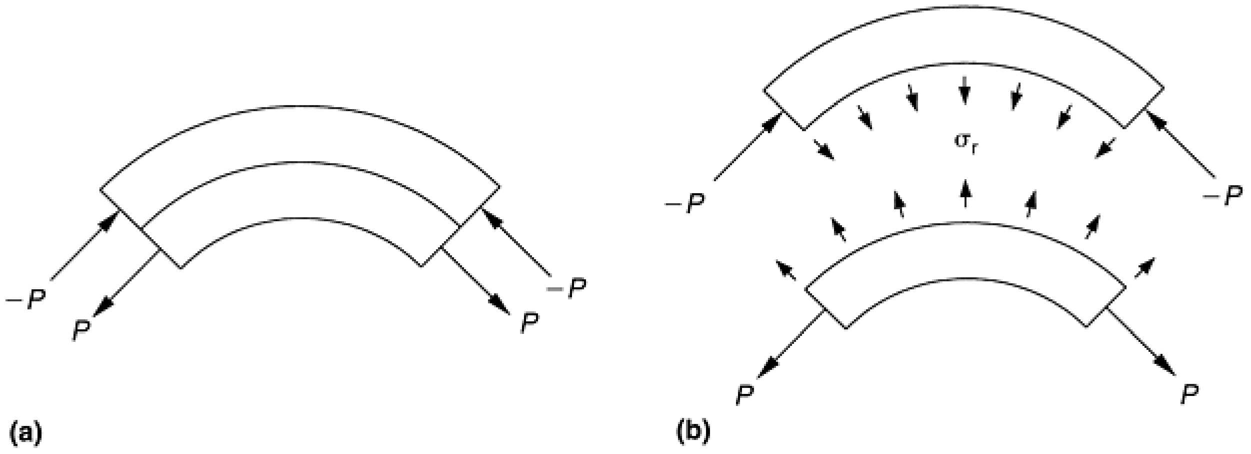

Fig. 5 Development of radial stresses in a curved laminate. (a) The force couples (–*P*, +*P*) act on the curved laminate. (b) The radial stresses (σ_r) must balance the vertical components of these loads.

Real curved laminates in actual structures will more likely be loaded by some combination of end moments, in-plane loads, shear loads, and surface pressures (Fig. 6). Lekhnitskii presents an elasticity solution for a nonhomogeneous curved bar subject to an end moment or end load in Ref 6. Although this approach is formulated for a general nonhomogeneous material, specific solutions can only be found for materials that have certain restrictions on their anisotropic nature. The solution actually provided by Lehnitskii is only applicable to materials with properties that vary in proportion to their radial position.

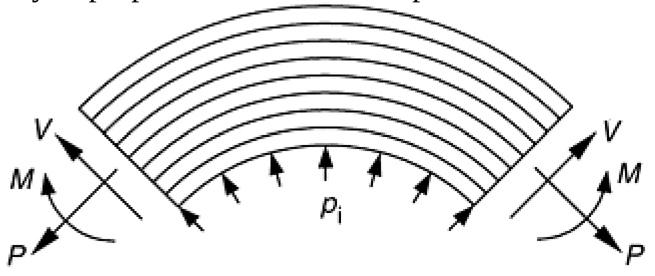

Fig. 6 Combined loads acting on a curved laminate. *P*, in-plane load; *V*, shear load; *M*, end moment; p_i, surface pressure

A somewhat simpler, and arguably more useful, strength of materials solution for balanced symmetric curved laminates is developed in Ref 7. This solution is similar to classical laminated plate theory in that it assumes the tangential displacement varies linearly through the thickness. Since the laminate is curved, the tangential strain distribution is nonlinear. It is this nonlinear strain that makes the curved laminate analysis somewhat more complicated than the analysis of conventional flat laminates.

The magnitude of the tangential strain is determined by equating the applied tangential load to the resultant of the tangential stress, and the applied moment to the moment due to the tangential stress. In this process, the tangential stress in a ply is expressed as the product of the assumed tangential strain and the tangential stiffness of the ply. This formulation leads to quantities, analogous to the [*A*] and [*D*] matrices of classical laminated plate theory, which define the tangential strain distribution for a given tangential load and bending moment. The magnitude of the tangential stress in each ply can then be evaluated. Once the tangential stress distribution is known, the shear stress ($\tau_{r\theta}$) can be found by summing the moments about the center of curvature. The tangential and shear stress distributions are required to calculate the radial stress distribution, which is found by summing the radial forces.

This sounds like a complicated procedure, but in practice it is not that much more difficult than classical laminate plate theory. If done by hand, implementing this process would be a daunting task, but the method can be coded into a computer program with modest effort. Once done, the analysis of a curved laminate is no more difficult than a conventional flat laminate analysis.

Flange Curling. An out-of-plane phenomenon that is related to the analysis of curved laminates is the curling of curved flanges subject to tensile loads (Fig. 7). The loads applied to the web of the structure shown in Fig. 7 act to increase the radius of the web. When this happens, the flanges bend upward to try to remain at their initial radius. This bending of the flanges is referred to as flange curling. The curling of the flange tends to open the radius that is formed when web plies wrap around to form the flange. As described in the previous section, this induces radial stresses through the thickness of the laminate, which can lead to the delamination of the structure. A similar phenomenon occurs when the curved flange is put in compression, but this load causes the flanges to bend downward, which closes the web to flange radius, thereby inducing radial compression.

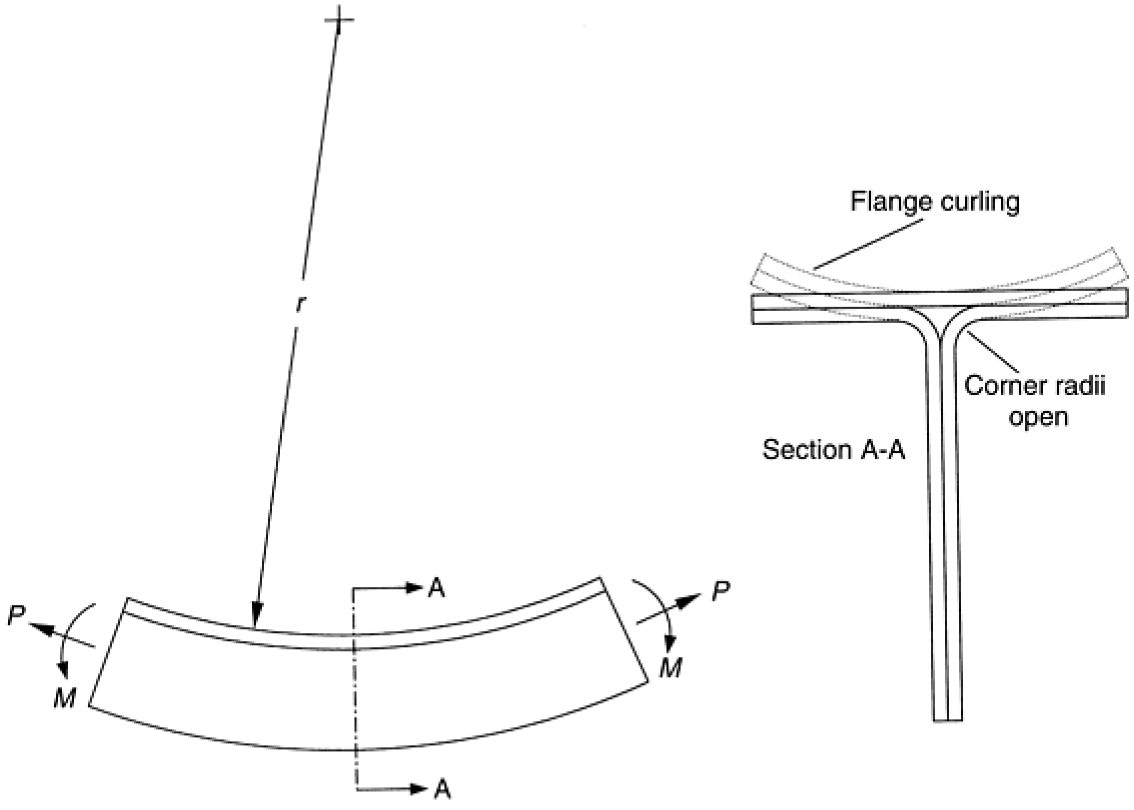

Fig. 7 Flange curling induced by loads on a curved substructure

Simple models for this problem do not exist, and it is most easily handled using a numerical technique such as the finite element method. A common approach uses the so-called global- local method. In this method, a relatively coarse global finite element model is generated and used to define the boundary conditions for more refined models of local details. For the flange curling problem, the global model can use laminated plate elements to define the shape that the corner radius takes on when it opens. This shape can then be used in a more refined analysis of the curved laminate that defines the corner.

Note that this problem only occurs in unsupported flanges. In practice, flanges are generally attached to some other structural component, such as a skin, that constrains curling. However, structural components such as frames or bulkheads are often tested in a free-standing condition. For these tests, it is important to perform a flange-curling analysis to ensure that the component will not fail prematurely in a mode that will not exist in the final structure.

Beams In Bending. One of the simplest examples of a structure subject to direct out-of- plane loading is a laminated beam in three-point bending. The shear diagram for this configuration, as shown in Fig. 8, identifies regions of constant shear between the point at which the load is applied and the supports. This leads to an average shear of P/A, where A is the cross sectional area of the beam. From beam theory, the distribution of this shear through the thickness is a simple parabola that satisfies the condition that the shear must be 0 on the traction-free surfaces. It can be shown that this distribution peaks in the center of the specimen at a value of 3/2 times the average shear.

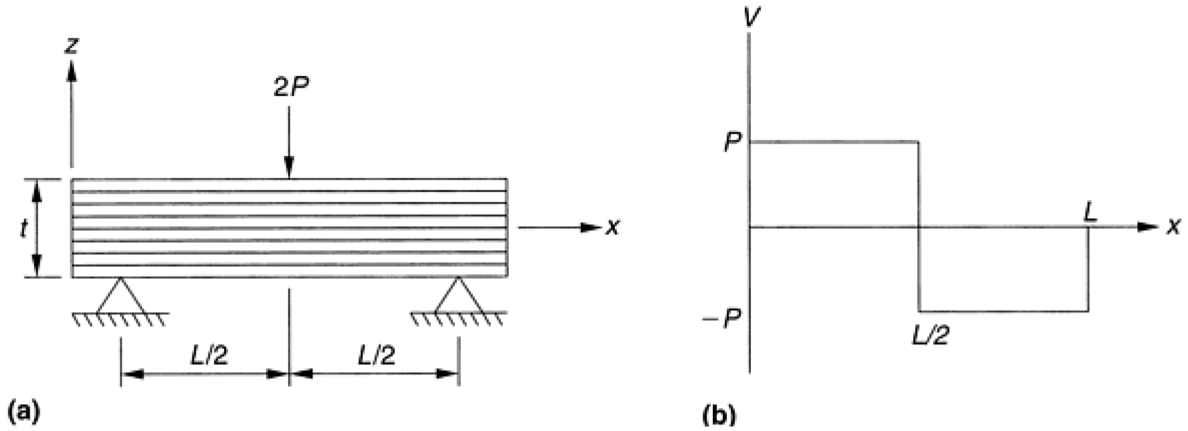

Fig. 8 Laminated beam in three-point bending. (a) Load diagram. (b) Shear diagram

This approach is fine for isotropic specimens, but researchers have shown that the parabolic distribution is not representative of the actual distribution in an orthotropic specimen. In Ref 8, Whitney presents a two-dimensional elasticity solution for the shear distributions in homogeneous orthotropic beams in three- or four-point bending in the form of an infinite series. Whitney shows convergence with 100 terms in the series, which presents little computational difficulty to a modern personal computer. The shear distribution predicted by this model shows that the peak shear is found near the applied load. The magnitude is greater than the peak calculated for a parabolic distribution, and its through-thickness location is shifted away from the centerline of the specimen, toward the side upon which the load is applied (Fig. 9).

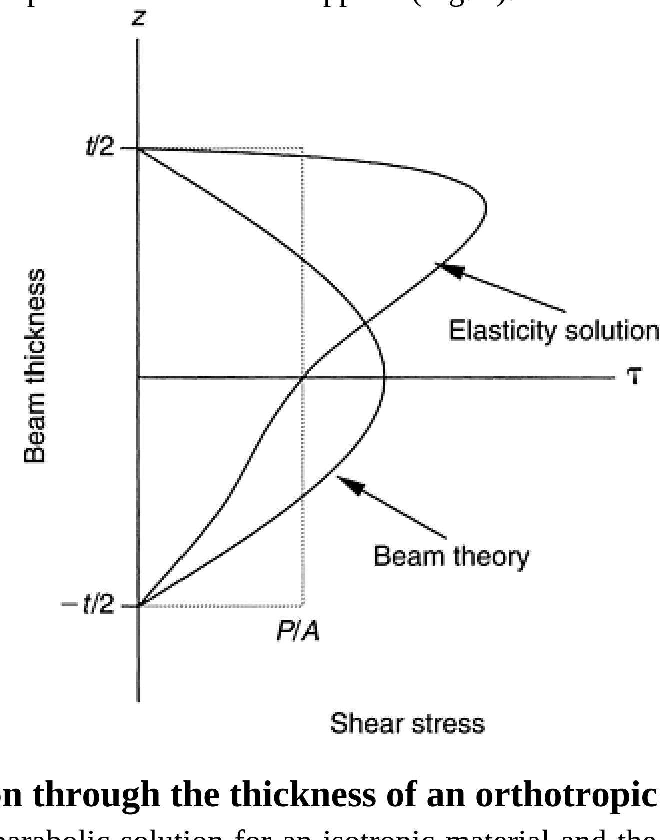

Fig. 9 Shear distribution through the thickness of an orthotropic beam

The difference between the parabolic solution for an isotropic material and the more complex distribution for the orthotropic material accounts for the problems associated with using the three- point bending test as a method for determining interlaminar shear strength. The problem is that the parabolic distribution is assumed when backing the interlaminar strength out of the failure load. A better approach would be to perform an analysis that accounted for the beam being orthotropic, and using the resulting distribution to determine the peak stress at failure.

Methods for determining materials properties that rely on the use of an analysis tend to be frowned upon. There is a saying that no one believes analytical results except the person who performed the calculations, and everyone believes experimental results except the person who conducted the test. This could explain why hybrid experimental/analytical techniques tend to offend everyone's sensibilities. Such an approach could,

however, lead to better quantitative results from a simple, inexpensive test that is generally considered only a qualitative test.

Stiffener Pulloff. A common direct out-of- plane load case is the transfer of a load from a composite skin into the supporting structure. A good example is the transfer of the pressure on the skin of an aircraft into the supporting ribs, frames, and spars (Fig. 10). The study of this load case is especially important for bonded or co-cured composite structures, because the loads must be carried across unreinforced (no *z*-direction fiber) interfaces. Being able to predict the peak value of the normal and shear stress distributions in the interface between the skin and substructure is essential.

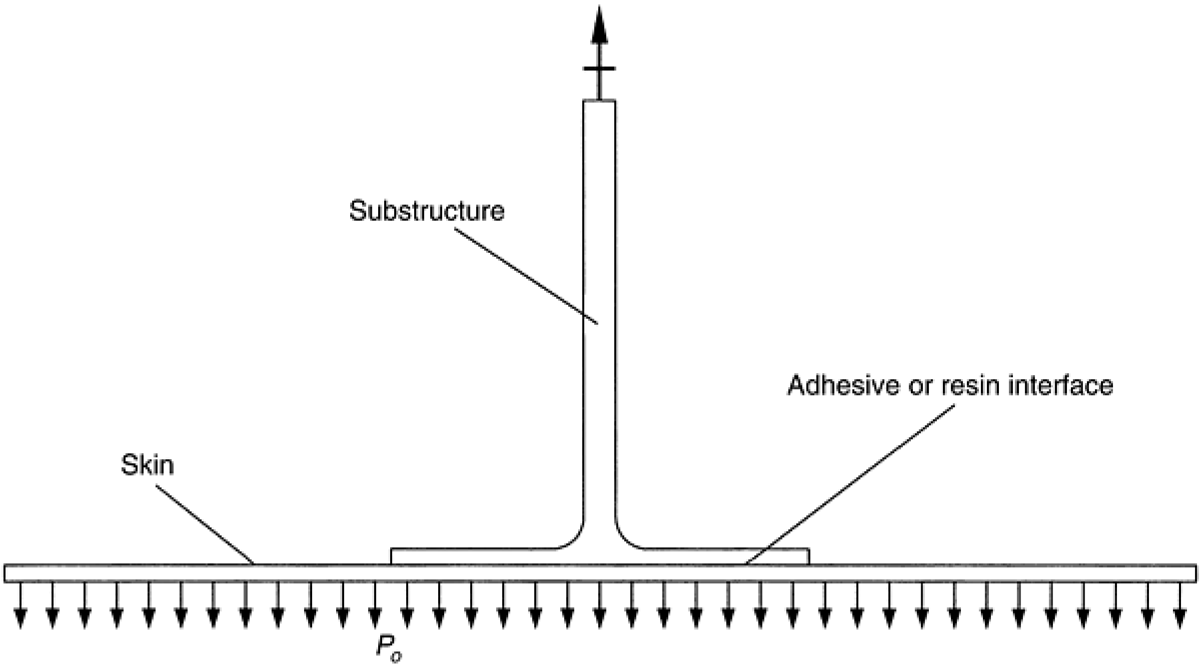

Fig. 10 Transfer of pressure loads on the skin through the substructure

One of the more simple models for this problem is based on treating the bonded or co-cured flange as a beam on an elastic foundation (Fig. 11). This problem has been studied extensively (Ref 9, for example), and solutions for many common load cases exist. Drawbacks to this type of solution are that bending in the skin is not accounted for, and the calculation of the foundation stiffness is very subjective. In addition, the beam on elastic foundation approach does not explicitly model the geometry of the so- called “noodle” or “nugget” of resin that exists in many skin-to-substructure joints (Fig. 12). The stress distribution in the interface can be sensitive to the geometry of this detail, and the peak stresses often occur in or near it. Because of these drawbacks, this formulation is not recommended for laminated composite materials.

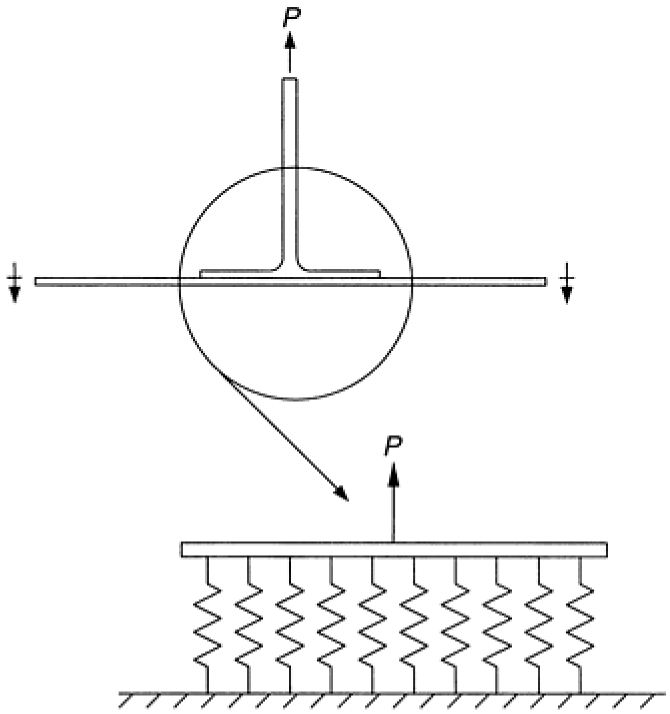

Fig. 11 Skin-to-structure interface modeled as a beam on an elastic foundation

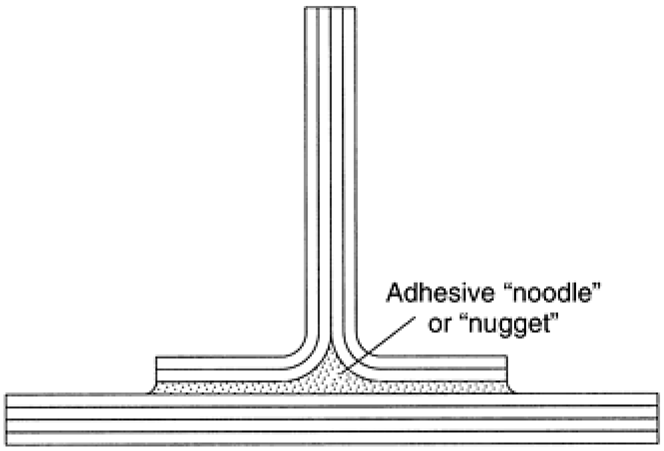

Fig. 12 Resin-rich region in a skin-to-structure interface

The most direct approach to explicitly including the geometry of the interface in the pulloff analysis is to use the finite element method. The modeling effort can be simplified by using a two- dimensional model that represents a slice through the structure that is perpendicular to the substructure. It is common to assume that the model is in a state of plane strain. Using this approach, plies can be modeled individually using solid elements, or can be lumped together into plate elements. This technique, when combined with *p*-version finite elements, is particularly powerful and efficient. (In *p*-version finite element analysis, the polynomial degree of elements can be varied over a wide range. Thus, the error can be controlled not only by mesh refinement, but also by increasing the polynomial degree of all elements.)

A finite element approach that uses frame elements to model the skin and substructure, and membrane elements to model the interface is presented in Ref 7. The stress distributions predicted with this model were shown to correlate well with similar distributions predicted by very detailed models that used solid finite elements to explicitly model each ply. For either type of finite element model, the geometry is usually simple enough that a preprocessor for generating the finite element mesh can easily be developed.

The frame-and-membrane type model is obviously easier to generate, but the solid-element approach has the advantage of providing interlaminar stresses in the skin and substructure, along with the stresses in the interface. The substructure often includes curved laminates in areas where webs are folded to form flanges. Pulloff loads tend to open the radii of these details, and the solid element models will predict the resulting radial stresses in the same analysis that yields the interface stresses.

3-D Composites. As previously mentioned, the through-thickness axis typically represents the weakest direction of a conventional laminated composite. Various schemes have been devised for reinforcing this otherwise weak direction. These include 3-D weaving, stitching, and various proprietary techniques for inserting through-thickness reinforcement, such as “T”- forming and “Z”-pinning. See the article “Fabrics and Preforms” in this Volume for illustrations of 3-D composites. These 3-D composites, also known as n-directionally reinforced composites, can be analyzed using many of the tools used to analyze conventional two-dimensional composites, but the generation of effective properties for them is somewhat more complicated.

The typical approach to calculating effective properties for a 3-D composite is based on defining a representative volume element (RVE). The RVE is the smallest volume that fully characterizes the composite in terms of the total fiber content and the distribution and orientation of that fiber. The properties of the RVE are therefore representative of the bulk properties of the composite.

Most procedures for calculating the effective properties of the RVE are based on volume averaging properties of the constituents. For 3-D composites, it is advantageous to volume average the stiffness or compliance matrices, rather than individual engineering properties, because the matrices account for all of the coupling (i.e., shear-extensional, shear-shear, etc.) that may be present in the material. The expressions for the effective stiffness and compliance are given by the following equations, respectively:

$$[C]^* = \frac{1}{V}\sum_{i=1}^{n} V_i \cdot [C]_i \qquad \text{(Eq 1)}$$

$$[S]^* = \frac{1}{V}\sum_{i=1}^{n} V_i \cdot [S]_i \qquad \text{(Eq 2)}$$

In Eq 1 and 2, it is assumed that the composite is comprised of n-unidirectional fiber bundles. $[C]_i$ and $[S]_i$ are the stiffness and compliance matrices of the i^{th} bundle transformed into global coordinates, V_i is the volume fraction of the i^{th} bundle, and V is the total volume of the RVE. It can be shown that volume-averaging the stiffness matrices results in an upper bound on the effective properties, and volume-averaging the compliance leads to a lower bound. This process has been extended to other effective properties, such as coefficients of thermal expansion and conductivities (see Ref 10).

If the composite is orthogonal, the effective through-thickness properties can be extracted from individual terms in an orthotropic compliance or stiffness matrix. For example, the through-thickness modulus of elasticity can be calculated from the knowledge that the S_{33} term in the compliance matrix for an orthotropic material is given by $1/E_{33}$. These relationships do not hold for the more general anisotropic case, but the orthotropic assumptions can sometimes be used as a first-order approximation.

It is important to bear in mind that the properties of the RVE only represent the composite if the fiber architecture does not change. For some 3-D composites, the fiber architecture is continuously variable. The architectures of integrally woven stiffeners or inserts are good examples. For these cases, there may be no single RVE that will provide the bulk properties of the composite. The typical approach used for these structures is to zone the component into a number of distinct regions and to define a unique RVE for each zone.

Out-of-Plane Analysis

Jonathan Goering, Albany International Techniweave, Inc.

Conclusion

In spite of the problems associated with models for conducting out-of-plane analysis, composite structural development programs are usually successful. This success can be attributed to the efforts of competent structural engineers to minimize out-of-plane loading, their prior knowledge of design details, failure analysis of previous unsuccessful designs, and a reluctance to stray too far away from tried-and-true methods. Although the conservative approach adopted by many designers and analysts *has* been ridiculed by some, a certain amount of conservatism is warranted. Most out-of-plane analysis methods are still approximate at best, and determining allowable properties is difficult, which can lead to unreliable results.

It is therefore important to experimentally validate any analytical tool before using it in a design environment, to establish the limits of applicability of an analytical method, and to strictly stay within those limits. The importance of using analytical techniques that are consistent with the methods used to generate design allowable should also be reemphasized. It is very easy to be lulled into a false sense of security by analytical models that produce color contour plots of stress distributions and report peak values to four decimal places, and also very easy to forget that the input materials properties were only good to two significant digits.

On the bright side, out-of-plane analysis is an area that is still being actively researched. New, hopefully more accurate and reliable, modeling techniques are being developed. Accompanying this analytical work is an interest in developing better test techniques. In the meantime, analysts should be cautioned to thoroughly understand the assumptions inherent in their models, and to verify the integrity of the experimental data they use.

Analysis of Sandwich Structures

Stephen Ward, SW Composites; Lawrence Gintert, Concurrent Technologies Corporation

Introduction

A SANDWICH STRUCTURE is comprised of layered composite materials formed by bonding two or more thin facings or facesheets to a relatively thick core material. In this type of construction the facings resist nearly all of the in- plane loads and out-of-plane bending moments. The thin facings provide nearly all of the bending stiffness because they are generally of a much higher modulus material and are located at the greatest distance from the neutral axis of the component. The core material provides spacing and transmits shear between the facesheets so that they are effective in bending about a common neutral axis. The core also provides most of the through-thickness shear rigidity of the sandwich construction and stabilizes the facesheets so they can be loaded to stress levels higher than the limits imposed by general buckling of thin plates. Core materials are generally selected to be lightweight and to be compatible with the facesheet material and the face-to-core attachment methods used in fabrication. The face-to- core attachment method, such as an adhesive bond, braze, or weld, is generally based on structural and environmental requirements for the sandwich system. By proper choice of materials for facings and core, constructions with higher ratios of stiffness-to-weight and strength-to- weight can be achieved, in comparison to other types of construction. A sandwich structure is also very good in fatigue

because the facings are continuously bonded to the core, resulting in minimal stress risers. In most cases, the main reason sandwich construction is used is to save weight, but it also may provide other benefits such as thermal and sound insulation, and reduced cost.
The following topics are discussed in this article:

- Sandwich panel failure modes
- Nomenclatures and definitions
- Strength checks
- Stiffness and internal loads
- Flat panels under pressure loading
- Curved sandwich panels
- Local strength analysis methods
- Flat panel stability

It is assumed that the reader is familiar with the general structural behavior of composite materials and is aware of the various combinations of materials that may be employed in the design of a composite component. Further information regarding the design and analysis of structural composites and sandwich composites may be found in MIL-HDBK-17, from which much of the information provided herein has been taken. Furthermore, at the time of this publication MIL- HDBK-17, Revision F, 2001, is in the process of incorporating a new section devoted to sandwich construction, combining sections of the canceled MIL-HDBK-23, which provided the basic principles from which sandwich analysis has evolved. These basic principles have been developed for polymer-matrix composites, but may be applied to metal-matrix composites and ceramic-matrix composites as well. Likewise many of the analytical procedures are specific to honeycomb core sandwich structures in which the facings are not truly continuously supported by the core. Each cell of the honeycomb leaves an unsupported portion of the facesheet and may constitute a critical parameter in the design of the sandwich structure, depending on the cell geometry and facesheet properties. Another source of analytical information is the series of Forest Products Laboratory Reports listed in Table 1.

Table 1 Selected Forest Products Laboratory (FPL) reports related to sandwich structures

FPL report number	Title
1810	Wrinkling of the Facings of Sandwich Construction Subjected to Edgewise Compression
1810-A	Wrinkling of the Facings of Sandwich Construction Subjected to Edgewise Compression; Sandwich Constructions Having Honeycomb Cores
1815	Effect of Shear Strength on Maximum Loads of Sandwich Columns
1817	Short-Column Compressive Strength of Sandwich Constructions as Affected by the Size of the Cells of Honeycomb-Core Materials
1827	Edgewise Compressive Strength of Panels and Flatwise Flexural Strength of Strips of Sandwich Constructions
1828	The Bending of a Circular Sandwich Plate under Normal Load
1829	Flexure of Structural Sandwich Construction
1830	Buckling of Cylinders of Sandwich Construction in Axial Compression
1833	Critical Loads of a Rectangular, Flat Sandwich Panel Subjected to Two Direct Loads Combined with a Shear Load
1834	Behavior of a Rectangular Sandwich Panel under a Uniform Lateral Load and Compressive Edge Loads
1838	Stresses within a Rectangular, Flat Sandwich Panel Subjected to a Uniformly Distributed Normal Load and Edgewise, Direct, and Shear Loads
1840	Buckling of Sandwich Cylinders in Torsion
1844	Analysis of Long Cylinders of Sandwich Construction under Uniform External Lateral Pressure
1844-A	Analysis of Long Cylinders of Sandwich Construction under Uniform External Lateral Pressure; Facings of Moderate and Unequal Thicknesses

1845	Stresses Induced in a Sandwich Panel by Load Applied at an Insert
1845-A	Stresses Induced in a Sandwich Panel by Load Applied at an Insert
1845-B	Stresses Induced in a Sandwich Panel by Load Applied at an Insert
1846	Transfer of Longitudinal Load from One Facing of a Sandwich Panel to the Other by Means of Shear in the Core
1847	Deflection and Stresses in a Uniformly Loaded, Simply Supported, Rectangular Sandwich Plate
1847-A	Deflection and Stresses in a Uniformly Loaded, Simply Supported, Rectangular Sandwich Plate; Experimental Verification of Theory
1852	Elastic Stability of Cylindrical Sandwich Shells under Axial and Lateral Load
1854	Compressive Buckling Curves for Sandwich Panels with Isotropic Facings and Isotropic or Orthotropic Cores
1857	Elastic Buckling of a Simply Supported Rectangular Sandwich Panel Subjected to Combined Edgewise Bending and Compression
1857-A	Elastic Buckling of a Simply Supported Rectangular Sandwich Panel Subjected to Combined Edgewise Bending and Compression; Results for Panels with Facings of Either Equal or Unequal Thickness and with Orthotropic Cores
1859	Elastic Buckling of a Simply Supported Sandwich Panel Subjected to Combined Edgewise Bending, Compression, and Shear
1867	Compressive Buckling Curves for Simply Supported Sandwich Panels with Glass-Fabric-Laminate Facings and Honeycomb Cores
1868	Buckling of Simply Supported Rectangular Sandwich Panels Subjected to Edgewise Bending
1871	Torsion of Rectangular Sandwich Plate
1874	Torsion of Sandwich Panels of Trapezoidal, Triangular, and Rectangular Cross Sections
1876	Compressive Buckling Curves for Sandwich Cylinders Having Orthotropic Facings
2171	Wrinkling of Faces of Aluminum and Stainless Steel Sandwich Subjected to Edgewise Compression

USDA Forest Service, Forest Products Laboratory, Madison, WI, www.fpl.fs.fed.us

While sandwich panels can be constructed in a variety of ways with a variety of materials, for the purposes of describing the structural analysis of sandwich panels, a honeycomb core panel with beveled core edges, as shown in Fig. 1, is used. The methods developed for the analysis of honeycomb sandwich panels of this type offer an example for describing the various failure modes of sandwich construction. The critical failure modes and properties for each of the panel constituents must be established in order to conduct the analyses as described herein. The panel constituents for this example include honeycomb core and orthotropic facesheets. The flat face is referred to as the tool side, and the opposite face is the bag side. The bag-side facesheet follows the contour of the core as it slopes down around the panel perimeter to meet the tool side. The sloping portion of the core is called the ramp region, and the solid laminate where the tool and bag faces come together is called the edgeband.
